incorporated in the design of airplanes intended for flight at high supersonic speeds. In order to determine the low-speed aerodynamic characteristics of such a wing, tests of a wing having an aspect ratio of 2.5 and 6-percent-thick, hexagonal airfoil sections have been conducted in the Langley 19-foot pressure tunnel. Reference 1 presents the lateral-control characteristics of the wing equipped with spoilers and with ailerons. The results of the investigation pertaining to the longitudinal characteristics of the wing are presented herein.

Inasmuch as a relatively low maximum lift coefficient was expected for the wing because of flow separation promoted by the sharp leading edge, tests were made to determine the separate and combined effects of drooped-nose flaps and plain flaps on the longitudinal characteristics of the wing with and without a fuselage. The effects of a horizontal tail on the longitudinal stability characteristics of the wing-fuselage configuration were investigated with the tail located at various vertical and horizontal positions. In order to expedite the issuance of this information, only a brief analysis has been made of these data.

The data presented herein were obtained at Reynolds numbers ranging from 2.8×10^6 to 7.6×10^6 and Mach numbers ranging from 0.05 to 0.15.

MODEL AND TESTS

Model

The details of the wing, fuselage, and horizontal tail are shown in figure 1. The wing had an aspect ratio of 2.5, a taper ratio of 0.625, and neither twist nor dihedral. The wing had sharp leading and trailing edges formed by wedges which extended 30 percent of the chord. The upper and lower surfaces of the middle 40 percent chord of the wing were parallel and 6 percent of the chord apart. The wing was provided with interchangeable tips having wedge and elliptical cross sections (fig. 1). In a few instances the trailing-edge thickness of the wing was increased to 0.25, 0.50, and 1.00 of the maximum local thickness.

The wing was equipped with drooped-nose flaps at the leading edge and plain flaps at the trailing edge. The drooped-nose flaps of 15 percent chord extended spanwise from 20 percent wing semispan to 95 percent wing semispan and could be deflected 10° , 20° , or 30° . The plain flaps of 25 percent chord extended from 20 percent (wing-fuselage juncture) to 55 percent wing semispan and from 20 percent to 95 percent wing semispan.

A fuselage of circular cross section used in combination with the wing was attached in a midwing arrangement at zero incidence. The fuselage was provided with two different afterbodies which were used alternately to provide tail lengths of either 2 or 3 mean aerodynamic chords. The fineness ratio of the fuselage was either 8 or 10, depending on the fuselage afterbody used.

The horizontal tail had NACA 0012 airfoil sections parallel to the plane of symmetry, an aspect ratio of 3.12, and a taper ratio of 0.625. The ratio of tail area to wing area was 0.200. The tail was

The values of effective downwash angle were determined from data obtained at three tail incidence angles. The pitching-moment coefficient due to the tail C_{m_t} was plotted against the tail incidence angle i_t for various values of the wing angle of attack α . The intersection of the faired points with the C_{m_t} zero axis indicated the tail incidence angle for which the angle of attack of the tail was zero. The effective downwash angle ϵ_e was then obtained from the relation

$$\epsilon_e = \alpha + i_t - \alpha_t \quad (1)$$

The values of effective dynamic pressure ratio at the tail $(q_t/q)_e$ were determined by computing the ratio of the values $C_{m_{i_t}}$ obtained through the angle-of-attack ranges of the various configurations to the value of $C_{m_{i_t}}$ for the comparable tail height of the flap-neutral configuration at zero lift.

The tail efficiency factor η represents the effective change in the lift-curve slope of the tail due to the effect of the fuselage interference. The values of η are based on the assumption that the efficiency of the tail located at $z = 0.40b/2$ was 100 percent inasmuch as the distance from the fuselage was large and the interference effect of the tail post would be small. The values of η were obtained from the relation

$$\eta = \frac{(C_{m_{i_t}})_o}{(C_{m_{i_t}})_o} \quad (2)$$

The following table presents values of $(C_{m_{i_t}})_o$ and η for the flap-neutral configuration:

Tail Height	Tail length, $2\bar{c}$		Tail length, $3\bar{c}$	
	$(C_{m_{i_t}})_o$	η	$(C_{m_{i_t}})_o$	η
0.400b/2	-0.0202	1.00	-0.0302	1.00
.177b/2	-.0189	.94	-.0287	.95
-.177b/2	-.0190	.94	-.0280	.93

Presentation of Data

Data showing the effects of Reynolds numbers ranging from 2.8×10^6 to 7.6×10^6 , wing trailing-edge thickness, and cross-sectional shape of the wing tip on the longitudinal characteristics of the wing are presented in figures 4 to 6. The effects of plain flaps and drooped-nose flaps deflected individually and in combination on the wing are indicated by the data presented in figures 7 to 13. Figure 14 shows the flow patterns of the wing with and without flaps deflected. The effects of flaps on the longitudinal characteristics of the wing in combination with a fuselage are indicated by the data presented in figures 15 to 18. The effects of the various arrangements of flaps on the lift characteristics of the wing with and without a fuselage are summarized in figure 19. The effect on the longitudinal stability characteristics of the wing-fuselage configuration of a horizontal tail located at various vertical and horizontal positions is shown by the data presented in figures 20 to 24.

An index of the various configurations tested and a summary of the longitudinal stability characteristics has been presented in tables I, II, and III.

BRIEF ANALYSIS OF DATA

Wing Configurations

The wing exhibited leading-edge separation characteristic of sharp-edge airfoil sections at a low angle of attack (fig. 14) and, consequently, an increase in stability (fig. 4) associated with a rearward shift of the center of pressure was obtained. The lift-drag ratio of the wing decreased rapidly with the onset of separation from a maximum value of approximately 12 to approximately 3 at maximum lift (fig. 4). It is of interest to note that, contrary to the results shown in reference 4, a small destabilizing change in the pitching-moment characteristics and an increase in the slope of lift curve occurred in the low angle-of-attack range of the wing with increase in Reynolds number through the range investigated (fig. 4). The maximum lift coefficient of the wing was increased from 0.71 to 1.07 with the 0.35b plain flaps ($\delta_f = 50^\circ$) and to 1.34 with the 0.75b plain flaps ($\delta_f = 50^\circ$), (fig. 19(a)). With the drooped-nose flaps deflected, the initial leading-edge separation occurred at approximately the same angle of attack as the plain wing but was confined to the inboard 20-percent wing semispan where the leading edge was not drooped rather than along the entire leading edge. Separation then spread rearward and outboard as the angle of attack was increased; however, the flow in the region of the tips remained unseparated through the stall with the drooped-nose flaps deflected 30° .

plane appeared, in most cases, more favorable than that obtained with the horizontal tail located 0.177 semispan below the wing chord plane.

RESEARCH MEMORANDUM

LOW-SPEED LONGITUDINAL CHARACTERISTICS
OF AN UNSWEPT HEXAGONAL WING WITH AND WITHOUT A FUSELAGE
AND A HORIZONTAL TAIL LOCATED AT VARIOUS POSITIONS
AT REYNOLDS NUMBERS FROM 2.8×10^6 TO 7.6×10^6

By Gerald V. Foster, Ernst F. Mollenberg,
and Robert L. Woods

SUMMARY

An investigation has been conducted to determine the low-speed static longitudinal characteristics of an unswept wing having hexagonal airfoil sections and an aspect ratio of 2.5. The wing with and without a fuselage was tested with plain flaps (with several degrees of trailing-edge bluntness) and nose flaps deflected individually and in combination. The effect of a horizontal tail on the wing-fuselage configuration was investigated at various vertical and horizontal positions. The tests were conducted at Reynolds numbers ranging from 2.8×10^6 to 7.6×10^6 and Mach numbers ranging from 0.05 to 0.15.

A brief analysis of these data indicates that the wing exhibited leading-edge separation at a low angle of attack which produced a rapid increase in drag and a stabilizing change in the pitching-moment characteristics. The drooped-nose flaps delayed the leading-edge separation and the associated changes in the drag and pitching-moment characteristics. The stabilizing effect of the horizontal tail varied with vertical position in a manner similar to that shown by previous investigations of swept wings; however, the change of static margin through the lift range obtained with the horizontal tail located 0.40 semispan above the wing-chord plane appeared, in most cases, more favorable than that obtained with the horizontal tail located 0.177 semispan below the wing-chord plane.

INTRODUCTION

Theoretical and experimental investigations indicate that thin, unswept, low-aspect-ratio wings can in many instances be advantageously

MODEL AND TESTS

Model

The details of the wing, fuselage, and horizontal tail are shown in figure 1. The wing had an aspect ratio of 2.5, a taper ratio of 0.625, and neither twist nor dihedral. The wing had sharp leading and trailing edges formed by wedges which extended 30 percent of the chord. The upper and lower surfaces of the middle 40 percent chord of the wing were parallel and 6 percent of the chord apart. The wing was provided with interchangeable tips having wedge and elliptical cross sections (fig. 1). In a few instances the trailing-edge thickness of the wing was increased to 0.25, 0.50, and 1.00 of the maximum local thickness.

The wing was equipped with drooped-nose flaps at the leading edge and plain flaps at the trailing edge. The drooped-nose flaps of 15 percent chord extended spanwise from 20 percent wing semispan to 95 percent wing semispan and could be deflected 10° , 20° , or 30° . The plain flaps of 25 percent chord extended from 20 percent (wing-fuselage juncture) to 55 percent wing semispan and from 20 percent to 95 percent wing semispan.

A fuselage of circular cross section used in combination with the wing was attached in a midwing arrangement at zero incidence. The fuselage was provided with two different afterbodies which were used alternately to provide tail lengths of either 2 or 3 mean aerodynamic chords. The fineness ratio of the fuselage was either 8 or 10, depending on the fuselage afterbody used.

The horizontal tail had NACA 0012 airfoil sections parallel to the plane of symmetry, an aspect ratio of 3.12, and a taper ratio of 0.625. The ratio of tail area to wing area was 0.200. The tail was

attached to the fuselage by means of a strut and could be located vertically at either 40.0 or 17.7 percent wing semispan above or 17.7 percent wing semispan below the wing chord plane extended. The incidence of the tail, measured with respect to the wing chord plane, could be varied through an angle range of 2° to -6° .

Tests

Tests were conducted in the Langley 19-foot pressure tunnel to determine the longitudinal aerodynamic characteristics of the wing and the effects thereupon of various flaps, a fuselage, and a horizontal tail located at various vertical and horizontal positions. The longitudinal characteristics were determined by measuring the lift, drag, and pitching moment through an angle-of-attack range of -4° to stall. Tests to determine the air-flow characteristics at the wing surface also were made by observation of wool tufts that were attached to the upper surface of the wing. The various configurations tested are listed in tables I and II.

The maximum Reynolds number of the tests of the model with 0.35b plain flaps either in a neutral or deflected position was 7.6×10^6 . For tests of the model with 0.75b plain flaps deflected, the Reynolds number was 5.4×10^6 . The Mach number of the tests ranged from 0.05 to 0.15.

A two-support system was used in testing all model configurations except tail-on configurations for which a three-support system was used (fig. 2).

As an aid in the analysis of these data, the tail was tested independently at Reynolds numbers of 2.3×10^6 and 3.0×10^6 which corresponds to wing Reynolds numbers of 5.7×10^6 and 7.5×10^6 .

RESULTS

Reduction of Data

The results of tests have been reduced to nondimensional-coefficient form and, with the exception of the results of isolated tail tests, have been corrected for support-strut tare and interference. The angles of attack have been corrected for air-stream misalignment and jet-boundary effects. Jet-boundary corrections also were applied to the drag characteristics of all configurations and pitching-moment characteristics of the tail-on configurations. The jet-boundary corrections were determined by the method of reference 2.

The values of effective downwash angle were determined from data obtained at three tail incidence angles. The pitching-moment coefficient due to the tail C_{m_t} was plotted against the tail incidence angle i_t for various values of the wing angle of attack α . The intersection of the faired points with the C_{m_t} zero axis indicated the tail incidence angle for which the angle of attack of the tail was zero. The effective downwash angle ϵ_e was then obtained from the relation

$$\epsilon_e = \alpha + i_t - \alpha_t \quad (1)$$

The values of effective dynamic pressure ratio at the tail $(q_t/q)_e$ were determined by computing the ratio of the values $C_{m_{i_t}}$ obtained through the angle-of-attack ranges of the various configurations to the value of $C_{m_{i_t}}$ for the comparable tail height of the flap-neutral configuration at zero lift.

The tail efficiency factor η represents the effective change in the lift-curve slope of the tail due to the effect of the fuselage interference. The values of η are based on the assumption that the efficiency of the tail located at $z = 0.40b/2$ was 100 percent inasmuch as the distance from the fuselage was large and the interference effect of the tail post would be small. The values of η were obtained from the relation

$$\eta = \frac{(C_{m_{i_t}})_o}{(C_{m_{i_t}})_o} \quad (2)$$

The following table presents values of $(C_{m_{i_t}})_o$ and η for the flap-neutral configuration:

Tail Height	Tail length, $2\bar{c}$		Tail length, $3\bar{c}$	
	$(C_{m_{i_t}})_o$	η	$(C_{m_{i_t}})_o$	η
0.400b/2	-0.0202	1.00	-0.0302	1.00
.177b/2	-.0189	.94	-.0287	.95
-.177b/2	-.0190	.94	-.0280	.93

The values of η presented are also representative of the values obtained for configurations with flaps deflected.

The contribution of the tail to the stability can be conveniently expressed by a tail effectiveness parameter τ derived in reference 3, which is defined as follows:

$$\tau = - \left[\left(1 - \frac{d\epsilon}{d\alpha} \right) \frac{q_t}{q} + \alpha_t \frac{d\left(\frac{q_t}{q}\right)}{d\alpha} \right] \eta \quad (3)$$

or

$$\tau = \frac{\frac{dC_{m_t}}{d\alpha}}{\frac{S_t}{S} \frac{l}{c} (C_{L_\alpha})_t} \quad (4)$$

where

$$(C_{L_\alpha})_t = 0.050 \text{ per degree}$$

Figure 3 shows the variation of lift coefficient with angle of attack of the isolated tail. A negative value of τ signifies that the tail is contributing to the stability.

The values of τ presented herein were obtained with a fixed tail incidence, and, consequently, large out-of-trim conditions occurred at high angles of attack. Examination of equation (3) shows that, for finite values of α_t , τ is affected by the variation of q_t/q with α . For the condition where the tail is free of the wake and the values of $\frac{d\left(\frac{q_t}{q}\right)}{d\alpha}$ are negligible, the values of τ are independent of tail load and hence are applicable to any center-of-gravity location or tail incidence angle. Through the angle-of-attack range for which the tail passes through the wake finite values of $\frac{d\left(\frac{q_t}{q}\right)}{d\alpha}$ are obtained; hence, the values of τ for that angle-of-attack range are more nearly representative of a center-of-gravity location for which the measured tail load would provide trim at the wake center.

Presentation of Data

Data showing the effects of Reynolds numbers ranging from 2.8×10^6 to 7.6×10^6 , wing trailing-edge thickness, and cross-sectional shape of the wing tip on the longitudinal characteristics of the wing are presented in figures 4 to 6. The effects of plain flaps and drooped-nose flaps deflected individually and in combination on the wing are indicated by the data presented in figures 7 to 13. Figure 14 shows the flow patterns of the wing with and without flaps deflected. The effects of flaps on the longitudinal characteristics of the wing in combination with a fuselage are indicated by the data presented in figures 15 to 18. The effects of the various arrangements of flaps on the lift characteristics of the wing with and without a fuselage are summarized in figure 19. The effect on the longitudinal stability characteristics of the wing-fuselage configuration of a horizontal tail located at various vertical and horizontal positions is shown by the data presented in figures 20 to 24.

An index of the various configurations tested and a summary of the longitudinal stability characteristics has been presented in tables I, II, and III.

BRIEF ANALYSIS OF DATA

Wing Configurations

The wing exhibited leading-edge separation characteristic of sharp-edge airfoil sections at a low angle of attack (fig. 14) and, consequently, an increase in stability (fig. 4) associated with a rearward shift of the center of pressure was obtained. The lift-drag ratio of the wing decreased rapidly with the onset of separation from a maximum value of approximately 12 to approximately 3 at maximum lift (fig. 4). It is of interest to note that, contrary to the results shown in reference 4, a small destabilizing change in the pitching-moment characteristics and an increase in the slope of lift curve occurred in the low angle-of-attack range of the wing with increase in Reynolds number through the range investigated (fig. 4). The maximum lift coefficient of the wing was increased from 0.71 to 1.07 with the 0.35b plain flaps ($\delta_f = 50^\circ$) and to 1.34 with the 0.75b plain flaps ($\delta_f = 50^\circ$), (fig. 19(a)). With the drooped-nose flaps deflected, the initial leading-edge separation occurred at approximately the same angle of attack as the plain wing but was confined to the inboard 20-percent wing semispan where the leading edge was not drooped rather than along the entire leading edge. Separation then spread rearward and outboard as the angle of attack was increased; however, the flow in the region of the tips remained unseparated through the stall with the drooped-nose flaps deflected 30° .

(fig. 14). The delay of separation over the outboard sections of the wings caused by drooped-nose flaps deflected at least 20° minimized the large stabilizing change in the pitching-moment characteristics through a lift-coefficient range to just prior to CL_{max} (fig. 10). The summary of lift characteristics (fig. 19) indicate that the sum of increments of maximum lift contributed by plain flaps and drooped-nose flaps considerably exceeded the increment of maximum lift obtained for the wing equipped with plain flaps and drooped-nose flaps in combination.

Wing-Fuselage Configuration

The results of figure 19 indicate that the addition of the fuselage increased the maximum lift coefficient of the wing equipped with drooped-nose flaps as much as 0.2 ($\delta_n = 30^\circ$) but had a negligible effect on the maximum lift coefficient of the wing equipped with plain flaps. In general, the results for the wing-fuselage configuration either with or without flaps indicate a fairly large forward shift of the aerodynamic center as compared with the wing alone.

Wing-Fuselage Configuration in Combination

With a Horizontal Tail

In general, all tail-on configurations investigated exhibited static longitudinal stability throughout the lift range for the center of gravity at $0.25\bar{c}$. The effect of vertical position of the horizontal tail on the tail effectiveness is similar to that reported for swept-wing airplane configurations (refs. 3 and 5). The values of τ (figs. 20 to 23) indicate that the horizontal tail was more effective through the moderate and high angle-of-attack range when located $0.177b/2$ below the wing-chord plane than when located at either $0.177b/2$ or $0.40b/2$ above the wing-chord plane. This is attributed to a smaller variation of downwash angle with angle of attack just below the wake center line than just above the wake center line. The pitching-moment characteristics (table II) tend to indicate that, although the change of static margin through the lift range was large for all tail-on configurations, the change of static margin through the lift range obtained with the horizontal tail located 0.40 semispan above the wing chord

plane appeared, in most cases, more favorable than that obtained with the horizontal tail located 0.177 semispan below the wing chord plane.
