BISMANOL PERMANENT MAGNETS, EVALUATION AND PROCESSING

Prepared by:

Edmond Adams
William M. Hubbard

ABSTRACT: Bismanol permanent magnets have been evaluated for stability under various operating conditions. The magnets showed a remarkable flux constancy over a wide temperature range after stabilization at low temperatures. There is some decrease in magnetic flux density at the low temperature; the exact flux loss being dependent on the temperature of stabilization. Because of their high coercive force, the magnets are extremely stable magnetically to shock, vibration, centrifugal force and stray magnetic fields. Except for a tendency to chip, bismanol magnets are sufficiently strong physically for most applications. Unprotected bismanol magnets corrode slightly at ordinary temperatures and humidity, and more rapidly at 95 per cent humidity. Magnets with applied protective coatings remained stable at room temperatures and moderate humidities for the six-month test period.

The processing techniques of bismanol magnets have been improved by eliminating magnetic separation. The new technique consists of the separation of excess bismuth from the melt by hot-pressing prior to pulverization. Since the publication of the previous report, (NavOrd 2440) bismanol magnets have been made with maximum energy products up to 5.3×10^6 gauss-oersteds. Present maximum value for the coercive force (Hc) is now 3650 oersteds and 4800 gauss for the residual flux density (Br). Various types of pulverizing equipment were also evaluated with respect to the magnetic properties of the resulting compacts. The methods of determining percentage purity (MnBi content), alignment and effective particle size in bismanol magnets are discussed.

U. S. NAVAL ORDNANCE LABORATORY
White Oak, Silver Spring 19, Maryland

i

The subject investigation of bismanol permanent magnets was
undertaken as part of the broad program of the development
of new and improved magnetic materials, Task NOL-Requ-56-1-53.
NAVORD Report 2440 dated May 20, 1952 described previous progress
in the preparation of bismanol permanent magnets from powdered
manganese bismuthide.

BISMANOL PERMANENT MAGNETS, EVALUATION AND PROCESSING

INTRODUCTION

1. This report covers six months progress in the development of bismanol permanent magnets since the publication of NavOrd Report 2440, dated May 20, 1952. The first part of this report concerns itself with the evaluation of bismanol magnets under various operating conditions such as, temperature, shock, vibration, centrifugal force, humidity and salt spray. The second part describes continuing progress in the improvement of bismanol processing techniques.

EVALUATION

TEMPERATURE CHARACTERISTICS

2. The dependence of the high intrinsic coercive force (H_{ci}) on a high value of the crystal anisotropy constant (K_1) was first established by Guillaud[1] in his study of powdered manganese bismuthide. He also showed that in MnBi, the value for this anisotropy energy decreased with the lowering of temperature, and at $84^{\circ}K$ would be zero. This effect is due to an inversion of the "easy" and "hard" directions of magnetization along the crystal axes of hexagonal MnBi. Because of the decrease in the anisotropy energy, it is apparent that the coercive force value will be less at low temperatures than at room temperature. The effect of low temperature on bismanol magnets in an open circuit is shown in Figure 1a. It should be noted, in this open circuit, that although at $-56^{\circ}C$ there is a 58 percent loss in flux density, the magnets become quite stabilized over a wide temperature range. However, in a closed circuit there is no loss in induction since the lower temperature reduces only the coercive force. Even at $-50^{\circ}C$, as shown in Figure 1b, the coercive force of the magnet is still quite high, i.e., 1600 oersteds. In the use of bismanol permanent magnets, therefore, the circuit should be designed for the flux density available at the operating temperature.

VIBRATION

3. Bismanol magnets were vibrated at frequencies of 50, 100 and 500 cycles per sec. for periods of one-half to an hour
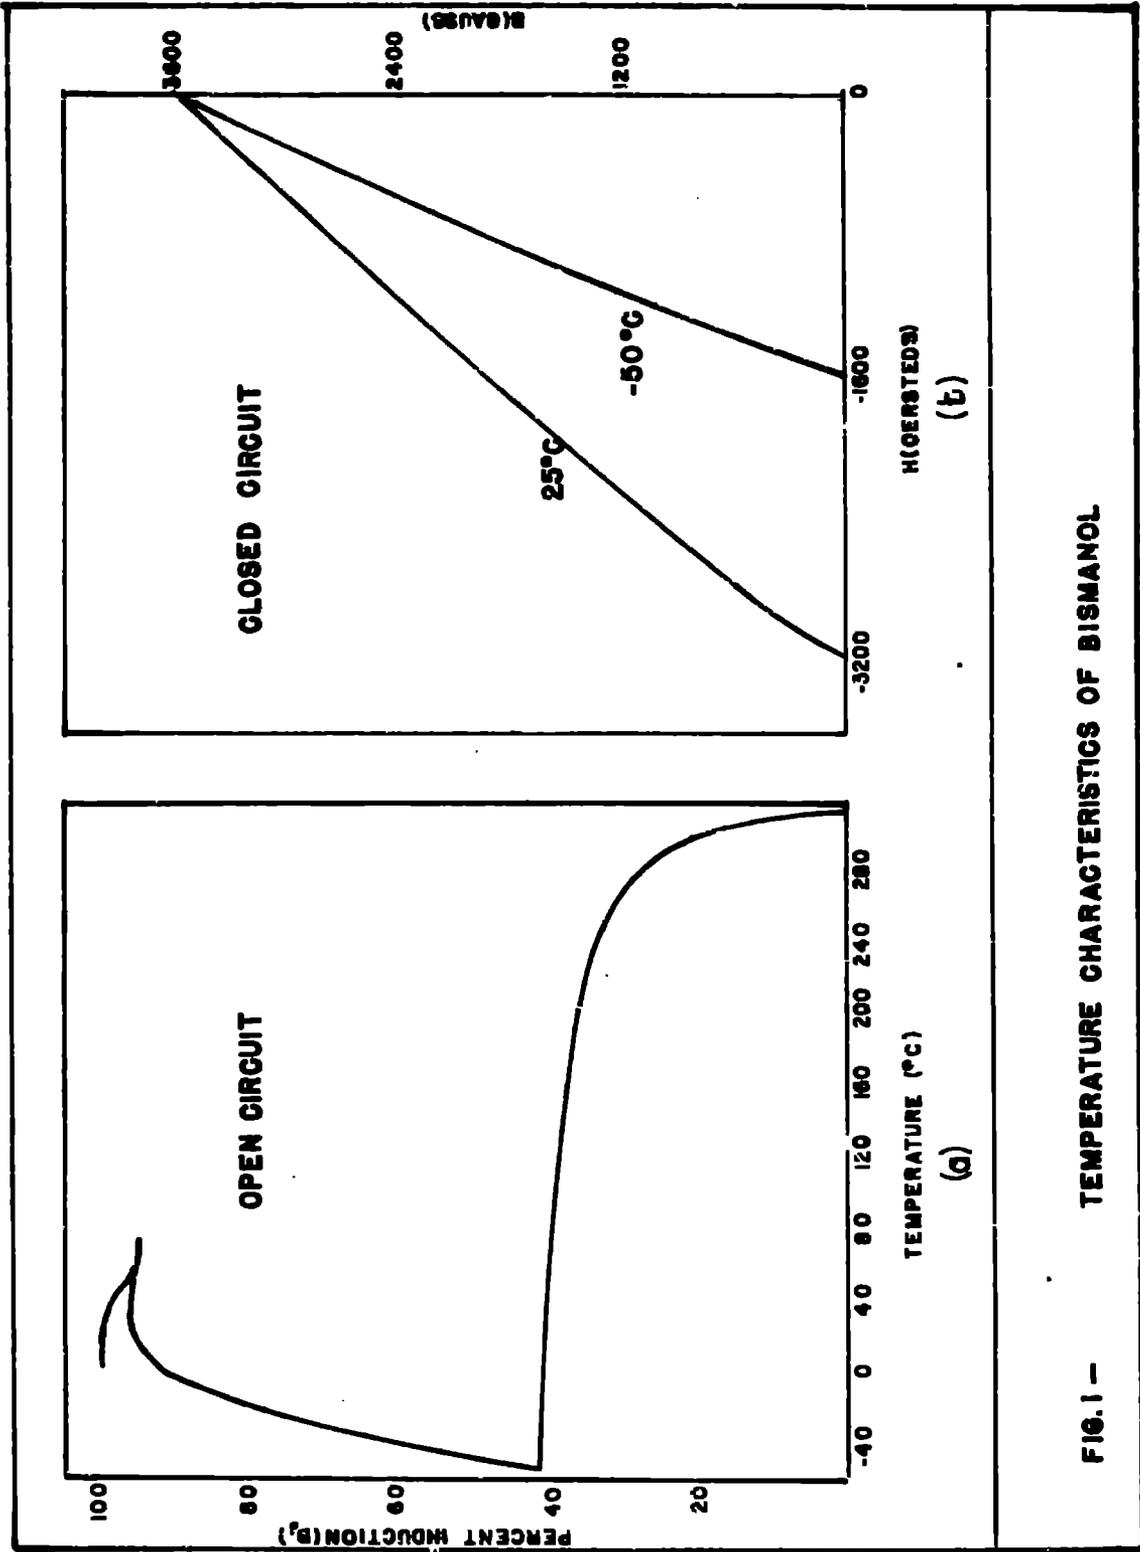

FIG. 1.— TEMPERATURE CHARACTERISTICS OF BISMANOL

at room temperature, 71°C and minus 54°C. No change in
magnetic or physical properties was noticed except those
due to temperature.

SHOCK

4. The shock tests performed on bismanol magnets were act-
ually drop tests. Table I summarizes the results of these
tests. As seen from Table I, the magnetic properties of
bismanol magnets are not affected by shock except by actual
physical damage to the magnet. This is what one would
expect from magnets prepared from high anisotropy materials.

CENTRIFUGE TESTS

5. Bismanol magnets were attached to a shaft with a steel
band around their periphery. The whole assembly was rotated
until they broke. The calculated maximum acceleration at
their outer radius was found to be 143,000 G's at the time
of fracture. This severe test suggests their possible use
as rotors in generator assemblies.

ROOM STABILITY

6. The magnets have been found to be stable, at room tem-
perature (70° ± 10°F) with a relative humidity not exceed-
ing 70 percent, for the six-month period measured. However,
unprotected bismanol magnets which received excessive hand-
ling became chipped along the edges and corroded at the
exposed portions. This is a result of damage to the thin
protective coating of bismuth present after hot-pressing.

HIGH HUMIDITY STABILITY

7. Bismanol magnets exposed to relative humidities of 95
percent or greater tend to corrode rapidly (72 hrs) with
some loss in their magnetic properties. Magnets protected
by external coatings, such as nickel, cadmium and zinc
plating, remain stable for somewhat longer periods (1-4
weeks). This problem has not been satisfactorily solved
at this time, but preliminary experiments have shown that
acid-dipping puts on a protective coating of a bismuth
salt. Evaluation studies of this type of coating are
currently incomplete.

SALT SPRAY STABILITY

8. Bismanol magnets subjected to standard ASTM Salt Spray
tests for over 100 hours, exhibit only superficial corrosion

TABLE I

RESULTS OF SHOCK TESTS ON BISMANOL MAGNETS

Sample	Feet Dropped	No. of Drops	Approx. G's Max.	Magnetic Change	Physical Change
1. On End	1	3	4000	None	None
1. On Side	1	2	4000	None	None

without any loss of their original magnetic properties.
Apparently, a stable coating of bismuth oxychloride prevents
further corrosion. This phenomenon is now being examined
as a possible protective coating for bismanol magnets.

STRAY MAGNETIC FIELDS

9. Because of the high coercive force of bismanol magnets,
extremely high accidental fields would be necessary to affect
the stability of the magnets. Exposure of the magnets to a
General Electric Demagnetizing Coil Unit at its full capacity
of approximately 800 oersteds showed no change in their flux
density.

PROCESSING TECHNIQUES

ENRICHMENT OF THE ALLOY

10. In order to prepare a magnet with the highest remanence
(Br), it is essential to prepare an alloy with the highest
percentage of the magnetic phase, manganese bismuthide.
Since the amount of MnBi in a melt is limited by its peri-
tectic nature, all attempts to increase the purity were made
after the preparation of the melt. The purification was
accomplished by one of two methods:

Method (A): This method, previously described in NAVORD
Report 2440, consists of the separation of the magnetic
and non-magnetic portion by means of a magnetic separator
after pulverization.

Method (B): In this new process, the excess bismuth in the
impure melt is squeezed out by hot pressing, before pulveri-
zation, at 25 tsi at 350°C in a loose fitting die. Adoption
of Method (B) has considerably speeded up the processing of
bismanol magnets by eliminating the slower process of
magnetic separation.

PULVERIZATION

11. It has been previously shown by Guillaud[1] that by
reducing the particle size of MnBi to about 3 microns, one
can obtain an intrinsic coercive force (Hci) as high as
12,000 oersteds. In order to increase the coercive force
of bismanol magnets, various methods of grinding were eval-
uated. Table II shows typical magnetic data on bismanol
magnets compacted from MnBi powder pulverized by various
means.

12. It is apparent from Table II that most bismanol magnets with the highest (Hc) values have a corresponding lower (Br) value. Conversely, magnets with a high (Br) show a lower (Hc) value. Because of the large number of variables involved, conflicting data makes it impossible to determine the exact explanation. However, it is known that finer particles have a larger surface area, increasing their tendency to oxidize, thus decreasing the purity. Small particles are also more difficult to align during pressing because of their lower magnetic moment.

13. Of the various grinding equipment evaluated, a high speed hammer mill of the "Mikropulverizer" type has proven the most satisfactory from a practical standpoint. Wet colloid milling yielded MnBi powder of extremely small particle size, but the decrease in (Br) values reduced the maximum energy product values. (Table II).

14. Powders ground from melts of Method (A) gave higher coercive force values, because the effective particle size is smaller than their apparent size due to the associated bismuth of the particles. Pulverization of Method (B) melts yielded powders requiring no magnetic separation. However, more efficient grinding was usually necessary to reduce the particle size small enough to obtain higher coercive force values.

15. It has been pointed out by Hoselitz[2] that the greatest improvement in (BH) max values for magnets where (Hc) = 0.45 x Br comes from increasing the value for (Br). This is a consequence of the geometry of the demagnetization curve. For magnets where (Hc) $\approx$ (Br), this curve must be a straight line with a slope approaching unity. For a high coercive magnet, such as bismanol, it is impossible to have a fuller demagnetization curve, otherwise the B-H curve would show that the magnetization would rise with a decreasing field. This, of course, is not possible. Figure 2 shows a typical normal and intrinsic hysteresis loop for a bismanol magnet.

PARTICLE SHAPE AND SIZE

16. The quantitative determination of the average particle size and distribution range of MnBi powder has not been made. It would be desirable to have such data but due to the large number of parameters involved, only a qualitative study was made. Figures 3 and 4 are photomicrographs of MnBi powder pulverized by various attrition mills. Except for sample (b), the particle size distribution appears to be unequal, usually

agglomerated large magnetic particles in a background of
extremely fine non-magnetic particles. This background
material, shown in focus in sample (f), may be chiefly
bismuth or small MnBi particles below domain size or insuf-
ficient magnetic mass to agglomerate. A typical alignment
of loose MnBi particles into agglomerated chains with equi-
distant spacing is shown in sample (e).

17. The results of particle size estimations by surface
area determinations* made by the BET nitrogen adsorption
method are shown in Table II. The values appear much lower
than those observed by other methods. This in part may be
due to the presence of extremely fine particles in an abnormal
particle distribution curve or errors in the BET method
dependent on the knowledge of the exact value for the nitrogen
adsorption coefficient of MnBi.

18. A semi-quantitative examination of a typical sample of
MnBi powder with an electron microscope* shows a few small
round particles ranging in size from 0.1 - 0.5 microns and
a few cubic twin crystals from 0.2 - 0.3 microns in diameter.
The bulk of the powder consists of irregular crystal fragments
and clusters ranging in size from 0.1 - 10 microns.

19. Because of the various discrepancies in the particle
size determinations, the method finally adopted consisted of
directly comparing the intrinsic coercive force of bismanol
magnets (compacted under standard conditions) with the curve
of particle size versus coercive force as experimentally
determined by Guillaud[1]. Assuming that these measurements
were correct this gives an approximate value of the effective
particle size.

COMPACTION

20. The dependence of the magnetic properties of bismanol
magnets on the compacting pressure, temperature and the
strength of the aligning field was established early. It
was determined that the optimum compacting pressure at 300°C
with an aligning field of 10,000 - 12,000 oersteds was 6,000 -
10,000 psi. A lower compacting pressure gives a lower density
with slightly higher (Hc) and lower (Br) values. However,
as previously shown, for high (Hc) magnets, such as bismanol,
a higher (Br) value is more important for a high maximum

* Determined by the National Bureau of Standards

energy product. The temperature of pressing can vary between
300 - 325°C. Higher temperatures tend to sinter the particles
thus reducing the (Hc) value. For this reason, such a com-
bination of pressure and temperature was experimentally
determined to produce magnets of optimum density, (Br), and
(Hc).

21. The die-body material in which the magnets are compacted
must be of non-magnetic material. Manganese-bronze,
beryllium-copper and austenitic stainless steel alloys were
found to be preferable, in the same order. The inside of
the die was plated with chromium in order to prevent the
adherence of bismuth to the walls. The rams were constructed
of chromium-plated hardened carbon steel. Ferro-magnetic
rams were used in order to concentrate the aligning field
and close the magnetic circuit. This is illustrated in
Figure 5. The filling factor for compaction in the die was
approximately 5 to 1, varying somewhat with the apparent
density of the MnBi powder. Bismanol magnets almost 2
inches in diameter with (BH) max values up to 5.3×10^6 have
been compacted using the techniques described. (Table II).
Magnets compacted in dies, where the pressing direction is
perpendicular to the applied field, did not improve the
quality of magnets.

PARTICLE ALIGNMENT, PURITY AND EFFECTIVE PARTICLE SIZE

22. In order to determine the degree of particle alignment
and percent purity, it is necessary to know the saturation
magnetization $(\sigma)_s$ per gram. This value is obtained by
measuring and plotting (B) vs (H) at (H) values from 7,000
to 14,000 oersteds. Then the value of (B-H) is found for
each point and (B-H) vs (H) is plotted. The value (B-H)s
can then be estimated by estimating the point where this curve
is flattening out or by actually subtracting (H_s) from the
(B)max value. From the relation $(B = H + 4\pi I)$, (I_s) is
equal to $\frac{(B-H)s}{4\pi}$. Since (I_s) is the saturation magnetization
per cc, to obtain $(\sigma)s$ per gram, it is necessary to divide
(I_s) by the density; $\sigma s = \frac{I_s}{d}$.

23. According to Guillaud[1], pure MnBi should have a
magnetic moment per gram $\sigma = 66$ at room temperature.
Therefore, the ratio between the two values determines the
fraction of MnBi in bismanol magnets.

24. The ratio between (B-H) at (H) = 0 and (B-H)s gives the fraction of the elementary MnBi domains aligned in the preferred direction of magnetisation, because for 100 per cent alignment the (B-H) curve would be a straight line from (H) = 0 to (H) = sat.

25. The (B-H) curve is drawn down far enough to intercept the (H) axis giving the intrinsic coercive force (Hci). As previously stated, a comparison of this (Hci) value with the curve showing the dependance of the coercive force on particle size as determined by Guillaud[1] give an approximate value of the effective particle size if the pressed magnets. Table II shows values for alignment, purity and effective particle size on some bismanol magnets.

CONCLUSION

26. Bismanol magnets, after low temperature stabilization, exhibit a magnetic flux constancy over a wide temperature range with some loss in original available energy.

27. The magnets were found to be extremely stable magnetically to shock, vibration, centrifugal force and stray magnetic fields.

28. The application of some protective coating is indicated to prevent corrosion in atmospheres of high relative humidity.

29. By squeezing out excess bismuth from the bismuth-rich melt prior to pulverization, the slower procedure of magnetic separation has been eliminated.

30. A high speed hammer mill of the "Mikropulverizer" type was found to be the most satisfactory of the various types of attrition mills evaluated.

31. Bismanol magnets up to 2 inches in diameter have been compacted with various thicknesses. Such magnets are ideally suited to applications requiring high magnetic flux density, e.g., loudspeakers.

ACKNOWLEDGEMENT

32. Acknowledgement is made to the Technical Evaluation Department, especially J. T. Lamb, for conducting the evaluation studies on bismanol. Work on the improvement of processing techniques was conducted by A. M. Syeles

and V. Glickman. The development of techniques for electro-
plating metallic coatings on bismanol magnets was done by
J. Gilfrich. The magnetic data on the magnets was obtained
by M. Pasnak and Mrs. G. Karol under the direction of
D. I. Gordon. Surface area determinations of MnBi powder
and electron photomicrograph studies were made by C. M. Hunt
and Max Swerdlow of the National Bureau of Standards.
