EXPERIMENTAL MEASUREMENTS OF THE VOLUMETRIC
AND PHASE BEHAVIOR OF MIXTURES OF NITRIC
OXIDE AND NITROGEN DIOXIDE

F. T. Selleck, H. H. Reamer, and B. H. Sage

Chemical Engineering Laboratory
California Institute of Technology
Pasadena, California

Experimental measurements were made of the volumetric behavior of mixtures of nitric oxide and nitrogen dioxide for pressures up to 7,000 pounds per square inch in the temperature interval between 40° and 340° F. Most of these compositions were investigated in detail and the remainder were studied at only one specific volume. These measurements were made in constant volume equipment (1, 2) by following the change in pressure with temperature at a constant weight of sample. The total quantity of mixture in the isochoric equipment was varied in the case of four mixtures by withdrawing portions of the sample at a homogeneous state and determining the change in weight of sample by weighing bomb techniques. Dew points and bubble points were established by discontinuities in the isochoric pressure-temperature derivatives.

The total volume of the spherical isochoric vessel used in these measurements was determined as a function of temperature and pressure from a knowledge of the volume at one state and the thermal expansion and Young's modulus of the steel employed in its construction. The spherical form of the vessel together with a nearly uniform wall thickness permitted such strain calculations to be made with accuracy. The volumetric characteristics

of the vessel were checked by calibration with water using the data of Smith and Keyes (3) for the volumetric behavior of the latter compound at elevated temperatures and pressures. Agreement with the calculated total volume of the sphere within 0.1% was obtained at temperatures between 40° and 340° F. and for pressures up to 7,000 pounds per square inch. In the course of the present work the volumetric characteristics based upon the properties of the steel were employed to determine the effect of temperature and pressure upon the total volume of the sphere.

Table I records corresponding values of pressure, temperature, and specific volume for each of the four mixtures which were investigated systematically. For each of these mixtures the pressure-temperature relations were determined for a number of different weights of sample. Table II records corresponding values of pressure, temperature, and specific volume for the 11 other mixtures investigated. In each of these cases only a single weight of sample was studied. The absence of a series of measurements at different weights of sample (different specific volumes) for a mixture of fixed composition results in difficult direct interpolation of the data to even values of pressure, temperature, and composition.

The pressures recorded in Tables I and II involve a standard error of 0.1% of the value or 0.3 pound per square inch, whichever is the larger measure of uncertainty. The weight of sample employed was known within 0.03% and the standard error in predicting the total volume of the

working vessel was 0.1%. It is believed that the specific volumes were established with a standard error of 0.15%. The temperature of the vessel was determined with a platinum resistance thermometer with a standard error of 0.03° F. from the international platinum scale. The estimates of small standard error were confirmed by the precision of the measurements which was about one-half of the total of the standard error of the several variables involved.

The results of the experimental measurements of the bubble point and dew point states are recorded in Table III for four mixtures which were investigated systematically and 11 mixtures which were studied at a single total weight of sample. These data were established from discontinuities in the nearly isochoric pressure-temperature derivative obtained from the data presented in Table I. The uncertainty in determining the bubble point and dew point states depends upon proximity to the critical state of the mixture. In the immediate vicinity of the critical state the change in slope of the isochoric pressure-temperature relation at the phase boundary is small. For this reason the uncertainty in the location is several times the standard error realized in determining experimentally the corresponding values of pressure and temperature. At a distance from the critical state the uncertainty in establishing the phase boundary is not more than twice the standard error of measurement.
