OBJECT

Studies toward the establishment of a theory of recoilless rifle blast.

SUMMARY

The study of the blast from recoilless rifles requires a theoretical analysis as a preliminary step to an extensive experimental mapping of the blast field. To this end, a theoretical analysis of the flow from a nozzle has been made. A single, wedge shaped nozzle with 7° half-angle of divergence was considered. The ratio of exit height to entrance height of the nozzle is $\sqrt{2}:1$. Chamber pressure and temperature have been assumed to be 5400 psi and 2400° K, respectively. The principal feature of the flow is a concentrated, almost stationary, region of strong shock called the Mach disk. This was not located in the course of the usual calculations because of the limited assumptions of the theory. On the basis of the growth of turbulence in the boundary layer, the distance of the Mach disk from the exit section of the nozzle was found to be between 40 and 140 exit diameters, the first value being the more probable. The pressure and temperature after the shock are 40 psi and 2300° K in the first case, 14.6 psi and 3100° K in the second case. Mach numbers as high as ten occur in the flow. A detailed map of the flow up to a point 140 exit diameters away from the exit section is given. This map should provide a guide for the study of the blast from recoilless rifles, since it enables one to interpret better the results of experimental studies. Furthermore, the location of the Mach disk can serve as a criterion for further improvements in the theory.

INTRODUCTION

The study of the blast from recoilless rifles must proceed in two parallel modes, the experimental and the theoretical. The first step in the theoretical analysis of the blast of gas from recoilless rifles is the study of flow from a very high pressure nozzle (chamber pressure greater than 1000 psi). This report gives the first approximation in the study of the free gas jet coming from such a nozzle. Such a study is only the first of a series of calculations, but by itself it yields significant information about high pressure jets in general, and thus may be useful as a guide in long range planning.

It is a general feature of high pressure jets that they are separated into two distinct regions by a very strong shock perpendicular to the axis of the nozzle, called the principal Mach disk. Studies of the region downstream (i.e., the region farthest from the nozzle) of this shock may be done independently of work on the upstream side.

This report covers the region of flow (in the two-dimensional case) between the nozzle and the principal Mach disk. The chief results of this work are contained in the maps of the flow field given in Figures 1 and 2 and Table I. These give approximate values of pressure and velocity at any point in the indicated region of gas flow. Preparations are being made to correlate the theoretical analysis of the blast with an experimental map of the flow field.

BASIC DEFINITIONS

The specialized vocabulary of fluid dynamics requires a set of definitions for the full understanding of any report on some phase of that subject.

Sonic Velocity

The velocity of sound in the medium at the point under consideration; usually assumed to be the square root of the ratio of the specific heats of the gas times the local pressure divided by the local density.

Hodograph

Refers to the "velocity" plane, the plane whose coordinates are the components of the gas velocity vector. By the hodograph 'transformation,' the determination of the flow at a point in the physical (x,y) plane is made by examining the flow at a corresponding point of the hodograph plane.

Sonic Circle

The locus of those points in the hodograph plane where the gas velocity is equal to the local sound velocity. This locus is a circle.

Mach Number

A dimensionless parameter equal to the ratio of gas velocity to local sound velocity. In supersonic flow the Mach number is always greater than one. On the sonic circle the Mach number is one.

Mach Angle

The angle whose sine is the reciprocal of the Mach number. This angle is real for supersonic flows only.

Characteristics

A network of lines which is derived from the equations of motion and is used to characterize a particular solution. The analytic definition is given in Appendix A. In two dimensions there are two characteristics through each point. The flow quantities (pressure, density, velocity) are determined at any point by their values on those neighboring points which are on one of the two characteristics passing through the point in question, if the characteristics are real. This is the case in supersonic flow.

Rotationality and Vorticity

These quantities refer to the angular momentum present locally in a flow without singularities. The vorticity is proportional to the local angular momentum; when the vorticity is zero in a region, the flow throughout the region is said to be irrotational.

Shock Bottle

A configuration of shocks usually seen in high pressure jets, such as are found at the muzzles of guns. There are two shocks near the jet boundary, curving inward as one goes away from the exit of the nozzle, terminating in a Mach disk. This structure has the outlines of a bottle, hence the name. There are usually two shocks leaving the Mach disk which look like reflections of the two shocks forming the sides of the bottle. The two shocks nearest the nozzle exit are called intercepting shocks. Those on the downstream side of the Mach disk are called reflected shocks. (Figure 4).

Boundary Layer

A very thin region of transition in what is usually considered the boundary of the flow. The flow in this region is considered, in general, as being determined by the flow in the main portion of the stream, i.e., the flow in which no boundary layer is taken into account. The boundary layer is subsonic and often turbulent.

BASIC ASSUMPTIONS

The following assumptions are made:

The most general features of this type of flow are contained in the flow from a circular nozzle whose expansion ratio and divergence are small. This assumption is not questionable, except when one wishes to consider the flow on the axis near the nozzle. High pressure, in general, tends to decrease the dependence of the flow on nozzle shape at large distances and increase it at small distances from the exit section. The critical distance is of the order $\sqrt{M^2-1} L$, where L is the principal nozzle dimension and M is the Mach number at the exit section.

The flow is isentropic from the throat of the nozzle to the first shock reached in the atmosphere. This neglects the effects of minor shocks arising in the nozzle from surface defects, and shocks on the axis from lip effects, both of which must be neglected if the calculations are to be made in a reasonable time. Conversations with various authorities in the field reveal that the first of these effects is not likely to be large, while the last can not be estimated at this time.

The flow is irrotational; the ratio of specific heats is constant; secondary combustion can be neglected. These assumptions are necessary to facilitate computation. Irrotationality is associated with isentropic flow. Variations in the ratio of specific heats can be neglected, if previous work in the field is any indication. The neglect of secondary combustion is necessary in order to compute the points where secondary combustion can occur. In other words, such combustion is viewed as a small perturbation of the flow, like the boundary layer.

Boundary layer effects are to be excluded. This assumption is usually made in calculations like these, and indeed it is necessary to do so; but this question will be treated more fully in the body of the report.

Sufficient accuracy is obtained when the flow is determined via the method of characteristics for the corresponding two-dimensional case. This is standard procedure in computing axially symmetric flows. There are points where the correction is likely to be considerable; but in view of the various other approximations it is doubtful that the computations necessary to make this correction are justified at this time. The two-dimensional approximation will be treated more fully in the body of the report.

PROCEDURE

A two-dimensional, wedge shaped nozzle, whose expansion ratio is $\sqrt{2}:1$, and whose half-angle of divergence is 7° , is chosen. The chamber pressure is taken as 5400 psi. The chamber temperature is taken as 2400° K. Atmospheric pressure is taken as 14.7 psi, γ = ratio of specific heats = 1.4.

The method of characteristics is used to map the corresponding two-dimensional flow field. The characteristics method is adequately described in standard texts¹ and is reported more fully in Appendix A. Only a general description of the method will be given here.

The flow equations, which are discussed in Appendix A, are partial differential equations of the hyperbolic type (in the case of supersonic flow). The construction of the solution of a partial differential equation of hyperbolic type was formulated in great generality by Riemann around 1860. Earlier the method had been suggested for electrodynamics by Huyghens, on physical grounds. Thus, it is often the practice to refer to the Riemann method of solution as a Huyghens construction, even though the equation is not from electrodynamics.

In general, linear equations permit of much more elegant and sophisticated methods of solution, and the method of characteristics is reserved for such tasks as delimiting the region in which a solution exists. This is particularly the case when the coefficients are constant; but if the coefficients vary widely, and/or the equation is nonlinear, such methods fail and recourse must be had to the characteristics method.

The success of this method is limited to two dimensions, by and large, by computational difficulties. The accuracy is limited by the size of the mesh, and even though the initial steps are quite small, the mesh becomes very large if there is large expansion, and there is a resulting loss in accuracy. One must assume the state of flow along some initial curve. Boundary conditions, such as containment within walls and the existence of a free surface in the atmosphere, can be applied automatically. Other types of boundary conditions are difficult to apply but luckily do not often arise.

It should be understood that the method is valid only up to the formation of a shock, but it can be continued formally beyond the shock to give a lower order of approximation there.

Appendix A describes the analytical techniques for obtaining pressure and density from a map of the flow characteristics. The details of preparing such a map are given in Appendix B.

¹A. Ferri, "Elements of Aerodynamics of Supersonic Flows," Macmillan, New York, 1949; pp 19-40 (ch 2).

RESULTS AND DISCUSSION

Figure 1 is the map of the flow in the nozzle, and of the flow immediately beyond the nozzle exit. Figure 2 is the map of the entire flow up to the principal Mach disk. Figure 3 is a plot of the static pressure along the line of fire, behind the gun. Tables I and II enable one to find the pressure, density, velocity, etc., in any particular square of the flow map.

Flow in the Nozzle

Flow in the nozzle is almost identical with that predicted by hydraulic theory. This will not be the case in general for nozzles of much higher angles of divergence. The most striking feature of the flow immediately beyond the exit section is the sharp turn, through 57° (Figure 1), made by the boundary streamline in order to form a free surface at a pressure of 14.7 psi. From this point to the region of influence of the principal Mach disk the boundary curves back towards the axis.

Formation of the Shock Bottle

Rarefaction waves from the exit section are reflected from the boundary, and return to the main stream as compression waves which form an envelope called the intercepting shock (the sides of the shock bottle). Computation of the flow is continued formally in the region between this shock and the boundary. Neglect of shock conditions gives a lower order of accuracy there. This shock is comparatively weak, and corrections are not large, except in the neighborhood of the Mach disk and its reflected shock.

The inclination of the shock to the stream direction is almost constant at 24° . The rotationality introduced in the downstream flow depends on the entropy gradient there. The entropy gradient will be high, since the variation in Mach numbers upstream of the shock is from 6 to 10, roughly.

Pressures in Front of the Shock Bottle

Static pressure along the axis is easily plotted and the results are given in Figure 3. Units of length are arbitrary and are determined by the half height of the throat which is 1.25 units of length. The point of inflection corresponds to a focus in the actual three-dimensional case, where the sudden change in the streamline slope at the exit section makes itself felt as a logarithmic singularity at the indicated point on the axis. That point is the intersection of cone whose base is the exit section and whose apex angle is the exit Mach angle. This effect was discovered by S. A. Pai at the Institute for Fluid Dynamics, University of Maryland.

Pressure along other radial lines requires extensive interpolation before it can be tabulated. The very low pressures (and, consequently, temperatures) and very high Mach numbers produced in the flow should be noted. These point to the possibility of condensation and consequent condensation shocks.

Location of the Mach Disk

It was hoped that the method of calculation employed here would yield the location and extent of the principal Mach disk. It was surprising to find that this did not occur. The intercepting shock reflected from the symmetry axis and it was not possible to discern any reason for the location of a Mach disk. The shock pattern found was revealed to be well within critical limits and on the basis of this work alone there was no reason to expect a Mach disk.

Nevertheless, such disks have invariably been found in jets whose pressures, while more than a few atmospheres, were much lower than those used here. Moreover, the shock bottle, whose top is a Mach disk, has been observed time and again at the muzzles of guns. D. C. Pack of the Institute for Fluid Dynamics, University of Maryland, has said that similar difficulties had been noted by a number of his students. Consequently, it is believed that some other mechanism, possibly one heretofore purposely neglected, is responsible for this phenomenon. Courant and Friedrichs² express the opinion that the process of mixing with the surrounding air is largely the determining factor.

Some hypotheses about the formation of the Mach disk are:

1. The disk is a stable configuration established early in the formation of the jet by the action of transient phenomena.
2. In steady state flows, the transition of the boundary layer from laminar to turbulent flow causes a disturbance in the main stream which sets up a Mach disk.

In either case the mechanism is the same: vorticity is produced at some point or region and propagates into the main stream (via the heat-conduction-convection equation). Extra vorticity can be introduced into the flow only by curving the shocks more strongly. After a point an oblique shock is no longer possible and a normal shock (Mach disk) comes into being. Presumably, there is a point where no laminar flow is possible anywhere in the jet and the usual jet structure breaks down.

In the first case, vorticity is produced either by mixing with the air or interference from the nozzle lips. Then at some point in the early development of the jet, the vortex ring and the back pressure associated with the short length of the growing

²Courant and Friedrichs, "Supersonic Flow," Interscience, New York, ¹⁹⁴⁸~~1959~~, p. 392.

jet causes the flow to choose one possible pattern rather than another, the chosen pattern being stable.³ Such ambiguities in supersonic flow are well known.

In the second case, the boundary layer changes abruptly from laminar to turbulent flow. In such a case the pressure on the main body of the stream changes sharply as the pressure gradient in the boundary layer changes from that characteristic of laminar flow to that characteristic of turbulence. Such a disturbance is propagated along a characteristic line to the rest of the flow. Such a disturbance can act not only as a source of vorticity but also as a strong pressure pulse. When this characteristic hits the intercepting shock, the curvature of the shock must change in order to take this new disturbance into account. If the pressure is sufficiently high (the critical value depends upon the nozzle) the shock must be normal. Unfortunately, the theory of the boundary layer transition is not formulated sufficiently at present for definite predictions to be made. Recent work on the transition from laminar to turbulent boundary layer flows shows that this transition is associated with Reynolds' numbers of the order 10^5 for conical flow (using velocity along the surface), 10^6 for flow over a flat plate. A quick, rough calculation shows that this magnitude Reynolds' number is likely to be reached at a point one-third of the way along the boundary of the jet between the exit section and the point of maximum expansion. This will reduce the distance of the Mach disk from the exit section to about one-third of the value shown in Figure 2.

It is reasonable to assume that the boundary layer transition will occur, if at all, between the lips of the nozzle and the point where the boundary becomes horizontal. The first point is the start of mixing with the surrounding atmosphere, the second the only other point distinguishable on physical grounds from any other point on the boundary. In other words, the assumption is made that the transition occurs in the first half of the main jet structure. This assumption is justified by Schlieren photographs of jets available from a number of sources.⁴

For the purposes of this analysis, the point of intersection of the characteristic from the horizontal part of the boundary with the intercepting shock was chosen as the location of the normal shock. This represents the maximum distance away from the nozzle of the Mach disk. This distance is of the order of 140 exit diameters. There are many indications that this is two or three times too large, indicating a transition point somewhat closer to the nozzle. Such an error is caused not only by improper location of the critical characteristic line, but also by neglect of any shocks or similar details on the axis caused by nozzle details. Otherwise, errors of this magnitude are not expected.

³Hartmann, J. and Lazarus, F., "The Air-jet with a Velocity Exceeding That of Sound." *Phil. Mag.* 31, 7, 35-50, 1941.

⁴Hartmann and Lazarus, loc. cit.; Payman and Sheperd, "Explosion Waves and Shock Waves," *Proc. Roy. Soc. A.* 186, plate 17, Figures 10-20, (1946).

Experimental studies of the flow of powder gas through a conical nozzle similar in cross-section to the one studied here show that the Mach disk occurs about 15 exit diameters from the nozzle exit. This corresponds to the point (Figure 2) where the characteristic leaving from the focus intersects the boundary. As a number of authorities have mentioned, this corresponds to the first point where the entire flow is aware of the presence of the atmosphere. Hence, this represents the point closest to the nozzle that the Mach disk can occur. This can then be used as a criterion for locating the disk with considerably better accuracy than the method mentioned previously. These experimental studies were conducted some time after the main body of the report was written.

CONCLUSIONS

The study presented here represents an attempt to understand the most general features of the jet from a nozzle backed by very high pressure. As soon as a reliable method for locating the Mach disk is available, this study will provide an adequate representation of the flow in the section nearest the nozzle. In the meantime this study establishes the maximum extent of that flow.

The pressures indicated in the graph in Figure 3 and the corresponding dynamic pressures give a good indication of the forces to be expected in the region upstream of the Mach disk. In the downstream region an analysis of the mixing with the air is needed before similar conclusions can be drawn.

The extrapolation to three dimensions can be carried out formally by a method outlined in: R. Sauer, "Method of Characteristics for Three-Dimensional Axially Symmetric Supersonic Flows," N.A.C.A. T.M. 1133, Washington, 1947. Examples given in this reference indicate that linear dimensions are decreased by a few per cent, in general. This arises from the extra room for expansion provided by the third degree of freedom. More quantitative statements than this can not be made at this time because of the difficulty in locating the principal Mach disk. The only effect opposing the decrease in linear dimensions is that of secondary combustion. The low temperatures and pressures before the disk and the high temperatures and pressures after the disk indicate that most secondary combustion will occur after the disk.

It should be pointed out that even a phenomenological theory for the location of the Mach disk is a new development in basic theory, and it is therefore recommended and requested that this work be pushed to its logical conclusion by both theoretical and experimental analyses.

FUTURE WORK

Future work on this particular phase of the blast program should be concentrated on experimental investigations designed to test the various hypotheses advanced as to the cause of the Mach disk. Two series of such experiments are planned:

A powder charge will be exploded in a suitably vented vessel and the development in time of the jet recorded with high speed spark or Schlieren photographs.

Different atmospheres will be introduced into a suitably chosen glass tube, and a jet formed by exhausting a high pressure (3000 psi) tank through a needle valve whose opening can be adiabatically controlled, will be studied.

The first of these experiments is in the process of development, while the second awaits adequate room and equipment.

Table II. Numerical Relations for the Two-dimensional Characteristics System

The table gives as a function of the characteristic number N (column 1) the following quantities:

Column 2 The value of ν , deviation of expansion from Mach number 1.

Column 3 The value of the stream Mach number (determined from column 2).

Column 4 The ratio of the local static pressure p to the critical static pressure p^* corresponding to the pressure for ($M = 1$).

Column 5 The Mach angle μ determined from column 3.

Note: $\frac{C_1 + C_2}{2} = N$

APPENDIX A

The Method of Characteristics for two-dimensional, steady, isentropic flow in two dimensions.

I. Theory

Let u and v be the x and y components of velocity q , respectively, and let θ be the angle the vector velocity $\vec{q}$ makes with some fixed reference line in the x, y plane. Let p be the pressure, C_p = specific heat at constant pressure, C_v = specific heat at constant volume, ρ the density, $k = \frac{C_p}{C_v}$ = the ratio of specific heats. The differential equations of motion for steady, perfect, irrotational, isentropic flow in two dimensions are: (see, e. g. Courant and Friedrichs, Loc. Cit.)

$$uu_x + vv_y = -\frac{1}{\rho}(p_x) \quad (1)$$

$$uv_x + vv_y = -\frac{1}{\rho}(p_y)$$

$$(ru)_x + (rv)_y = 0 \quad (2)$$

$$v_x - u_y = 0 \quad (3)$$

$$p = p(r) \text{ only}$$

$$p = ar^k$$

$$a = \text{const.}$$

From the sound speed c , $c^2 = \frac{k p}{\rho}$, we have $r_x = \frac{1}{c^2} p_x$. This together with (1) and (2) gives

$$(u^2 - c^2)u_x + uv(u_y + v_x) + (v^2 - c^2)v_y = 0 \quad (4)$$

The relation (3) implies the existence of a function $\varphi(x, y)$, called the potential function, which satisfies

$$u = \varphi_x, \quad v = \varphi_y$$

In (4) this gives:

$$(u^2 - c^2) \varphi_{xx} + 2uv\varphi_{xy} + (v^2 - c^2) \varphi_{yy} = 0. \quad (5)$$

a nonlinear differential equation for the determination of the potential $\varphi(x, y)$. It is well known that such a partial differential equation defines a family of curves $S(x, y) = \text{Const.}$, called the characteristics. They are obtained by the substitution

$S_x^2 = \varphi_{xx}$, $S_y^2 = \varphi_{yy}$, $S_x S_y = \varphi_{xy}$. Then from (5):

$$(u^2 - c^2) S_x^2 + 2uv S_x S_y + (v^2 - c^2) S_y^2 = 0 \quad (6)$$

The slope of a surface $S(x,y)$ is given by $m = \frac{dy}{dx} = \frac{-S_x}{S_y}$ so that (6) gives $(u^2 - v^2)m^2 -$

$2uv m (v^2 - c^2) = 0$. This quadratic equation has the two solutions

$$\left. \begin{matrix} m+ \\ m- \end{matrix} \right\} = \frac{2uv \pm \sqrt{4u^2v^2 - 4(u^2 - c^2)(v^2 - c^2)}}{2(u^2 - v^2)}$$

Evidently, at any point in the physical (x,y) plane there are defined two curves, depending on velocity solutions u,v of equation (5). These slopes are real if and only if

$$\begin{aligned} 4u^2v^2 - 4(u^2 - c^2)(v^2 - c^2) &> 0 \\ \text{i.e., } u^2 + v^2 &= q^2 > c^2 \end{aligned} \quad (7)$$

the flow is supersonic. If the above quantity (7) is equal to 0 at a point, the flow is sonic there, and there is only one characteristic at the point. Evidently the net formed by the two characteristics through each point is degenerate on a sonic line in the flow.

The characteristics can be shown to have the following properties:

1. Discontinuities in the derivatives of u and v can only occur on these characteristic, or "Mach", lines. Thus the Mach lines can be visualized as wave fronts in supersonic flow.

2. The characteristics at a point make equal angles A with the streamline, and this angle is the so-called Mach angle. We find

$$\sin A = \frac{c}{q}$$

3. The characteristic net represents a coordinate system in the physical plane (except on degenerate sonic lines). If we introduce parameters a, b along the Mach lines, we have the characteristics given by

$$C^+: y_a = m_+ x_a$$

$$C^-: y_b = m_- x_b$$

We may interchange dependent and independent variables in equation (4) by the transformation

$$u_x = jy_v, u_y = jx_v, v_x = jy_u, v_y = jx_u$$

as long as the Jacobian determinant $j = u_x v_y - u_y v_x$ does not vanish in the region under consideration. We find, analogous to equations (3) and (4),

$$(a) \quad x_v - y_u = 0$$

$$(b) \quad (u^2 - c^2)y_v - uv(x_v + y_u) + (v^2 - c^2)x_u = 0 \quad (8)$$

By the first, there exists a function (u,v) , a "hodograph potential," which satisfies

$$(u^2 - c^2) \phi_{vv} - 2uv \phi_{uv} + (v^2 - c^2) \phi_{uu} = 0 \quad (9)$$

$\phi(u,v)$ is the Legendre (contact) transformation of $\phi(x,y)$: $\phi = ux + vy - \phi$. Note that this equation is linear. A new set of characteristics $T(u,v)$ is found as before to satisfy:

$$(u^2 - c^2)T_v^2 - 2uvT_u T_v + (v^2 - c^2)T_u^2 = 0$$

The slope of these u, v characteristics is found to be $\frac{du}{dv} = \frac{-m_-}{-m_+}$, ~~or~~

$$G^+: u_a = -m_- v_a$$

$$G^-: u_b = -m_+ v_b \quad (10)$$

1. These characteristics are independent of the solution $x = x(u,v)$, $y = y(u,v)$, and are thus fixed in the u,v plane.

2. The relations $u_a x_b + v_a y_b = 0$ can be obtained, and indicate the following

$$u_b x_a + v_b y_a = 0$$

vital fact: Consider the image point u,v of a physical point x,y ($j(x,y) = 0$). The C^+ characteristic through x,y is perpendicular to the G^- characteristic through u,v , and the C^- characteristic through x,y is perpendicular to the G^+ characteristic through u,v . This is the basis of the graphical construction method. Equations (10) are integrated directly using Bernoulli's equation for c :

$$u^2 q^2 + (1 - u^2)c^2 = c_*^2, \quad u^2 = \frac{k-1}{k+1}$$

One finds the characteristics:

$$\begin{aligned} \mp 2\theta = & \sqrt{\frac{k+1}{k-1}} \sin^{-1} \left[(k-1) \frac{q^2}{c_*^2} - k \right] \\ & + \sin^{-1} \left[(k+1) \frac{c_*^2}{q^2} - k \right] + 2\epsilon \end{aligned} \quad (11)$$

where $q = c_*$ at $M = 1$. These curves are epicycloids, and are generated by the motion of a rim point of a circle of diameter $c_* \left(\frac{1}{u} - 1 \right)$ rolling on a circle of radius c_* . The pressure ratio is related to the velocity by

$$\frac{q^2}{c_*^2} = (1 - p/p_0) \frac{k-1}{k} \left(\frac{k+1}{k-1} \right) \quad (12)$$

where p_0 is the stagnation pressure (chamber pressure). Thus the pressure is constant on circles concentric with the sonic circle in the u, v plane.

For practical use, it is better to consider θ positive. This can be done by taking $\theta = 200$ degrees for an undisturbed flow, $v = 0$. (See p 36, A. Ferri.) Every characteristic can then be distinguished by the value of the constant C in equation (11). For the G^+ characteristic,

$$-\theta = f(q) - c_1 \quad (13)$$

where C_1 is the absolute magnitude of the constant that in equation (11) is negative. For the G^- characteristic,

$$\theta = f(q) - c_2; \quad (14)$$

eliminating f , then θ in (13) and (14), we have

$$\theta = \frac{c_1 - c_2}{2} \quad (15)$$

$$f(q) = \frac{c_1 + c_2}{2} = N$$

From (12) and (15), $f(q)$ is determined by $\frac{c_1 + c_2}{2}$ and the corresponding values of $\frac{p}{p^*}$, the Mach number M , the Mach angle, and the angle for the corresponding Prandtl-Meyer flow are given in Table II. Thus, entering in Table VI the values of $\frac{c_1 + c_2}{2}$ for points in the flow, taken from Table I, yields the values of the flow quantities at those points.

II. Application of method of characteristics to the construction of the flow through a nozzle.

Given a nozzle symmetric about the center line (which is chosen to be the x-axis), locate the throat of the nozzle at the y-axis. Now plot the nozzle contour so that it is congruent with the actual contour but of convenient size. The hodograph is now mounted so that the line whose direction number is 200 is parallel to the x-axis.

Since the Mach net is degenerate on the sonic line $x = 0$, choose the initial curve in this way: Through that point where the nozzle has at least a slope of 1° (or a multiple thereof) pass a circular arc whose center is the intersection of the tangent to the nozzle contour at that point with the x-axis. By the hydraulic theory, compute the flow quantities on this arc. From Table II, find the pressure number, N . Divide the arc into equal sub-arcs whose included angle is 1° (or a multiple thereof). At the end point of each arc label the point in a suitable fashion. The pressure number corresponding to each point is N . The direction number is 200 plus the included angle (in degrees) with the x-axis. The two characteristics in the hodograph plane which pass through the image of each point can now be deduced. Two adjacent points in the x, y plane determine a third point as follows:

Let the upper point be A , the lower one, B . Corresponding to the upward-going G^+ through the image of A in the hodograph plane, there is a downward sloping Mach line (G^-) through A , perpendicular to the G^+ characteristic. Similarly, there is a line C^+ through B , sloping upwards, perpendicular to the G^- (downward sloping) characteristic through the image of B in the hodograph plane. The intersection of the C^+ line from A and the C^- line from B determines a third point, P , where the flow quantities are determined by the location of the intersection of the corresponding G^+ and G^- characteristics in the hodograph plane. This process may now be continued.

At boundaries, if the boundary is a rigid wall, the new point is determined by one characteristic and the fact that the direction number must correspond to the slope of the wall. At a free surface, the new point is determined by one characteristic and the requirement that the pressure index, N , has a certain value which corresponds to receiver pressure.

III. Construction of the Hodograph

The equipment usually used includes a hodograph with a suitable ellipse and a drafting tool. Their use is outlined in I. From the knowledge of the pressure and direction of flow at a point, one can, using the hodograph, determine the Mach angle and the directions of the characteristics passing through that point. Or, knowing which two characteristics pass through a point in space, one can find the flow quantities there by using the hodograph.

In order to fix the quantities involved in such calculations, it is necessary to index the characteristics in a standard fashion. That method of indexing used here is the one proposed by Buseman and is in general use. The procedure is as follows:

1. Choose a radius for the sonic circle.
2. The hodograph can now be drawn according to the directions given in I.
3. Draw one characteristic leaving the sonic circle every two degrees, curving downward, and another set, leaving from the same points, curving upward.
4. Number the lines in each set so that at any point along the sonic circle the sum (a) of the number given one line, and (b) of the number from the line at that point which belongs to the other family is 1000.
5. At that point which is the intersection of the sonic circle with the radius which is paralleled to the arbitrarily chosen fixed line in space, make the difference of the numbers referred to in (4) be 200. Then the sum (called the pressure index) of the numbers of the two characteristics through some point in space gives the ratio: Critical speed/flow speed. (This relationship is shown in Table II.) The difference of the two numbers gives the direction of the flow with respect to the axis fixed in space. From the former number other pertinent quantities can be obtained (Table II).

The initial curve is taken to be the arc of the circle whose center is the vertex of the nozzle and which passes through the endpoints of the throat section. On that line it is assumed that the flow velocity-local sound velocity (equals throat, or critical, velocity) and the pressure index is then 1000 there. The flow is now determined by fixing the atmospheric pressure, which is assumed to be 14.7 psi.
