LIST OF FIGURES (PHOTOGRAPHS)

Figure 1. Ah-1/1/1. Bluff 55-60 feet high of till, over lacustrine sand gravel, over till. Fresh steep slope indicates recent wave erosion. Narrow beach of sand and coarse gravel. Physiographic Unit No. 54.

Figure 2. Dh/Ah-4/1-Cb. Old bluff on left 175-200 feet high including capping of high dunes. Belt of foredunes 10-15 feet high, with nip 6-8 feet high. Sandy beach. Physiographic Unit No. 514.

Figure 3. Ah-2/5/4-A1-4. Old bluff at left 130 feet high; lower plain at right and in middle distance has bluff 15-20 feet high. Higher bluff is of glacial sand and gravel, over lacustrine clay and silt, over lacustrine sand and gravel; low bluff is of lacustrine sand and gravel. Narrow beach of sand, gravel, and cobbles. Physiographic Unit No. 463.

Figure 4. A1-1. Bluff of till 13-14 feet high. Beach of sand, gravel, and boulders. Fresh slope and fallen tree indicate rapid wave erosion. Physiographic Unit No. 42.

Figure 5. A1-5. Bluff 15 feet high of lacustrine silt and clay. Beach of sand. Fresh bluff face and overhanging sod indicate rapid wave erosion. Physiographic Unit No. 42.

Figure 6. B-4. Low wooded plain of lacustrine sand and gravel. Broad beach of sand and a few boulders, which may come from till below. Beach appears to be aggrading. Physiographic Unit No. 209.

Figure 7. B-4. Low plain of bouldery lacustrine gravel, with boulder and cobble beach. Undermined trees show that wave erosion is taking place. Physiographic Unit No. 195.

Figure 8. B-4. Low plain of lacustrine sand and gravel with broad sandy beach. House stands on estate held by boulder sea wall, that now projects 135 feet into lake beyond water line on north and south. House was built in 1938, and seawall was built in 1950. Active wave erosion between 1950 and 1956 is indicated. Physiographic Unit No. 1.

Figure 9. B-4-r. Low plain of coarse lacustrine gravel (shows at right) overlying slabby dolomite bedrock which forms bench in beach zone. Bench strewn with blocks and slabs. Physiographic Unit No. 138.

Figure 10. B-4-r. Low plain of coarse lacustrine gravel and sand (exposed at right). Narrow beach zone of gravel, cobbles, boulders, and dolomite slabs. Dolomite bedrock is exposed near this area and is inferred here. Physiographic Unit No. 69.

Figure 11. B-4-Cb-r. Low wooded plain of lacustrine sand and gravel, with marginal belt 75-90 yards wide of foredunes 8-15 feet high. Nip 10 feet high. Beach of sand, coarse gravel, and angular shingle. Bedrock reef inferred. Physiographic Unit No. 305.

Figure 12. Dh-Cb. Wooded dunes in right distance 50-55 feet high. Belt 100-200 feet wide of foredunes 10-30 feet high, with low nip above broad sand beach. Small river on right lies back of foredunes. Physiographic Unit No. 334.

Figure 13. Dh-b. Dunes 120-140 feet high; dune sand rests on 15 feet of lacustrine sand and gravel at base of bluff. Fresh bluff indicates recent active wave erosion. Narrow sandy beach. Physiographic Unit No. 594.

Figure 14. Dh-Cb. Wooded dunes at right 130 feet high. Foredunes (foreground) 15-20 feet high, with 6-8 foot nip. Beach zone of sand and gravel. Recent erosion is indicated. Physiographic Unit No. 594.

Figure 15. Dlb. Dunes about 35 feet high, with wave-eroded bluff 20-25 feet high. Broad beach of sand and fine gravel. Physiographic Unit. No. 607.

Figure 16. Dlb/B-4. Dunes 15-25 feet high rest on plain of lacustrine sand and gravel 12-14 feet above lake level. Fresh bluff on dunes shows wave erosion in recent years. Broad beach of sand and pebbles. Physiographic Unit No. 48.

Figure 17. D1-r. Low wooded dunes (left background) with very broad beach mainly of sawdust and driftwood with about 20% sand. Rock reefs near water line defend beach at places. Physiographic Unit No. 329.

Figure 18. D1-B-4. Gravel bar enclosing lagoon. At left beyond view is gravel foreland or plain in front of low dunes. Physiographic Unit No. 443.

Figure 19. Fh. Vertical cliff of dolomite 35-45 feet high. Narrow beach zone of angular slabs, blocks and shingle. Physiographic Unit No. 114.

Figure 20. Fh-B-4. Cliff of shaly dolomite and limestone, 30-35 feet high. At left is low gravel foreland 6-8 feet above lake. Beach is of angular shingle and slabs. Physiographic Unit No. 249.

Figure 21. F1. Plain of dolomite about 18 feet above water, with vertical cliff 12-15 feet high. No beach zone. Physiographic Unit No. 149.

Figure 22. F1-r. Plain of dolomite about 18 feet above water. Vertical cliff about 14 feet high. Narrow beach zone of cobbles and small boulders. Physiographic Unit No. 149.

Figure 23. B-4-r-M. Beach and offshore zone of low plain of lacustrine sand and gravel. Beach zone of sand, coarse gravel, and slabs. Reefs of dolomite show through beach deposits at places. Offshore zone 50-300 yards wide is filled with reeds. Physiographic Unit No. 396.

Figure 24. Ah-4. Margin of a plain of lacustrine sand and gravel 25-30 feet above lake. Road rests on fill stabilized by grass and protected at base from waves by riprap ridge. Physiographic Unit No. 235.

GEOMORPHOLOGY OF THE LAKE MICHIGAN SHORELINE

INTRODUCTION

The Project

Proposal. In October, 1956 William E. Powers proposed, with the endorsement of appropriate officers of Northwestern University, a project for studying the shoreline of Lake Michigan. This project, entitled "Lake Michigan Shore Erosion and Geomorphology Project," was submitted to the Office of Naval Research, U.S. Department of the Navy, with a request for equipment and funds to carry on field work for 2 summers, and office work, correspondence, research, and drafting necessary to prepare approximate reports of progress, summary reports, and a final report on the findings of the study. The proposal was approved by the Office of Naval Research as Project No. NR 287-015, and in March 1957, Contract No. Nonr-1223(07) was negotiated between the Department of the Navy and Northwestern University to support the project for a period of one year beginning March 15, 1956. Preliminary studies and organizational work led to a successful program of field study during the summer of 1956. Early in 1957 the project was approved for extension during a second year as originally requested, and in April 1957 the Department of the Navy entered into such extension of Contract Nonr-1228(07) to March 14, 1958. A second summer of field work and a second year of office work, research, and preparation of reports was provided for.

Objectives. The proposal for this study stemmed from the need for more complete understanding of the characteristics and development of the shorelines of large inland lakes. Such shorelines present a large variety of shore features and conditions, which are of great influence on all aspects of man's use of the shore. In places the continuing processes of shoreline development -- such as the retreat or retrogradation of a bluff under wave erosion -- have

made it difficult and expensive for man to maintain his use of the shore areas. Both the kinds and associations of shore features on Lake Michigan, and their developmental processes, have their counterparts in other large inland lake shores. Thus governmental or military operations elsewhere can benefit by a clear understanding and description of Lake Michigan shore features. Individuals and municipalities who own shore properties are also in a position to benefit by the results of this study project.

Specifically, four objectives were set up:

1. To identify the diverse shoreline features of Lake Michigan, and to set up types and associations into which they may be grouped. To accomplish this, it was proposed to map, on foot or by automobile, the entire shoreline of Lake Michigan except (1) the Illinois shoreline (Lake and Cook Counties), and (2) the shoreline of Milwaukee County, Wisconsin. Both of these areas are comprehensively described in recent reports of the U.S. Army, Corps of Engineers.*

* Illinois Shore of Lake Michigan, Beach Erosion Control Study, by U.S. Army, Corps of Engineers: 83d Congress, 1st session, House Document No. 28, 1953.

Beach Erosion Study, Lake Michigan Shoreline of Milwaukee County, Wisconsin, by U.S. Army, Corps of Engineers: 79th Congress, 2nd Session, House of Representatives Document No. 526, 1946.

City of Kenosha, Wisconsin, Beach Erosion Control Study: 84th Congress, 2nd Session, House Document No. 273, 1955.

Other control studies on Lake Michigan by the U.S. Army, Corps of Engineers, are:

Racine County, Wisconsin, Beach Erosion Control Study: 83d Congress, 1st Session, House Document No. 88, 1955.

2. To appraise and measure shore developments now going on, including the total past changes due to such processes. More specifically, to identify shoreline areas of retrogradation and progradation; to measure if possible

the rate of such changes; and to determine whether such changes proceed at a uniform rate with respect to time, or occur in a non-uniform pattern related to cycles of lake levels, unusual storms, etc.

3. To summarize and present in appropriate reports information on shore features and processes, so that future changes can be anticipated.

4. To develop methods of applying the findings concerning the Lake Michigan shoreline to an understanding of the shores of large inland lakes in other parts of the world.

Field Work. Field studies were carried on by the director from June to September, 1956, and from June to August, 1957. During 1956 he was ably assisted by Mr. Harold A. Winters and Mr. John W. Kunstmann, graduate students in the Department of Geography, Northwestern University. In 1957, Mr. Winters alone served as field assistant.

During field work, the director and his assistants inspected the entire shoreline of Lake Michigan* at intervals of one mile or less, with few

* Hereafter in this report, the expression "Lake Michigan shoreline" will be understood to refer to the entire shore of the lake exclusive of Milwaukee County, Wisconsin, and Lake and Cook Counties, Illinois.

exceptions. Field mapping was done on areal photographs procured from the U.S. Department of Agriculture, Production and Marketing Division. These photos on a scale of approximately 1:20,000 served as photomaps; and in complete stereo coverage, they made possible the photointerpretation of the shoreline between points visited. All available topographic and planimetric maps of the shoreline were procured and made use of. Approximately 40 per cent of the shoreline is covered by topographic maps (Table I). For other areas, county maps giving the government Township and Range System and the road pattern were very useful, particularly by furnishing an interpretation of

the roads and fence lines on aerial photos with respect to Section and Township boundaries.

Table I. Published **Topographic Maps** of Lake Michigan Shore.

The narrow width of most elements of the shoreline did not permit them, in general, to be mapped as areal units. Instead, a code was developed to permit an orderly description and summary of significant elements of the shoreline. This code will be described below. Detailed stratigraphic descriptions were made of exposed bluff and shore materials, and more than 700 samples of beach and bluff materials were collected. These will form the basis for a detailed description of the structure of many parts of the bluff and backland area, and a statistical study of the distribution of beach materials around the Lake Michigan basin.

Acknowledgments. The director is deeply appreciative of the support given to all phases of this project by the Office of Naval Research. In particular, he is indebted to Dr. Louis C. Quam, Head of the Geography Branch of the O.N.R., and to Mr. James A. Williams of the Chicago office of the O.N.R., who has been ever efficient and courteous in procuring necessary materials and in giving helpful advice on administrative problems. Messrs. Harold A. Winters and John W. Kunstmann served efficiently both as field assistants and as research and cartographic aids in the office.

Reports. To date, the following progress reports have been issued in mimeographed form:

1. Report of Progress No. 1, November, 1956.
2. Report of Progress No. 2, September, 1957.
3. Status Report, November, 1957.
4. Summary Report, November, 1957. *XP-146 034*

The present Final Report will present in scientific form the major findings on the geomorphology, detailed description, and classification of the shoreline features of Lake Michigan, as well as an analysis of shoreline changes at about 145 points selected for remeasurement. The mass of material collected cannot all be presented within a single report, and therefore it is anticipated that certain additional scientific studies will be made and, if given approval by the Office of Naval Research, will be submitted for publication to appropriate journals.

THE LAKE MICHIGAN BASIN

General Description

Lake Michigan is hydrologically a unit with Lake Huron, and constitutes the part of this great double water body which lies west of the Strait of Mackinac between Mackinaw City and St. Ignace, Michigan. The Lake Michigan basin is slightly curved in outline but is generally elongated in a north-south direction, with a curve toward the northeast at the northern part of the basin. The trend and curvature of the basin are rather closely adjusted to rock structure, the basin lying in a weak-rock belt of Devonian shale (see below). From the southernmost point at Gary, Indiana, to the northernmost point near Naubinway, Michigan, the length is about 315 miles. The maximum width is about 76 miles, in the latitude of Grand Haven and Milwaukee. Throughout most of its length the lake is 50 to 60 miles or more in width. The total area of water surface is nearly 22,450 square miles.

The greatest depth, 924 feet, occurs in the north-central part, approximately in the latitude of Kewaunee. A broad submerged ridge less than 240 feet deep crosses the basin in roughly the latitude of Milwaukee and Muskegon. The basin south of this ridge is 564 feet deep and constitutes the southern third of the lake.

The southern two-thirds of the Lake Michigan basin is marked by shores smoothly curved in plan, with no bays and almost no natural harbors suitable for large craft. Those harbors which have been developed here are mainly of two types: (1) small rivers dredged to float large vessels, as the Milwaukee, Chicago and Pike Rivers; and (2) elongated coastal lakes such as Muskegon Lake. Such lakes were once stream valleys eroded to a lower former level of Lake Michigan, then drowned and partly cut off by sand bars as the Lake Michigan level rose. It has been shown by Hough that Lake Michigan's predecessor,

called Lake Chippewa, stood 360 feet lower than the present level.*

* Hough, J.L., Pleistocene Chronology of the Great Lakes Region: Final Report, Office of Naval Research -- University of Illinois Project NR-018-122, Urbana, Illinois, 1953.

Hough, J.L., Geologic History of Great Lakes Beaches: Proceedings, Fourth Conference on Coastal Engineering, Council on Wave Research, University of California, Berkeley, 1954, pp. 79-100.

Three large embayments are present in the northern part of the Lake Michigan basin. Green Bay on the northwest is about 15 by 116 miles in size. It lies parallel to Lake Michigan and separated from the latter by dolomite peninsulas called the Door and Garden Peninsulas, respectively (see Plate I). At the north, Green Bay is divided by a second peninsula -- the Stonington -- into two parts, Big Bay de Noc on the east and Little Bay de Noc on the west. Between Garden and Door Peninsulas the dolomite ridge or cuesta is partly submerged and gives access to Green Bay between several rocky islands. On the east of Lake Michigan, Little Traverse Bay trends east-west, with a length of about ten miles. South of it, Grand Traverse Bay forms an indentation about 10 by 30 miles in size, trending south from its entrance at the north. A narrow peninsula, Old Mission Point, divides the bay for more than half its length. The east and west arms of Grand Traverse Bay were parallel to glacial advance during at least part of the Ice Age, and were deeply scoured. A depth of 534 feet in the eastern arm, and 390 feet in the western arm, have been measured.

Several islands occur in the northeastern quarter of Lake Michigan, but none is present farther south.

A surrounding land area of more than 47,000 square miles drains to Lake Michigan. The divide bounding this drainage area lies more than 115 miles from the Lake Michigan shore east of South Haven, Michigan; and less than 5 miles from the shore between Waukegan, Illinois, and the Wisconsin-Illinois boundary. In an arc extending from the Indiana-Michigan boundary around southern Lake Michigan and northward to Port Washington, Wisconsin, the divide is everywhere less than 20 miles from the lake shore. Throughout much of this distance the divide follows the crest of the Valparaiso glacial moraine. The divide lies about 100 miles northwest of Green Bay.

No major river flows into Lake Michigan. The principal streams now or formerly entering the lake are as follows, clockwise beginning at the south:

In Indiana:

Trail Creek (at Michigan City)
Grand Calumet River (at Gary, formerly Miller)

In Illinois:

Chicago River
Waukegan River

In Wisconsin:

Pike River (at Kenosha)
Root River (at Racine)
Milwaukee River
Sucker Creek (near Port Washington)
Sheboygan River
Pigeon River (at Sheboygan)
Manitowoc River
East and West Twin Rivers (at Two Rivers)
Kewaunee River
Ahnapoo River (at Algoma)
Fox River (at Green Bay)
Duck Creek (at Green Bay)
Pensaukee River
Oconto River
Peshtigo River
Menominee River (Wisconsin-Michigan boundary)

In northern Michigan:

Cedar River
Ford River
Escanaba River
Rapid River
Whitefish River
Sturgeon River

In northern Michigan (continued)

Fishdam River

Manistique River

In southern Michigan:

Betsie River

Manistee River

Big Sable River

Lincoln River

Pere Marquette River (at Ludington)

Pentwater River

White River

Muskegon River

Grand River (at Grand Haven)

Black River (Macatawa Lake)

Kalamazoo River

Black River (at South Haven)

Pawpaw River (at St. Joseph)

St. Joseph River

Galien River

Of those, the Chicago River was reversed in 1900 by the Chicago Sanitary District development and now taken water from Lake Michigan; while the Grand Calumet River's mouth at Gary has long been closed, the river discharging through Burns Ditch, an artificial cut east of Gary, and the Lake Calumet harbor canal, in south Chicago. Only eight streams have an average discharge into Lake Michigan of more than 1000 cubic feet per second. These are

	Ft. ³ /sec.
Fox River	4,317
Menominee River	3,202
Grand River	3,080
St. Joseph River	2,791
Manistique River	1,747
Muskegon River	1,726
Kalamazoo River	1,236
Manistee River	1,088

Most streams entering Lake Michigan have their maximum flow between March and June, due to melting of winter snow and to a general maximum of precipitation at that season in this region. A considerable variation occurs in stream flow, the maximum recorded flows exceeding the average by factors ranging from 4.7 to 11 in the larger streams and from 3.2 to 38 in the smaller

ones. The maximum flow exceeds the minimum by factors of from 24 to 154 in the larger streams, and from 52 to more than 1000 in the smaller.

The amount of sediment now being carried into Lake Michigan by tributary streams is small in comparison with sediments eroded from bluffs of unconsolidated materials by wave action. The prevalence of abrupt bluffs or cliffs along a large portion of the shoreline (see Section Maps 1 to 26, and text below) is indication that such shores are retreating under wave attack. Deltas, which indicate a substantial contribution of sediment by the streams that build them, are generally absent except on the west side of Green Bay. Here the Oconto, Peshtigo and Menominee Rivers have built small deltas, each indicated by a projecting point of land at the mouth of the stream.

Relief

Lake Michigan is surrounded by plains of relatively low relief, that originated mainly as glacial till plains or as lacustrine plains submerged by former higher stages of the lake during retreat of the continental glacier. In places these plains rise gently with increasing distance from the present shore, as on the west side of Green Bay. In other places the adjoining land was originally higher, and wave erosion has developed steep bluffs ranging in height from ten or twenty feet to as much as 540 feet (at Sleeping Bear point in Leelanau County, Michigan). Such bluffs commonly slope from 20 to 35 degrees to the horizontal. At places sand dunes have developed along the shore and form a belt of varying width, but commonly less than one mile wide. These dunes range in height from a few feet to more than 200. Their slopes range from a few degrees to more than 35 degrees. Such dune belts are most common on the north, east and south shores of the lake, and are generally associated with areas of lake plain inland. Bedrock occurs at or just above lake level

at many points on the north coast, but bedrock areas inland generally rise only a few feet or tens of feet above the lake. A few exceptions occur where bedrock makes an upland from 50 to 200 feet or more above lake level, with a steep or vertical rock cliff formed by wave action. Notable examples are parts of the west shore of Door Peninsula, Wisconsin, and Garden and Stonington Peninsulas, Michigan.

Inland from the shore, relief remains small and all parts of the drainage area tributary to Lake Michigan may be classed as rolling to flat plain.

Coastal Landform Types

An inventory of landforms along the Lake Michigan coast indicated that the following major types are present:

- A. Upland with bluff facing lake. Categories of upland as to origin or structure include:
 1. Glacial till plain
 2. Glacial sand and gravel outwash plain
 3. Dune sand plain
 4. Lacustrine plain, or sand and gravel
 5. Lacustrine plain of silt and clay
- B. Low plain without bluff. Categories as to origin and structure include:
 - 1-5. Same as under upland
 6. Stream alluvial plain or delta
 7. Swamp
 8. Bedrock plain.
- C. Foredune belt; i.e., low dunes not more than a few decades old, lacking large trees or forest. Some foredune areas are marked by a low ridge or bluff marking recent erosion by waves.
- D. Old dunes, generally higher than foredunes and partly or wholly fixed by forest and other vegetation. Some old dune areas are marked by wave-eroded bluffs facing beach.
- E. Sand bar or spit. Several long lakes emptying into the eastern side of Lake Michigan were originally river valleys eroded to a lower level of the lake, but are now drowned by rise of lake level and are partly cut off by bars or spits built by wave action. On some of these bars and spits, sand dunes have been built.

- F. Bedrock upland with cliff. The fact that such rocky cliffs are generally far steeper than bluffs in unconsolidated materials indicated that they belong in a different category from the bluffs and uplands of type A above.
- M. Reed marsh coast. This type, in contrast to types A to F above, generally has no beach associated with it. Type M always associated with one or the other basic types of shore.
- R. Artificial fill, placed by man to control shore erosion or to support a highway or some other man-made structure.

For purposes of field mapping, a code was developed to indicate the above landform types and their combinations, together with minor subdivisions of and additions to them. This code and its use will be explained below. It will be noted that types A, B, D and F indicate the character of the backland area. Bluffs and cliffs generally display excellent cross sections of the geological materials and structure of the backland.

Geological Setting of the Lake Michigan Basin

Underwater Conditions. The lake basin consists of two depressions separated by a broad submerged swell between Muskegon and Milwaukee. The southern basin slopes gently inward from all sides to its deepest point of 564 feet. The submerged ridge is less than 240 feet deep at several places. It probably is the submerged terminal moraine of the Valders glacial lobe, whose red drift marks the last major glacial advance down the Lake Michigan basin into eastern Wisconsin. The larger northern depression is irregular in form, with generally steeper submerged slopes on the east side than on the west. The maximum depth of 924 feet lies almost due east of Kewaunee. Underwater contours suggest that its eastern margin may be a drift-mantled westward-facing cuesta similar to that forming the west side of the Door Peninsula. The northeastern part of the basin is very irregular in form. Most of the islands stand like tablelands with steeply sloping margins, rising

from depths of 250 to 300 feet. Several submerged platforms would form islands if water level should drop 50 to 100 feet. Grand Traverse Bay is a double submerged valley almost fiord-like in form. The two arms have depths of 390 and 534 feet in the south, although the northern entrance to the bay is a threshold only 138 feet deep. Extending eastward through the Strait of Mackinac is a narrow submerged gorge known to be more than 150 feet deep. This probably was the outlet valley for the former lake stage (Lake Chippewa) when the water stood 350 feet lower than at present. Green Bay is generally shallow, largely less than 100 feet deep, and appears to be an elevated platform overhanging the deeper Lake Michigan basin on the east.

Exposed Bedrock Geology. Although bedrock exposures are limited along most of the Lake Michigan shoreline, the lake basin nevertheless is clearly related in form and trend to the regional bedrock and structure. From an outcrop on the beach near 79th street in Chicago no bedrock is exposed around the south end of the lake and northward past Grand Traverse Bay to near Norwood in Charlevoix County, Michigan, where a low cliff of shale is present. Frequent rock outcrops occur between Norwood and Petoskey, and from Mackinaw City west to Waugoshance Point, Michigan. North of the lake, bedrock forms many reefs, ledges, and low points from St. Ignace westward to the Garden and Stonington Peninsulas. Door Peninsula is a rocky cuesta, high on the west. South of it, the only bedrock exposures on the west side of Lake Michigan are near Algoma, at Sheboygan, north of Racine (Wind Point), and probably in the water off Glencoe, Illinois.

Rock formations underlying Lake Michigan or its shores range in age from Ordovician to Mississippian, with the Silurian and Devonian systems also represented. It is difficult to draw up generalized stratigraphic sections for

the states of Wisconsin, Michigan, Illinois and Indiana, partly because local names and degree of differentiation vary, but also because stratigraphy varies and correlations are not agreed upon for many units. The following description, given in order of age, suggests stratigraphic relations that appear to hold generally throughout the area.

Ordovician. The Trenton-Black River (mainly limestones) of Michigan correlate with the Galena-Black River dolomites of Wisconsin and Illinois. These are resistant units and lie northwest of Green Bay. The Maquoketa shale of Illinois correlates with the Richmond shale of Wisconsin, which underlies southern Green Bay. This time interval is represented in northern Michigan by the Queenston Shale, Big Hill limestone, Stonington limestone and Bills Creek Shale. The resistant Stonington makes the peninsula of that name, while the Bills Creek shale forms Little Bay de Noc lowland. Queenstown shale underlies western Big Bay de Noc.

Silurian. The massive Niagaran dolomite of Wisconsin and Illinois forms the Door Peninsula cuesta. Its correlatives in northern Michigan are the Guelph (youngest), Engadine and Manistique dolomites, Burnt Bluff limestone, Mayville dolomite, Cabot Head shale, and Manitoulin limestone. The Garden Peninsula cuesta appears to be formed of the Manistique, while the Engadine forms reefs and low ledges along much of the north shore of Lake Michigan.

The Salina series (salt, limestone, shale, dolomite, and gypsum) of upper Silurian age forms a weak rock belt containing Brevort Lake, northwest of St. Ignace.

Devonian. The Lake Michigan basin is eroded largely in Devonian rocks. At the south, in Indiana, the rock units are the New Albany shale (youngest Devonian present), Beechwood and Silver Creek limestones, and Jeffersonville

shale. At the north, the Straits of Mackinac area is underlain by the Devonian Onondaga series, including the Mackinac and Dundee limestones. South of the Straits area, extending as far as Frankfort, the younger Devonian Traverse series underlies the coast and the eastern part of the Lake Michigan basin. The Traverse series includes, where differentiated, the Thunder Bay, Alpena and Long Lake limestones, and the Bell shale.

Mississippian. The coast and eastern part of the Lake Michigan basin south of Frankfort are underlain by rocks of the Mississippian system. The formations which reach the coast or basin are the Antrim shale (oldest), Coldwater shale, and lower Marshall sandstone. Younger, higher stratigraphically Mississippian formations are found inland, toward the east.

Unconsolidated mantle. The bedrock formations enumerated above are almost wholly covered, except on the northern and northwestern shore areas of Lake Michigan, by glacial deposits of till, gravel and sand; by glaciolacustrine deposits of sand, gravel, silt and clay; by eolian deposits of dune sand; or by marsh vegetation and muck.

Geological Structure. Lake Michigan lies on the west and northwest flanks of a shallow basin structure in sedimentary rocks, centered in southern Michigan. In the central and southern parts of Lake Michigan, the associated sedimentary bedrock formations dip or slope down toward the east at an angle of 100 feet or less per mile. The northern Lake Michigan basin lies northwest of the center of the structural basin, so that the dip is there to the southeast, at 50 to 100 feet per mile. The curved basin of Lake Michigan thus follows closely the curved outcrop of the weaker rock formations mainly of Devonian age, and may be said to lie in a "strike valley." The term "strike" means the direction at right angles or normal to the direction of rock dip.

Relation of Lake Michigan Basin to Moraines. Most if not all the glacial drift in and adjacent to the Lake Michigan basin appears to have been dropped by glacial lobes that advanced down the basin lowland from the northeast, and then spread outward from the center of the basin onto the surrounding higher plains. Marginal moraines therefore trend roughly parallel to the present shoreline. However, later glacial advances did not reach quite as far south as earlier ones.

South of Milwaukee and Muskegon, the glacial moraines at and near the shore belong to the Lake Border morainic system built during the Cary glacial substage of the last or Wisconsin glacial stage. Inland from (or outside of) the several Lake Border moraines are older moraines called in Illinois the Tinley and Valparaiso, also deposited during the Cary substage. Tinley or Valparaiso drift may occur beneath Lake Border drift, where exposed in bluffs along the shore. North of Milwaukee and Muskegon, red drift called Valders in Wisconsin and Manistee in Michigan forms the moraines along the shore. This drift is of the Mankato substage of the Wisconsin glacial stage, the glacial lobe of which reached only as far as the two cities mentioned. However, it is known that a Cary glacial lobe — called the Port Huron — later than the Lake Border, advanced into the northern Lake Michigan basin before Mankato time.* Therefore, it is to be expected that the red Valders-Manistee drift

* Bretz, J.H., The stages of Lake Chicago: Their causes and correlations: American Journal of Science, vol. 249, 1951, pp. 401-429.

may be underlain by deposits of Port Huron, Lake Border, or even older glacial age. Sections of glacial drift exposed in bluffs in the northern part of the basin generally show several drift sheets which attest the successive glacial advances and retreats.

PHYSIOGRAPHIC UNITS OF THE LAKE MICHIGAN SHORE

Physical Elements of the Shore Zone

Definitions. The shore zone is commonly divided into the offshore, the shore, the landface, and the backland. The offshore extends seaward from the low water mark (or waterline, in the case of lakes with slight fluctuations in water level). The shore is the zone between low water mark and the highest limit reached by waves or ice shove. The landface is a zone extending landward from upper limit of shore, to limit of direct influence of shore processes. The backland is a zone extending indefinitely landward from the inner limit of landface. The shoreline is technically the boundary between offshore and beach; and in practice this means the outer limit of the shore, or the low water line. The coast is a zone of indeterminate width extending landward from the shore; it therefore includes the landface and backland. The coast-line is the boundary between shore and landface. The term shore zone refers to the combined offshore, shore, and landface.

The present study deals with the shore, landface, and outer margin of backland. The shore at most places includes a beach, generally of sand but in some cases composed of gravel, cobbles, boulders or other loose materials. The beach is commonly subdivided into the foreshore or lower beach, reached by ordinary storm waves; and the backshore or upper beach, reached by waves only during exceptional storms, and perhaps reached by ice-shove during winter freezes.

The landface may be a cliff, a bluff, a nip, or a gentle slope marking the outer edge of backland. A cliff is a steep or vertical slope in rock. Cliffs overlooking and near to the Lake Michigan shore were developed by wave erosion at their base. The term bluff refers to a sharp slope in

unconsolidated material such as glacial till or dune sand. Such materials, when eroded below by wave action along the shore, tend to slide down until they attain their angle of repose for the conditions present. Old bluffs in glacial till commonly are no steeper than 25° , but where recently undermined by wave action, bluffs in till may attain slopes of 40° to 50° or more. Loose dune sand makes bluffs at its angle of repose, generally about 32° . A recently formed low bluff only a few feet high is often called a nip. Low plains not subject to recent wave erosion may have merely a gentle slope down to the beach as a result of former wave work. Such a declivity is not a true nip or bluff.

Elements Present. The elements composing the Lake Michigan coast and shore have been in part enumerated under Coastal Landform Types. In terms of the nomenclature of shore zones, these elements include the following:

- Backland:
 - a. Uplands of several types of unconsolidated deposits, or of bedrock
 - b. Low plains of the same materials
 - c. Foredune areas
 - d. Old dune areas
 - e. Artificial fill
- Shore:
 - a. Foreshore zone
 - b. Backshore zone
 - c. Rock reefs or ledges in shore
 - d. Sand bar or spit
 - e. Reed marsh coast, generally without a true beach
- Landface:
 - a. Bluff or nip
 - b. Cliff

A Code for Mapping Elements of the Shore Zone

Test mapping procedures resulted in a workable code system for setting down all significant elements of the shore zone, except descriptions of the foreshore and backshore. Because a beach zone, with foreshore and backshore, generally occurs along with all types of landface, it was believed that the addition of coded information on beaches to the code for the backface would

prove cumbersome to the user of the report. Therefore, the code deals only with the backland, landface, and such unusual features of the shore as rock reefs or marsh.

The mapping code is as follows:

A. Upland with bluff.

Ah — high bluff, more than 20 feet high.

Al — low bluff, less than 20 feet high.

Materials of bluff and backland:

1. Glacial till
2. Glacial sand and gravel
3. Dune sand
4. Lacustrine sand and gravel
5. Lacustrine silt or clay

Examples: Ah-1, high upland of till, with bluff.

Al-1/4, low upland of till over lacustrine sand and gravel, with bluff.

B. Low plain, generally without nip.

Materials of plain:

- 1 to 5. Same as above
6. Stream alluvium, mainly gravel, sand mud and silt
7. Swamp
8. Bedrock

If rock ledge or reef occurs in beach zone, r is added.

Example: B-2-r, low plain of glacial sand and gravel, with reef on beach.

C. Foredunes, mostly less than 20 feet high.

Cb, if low bluff or nip is present.

C, if no bluff or nip is present.

D. Old dunes, generally wooded and mostly more than 20 feet high.

Dh — high dunes, more than 40 feet high.

DI — low dunes, less than 40 feet high.

If bluff is present b is added.

Example: DIb, low dunes with bluff.

E. Sand bar or spit.

If dunes are on top, d is added.

Example: Ed, spit or bar with dunes.

F. Bedrock upland with cliff.

Fh — high cliff, more than 20 feet high.

Fl — low cliff, less than 20 feet high.

M. Reed marsh in offshore or foreshore. Generally no beach is present. This type occurs with other basic types of coastal features.
Example: B-4-ii: Low plain of lacustrine sand and gravel, with reed marsh offshore.

R. Artificial fill. This generally occurs with some other basic types of coastal features.
Example: A1-2-R, upland of glacial sand and gravel with bluff less than 20 feet high, with artificial fill along "shore."

All coastal features of Lake Michigan, in their various combinations and associations, were mapped by use of the code described above. In field notes, detailed descriptions were taken of (a) the shore, including width and materials of the foreshore and backshore; (b) the height, angle of slope, materials and structure of the landface (i.e., bluff or cliff); nature of backland area; (c) the stability of shore and landface, specifically whether stable, retrograding under shore erosion, or prograding under processes of deposition; (d) evidence, if any, for direction of longshore current. Many bluffs showed detailed stratigraphy involving several units of glacial till, glacial or lacustrine sand, gravel, silt or clay -- and these sections were recorded and described in detail. They will form the basis for an analysis of the glacial stratigraphy of the Lake Michigan area. Samples of beach sands from the foreshore and backshore, and of the materials composing the adjacent bluffs or backland, were collected at 184 selected stations, to a total of 704 samples.

Associations of Coastal Features of Lake Michigan

Along the thousand miles and more of Lake Michigan's shore zone, the coded elements as listed above are found in a variety of combinations. An enumeration of some of these indicates how necessary it was to develop a code or symbolism to record the elements associated at each station studied.

High Bluff. Characteristic associations are:

- Ah — High bluff alone.
- Ahr — High bluff with rock reef on shore below.
- Ah-B — High bluff above low plain.
- Ah-C — High bluff with foredunes at base. If dunes have nip or bluff, Ah-Cb.
- Ah-Al — High bluff, back of low bluff.
- Ah-Dl — High bluff with low dunes at base. These dunes may have their own bluff, Ah-Dhb, or may have foredunes adjacent to beach: Ah-Dh-C or Ah-Dh-Cb.

Low Bluff. Characteristic associations are:

- Al — Low bluff alone.
- Al-B — Low bluff above low plain. If rock reef on beach, Al-B. Or if reed marsh in offshore, Al-B-M.
- Al-C — Low bluff with foredunes at base. If nip in dunes, Al-Cb.
- Al-M — Low bluff with reed marsh in offshore.
- Al-Al — Two low bluffs, one back of the other.
- Al-Ah — Low bluff above and back of high bluff.

Low Plain. Characteristic associations are:

- B — Low plain alone. If rock reef on beach, B-r.
- B-M — Low plain with reed marsh in offshore.
- B-C — Low plain with foredune belt. If nip in dunes, B-Cb.
- B-E — Low plain with marginal sand bar or spit. If foredunes on plain, B-C-E.

Foredunes. These always are associated with other elements of land-face or backland, and are therefore included with the latter.

High Old Dunes. Characteristic associations are:

- Dh — High dunes alone.
- Ch-C — High dunes with lower foredune belt. If nip in foredunes, Dh-Cb.
- Dh-Dl — High dunes back of low old dunes. If bluff in latter Dh-Dlb. If foredunes also occur, Dh-Dl-C or Dh-Dl-Cb.
- Dh-B — High dunes on low plain. If foredunes near lake, Dh-B-C or Dh-B-Cb.
- Dh/Ah — High dunes on upland with high bluff. If foredunes at base, Dh/Ah-C or Dh/ah/cb.
- Dhb — High dunes with eroded bluff. If foredune belt is present, Dhb-C or Dhb-Cb.
- Dhb/Al — High dunes with old bluff on upland with low bluff.
- Dhb-B — High dunes with old bluff on low plain.

Low Old Dunes. Characteristic associations are:

- Dl -- Low old dunes alone. If rock reef on beach, Dl-r.
- Dl-C -- Low old dunes with foredunes. If nip, Dl-Cb.
- Cl-B -- Low dunes on low plain. If foredunes also, Dl-B-C.
- Dl/Al -- Low dunes on upland with low bluff.
- Dl/Ah -- Low dunes on upland with high bluff.
- Dlb -- Low dunes with bluff. These may occur on low plain,
Dlb-B; or on spit or bar, Dlb-E.
- Dlb-C -- Low dunes with bluff, above foredune belt.

Spit or Bar. The most common association is with foredunes, E-C or E-Cb; or with old low dunes, E-Dl. or EDbb.

High Bedrock Cliff. Characteristic associations are:

- Fh -- High cliff alone. If reefs on beach, Fh-r.
If reed marsh in offshore, Fh-M.
- Fh-B -- High rock cliff back of low plain.
- Fh-Al -- High rock cliff above upland with low bluff.

Low Bedrock Cliff. Characteristic associations are similar to those of high bedrock cliff.

Description of Lake Michigan Shore Zone in Terms
of Physiographic Units

The shore zone of Lake Michigan varies significantly from place to place. Detailed mapping of the shore zone elements indicates that more than 600 distinct physiographic units are present, each distinct from those adjacent to it. These physiographic units are shown on Section Maps, Numbers 1 to 26. The locations of these section maps are indicated on Plate I. In addition to the physiographic units of the shorezone, these section maps give also the code mapping symbols for nearly 1700 shore stations, and a smaller number of symbols indicating graphically the general character of the coast (whether high bluff, low dune, cliff, etc.) and the height of bluffs, dunes, and cliffs composing the landface of backland. See Appendix I, page 102, which is an explanation of these symbols used on the 26 Section Maps. Appendix II, page 103, is a copy of the code used in field mapping, which

explains the letter and graphic symbols used on the Section Maps.

Below is a table listing the basic elements by symbols, and basic information on the landface and shore, for the more than 600 physiographic units. The following abbreviations are used for the beach sediments:

s	--	sand
fn	--	fine
cs	--	coarse
med	--	medium
gr	--	gravel
cobs	--	cobbles
bldrs	--	boulders

Figure 1. Ah-1/-4/1. Bluff 55-60 feet high of till, over lacustrine sand and gravel, over till. Fresh steep slope indicates recent wave erosion. Narrow beach of sand and coarse gravel. Physiographic Unit No. 54.

Figure 2. Dh/Ah-4/1-Cb. Old bluff on left 175-200 feet high including capping of high dunes. Belt of foredunes 10-15 feet high, with nip 6-8 feet high. Sandy beach. Physiographic Unit No. 54.

Figure 3. Ah-2/5/4-A1-4. Old bluff at left 130 feet high; lower plain at right and in middle distance has bluff 15-20 feet high. Higher bluff is of glacial sand and gravel, over lacustrine clay and silt, over lacustrine sand and gravel; low bluff is of lacustrine sand and gravel. Narrow beach of sand, gravel, and cobbles. Physiographic Unit No. 463.

Figure 4. A1-1. Bluff of till 13-14 feet high. Beach of sand, gravel, and boulders. Fresh slope and fallen tree indicate rapid wave erosion. Physiographic Unit No. 42.

Figure 5. A1-5. Bluff 15 feet high of lacustrine silt and clay. Beach of sand. Fresh bluff face and overhanging sod indicate rapid wave erosion. Physiographic Unit No. 42.

Figure 6. B-4. Low wooded plain of lacustrine sand and gravel. Broad beach of sand and a few boulders, which may come from till below. Beach appears to be aggrading. Physiographic Unit No. 209.

Figure 7. B-4. Low plain of bouldery lacustrine gravel, with boulder and cobble beach. Undermined trees show that wave erosion is taking place. Physiographic Unit No. 195.

Figure 8. B-4. Low plain of lacustrine sand and gravel with broad sandy beach. House stands on estate held by boulder sea wall, that now projects 135 feet into lake beyond water line on north and south. House was built in 1938, and seawall was built in 1950. Active wave erosion between 1950 and 1956 is indicated. Physiographic Unit No. 1.

Figure 9. B-4-r. Low plain of coarse lacustrine gravel (shows at right) overlying slabby dolomite bedrock which forms bench in beach zone. Bench strewn with blocks and slabs. Physiographic Unit No. 138.

Figure 10. B-4-r. Low plain of coarse lacustrine gravel and sand (exposed at right). Narrow beach zone of gravel, cobbles, boulders, and dolomite slabs. Dolomite bedrock is exposed near this area and is inferred here. Physiographic Unit No. 69.

Figure 11. B-4-Cb-r. Low wooded plain of lacustrine sand and gravel, with marginal belt 75-90 yards wide of foredunes 8-15 feet high. Nip 10 feet high. Beach of sand, coarse gravel, and angular shingle. Bedrock reef inferred. Physiographic Unit No. 305.

Figure 12. Dh-Cb. Wooded dunes in right distance 50-55 feet high. Belt 100-200 feet wide of foredunes 10-30 feet high, with low nip above broad sand beach. Small river on right lies back of foredunes. Physiographic Unit No. 334.

Figure 13. Dhb. Dunes 120-140 feet high; dune sand rests on 15 feet of lacustrine sand and gravel at base of bluff. Fresh bluff indicates recent active wave erosion. Narrow sandy beach.

Physiographic Unit No. 594.

Figure 14. Dh-Cb. Wooded dunes at right 130 feet high. Foredunes (foreground) 15-20 feet high, with 6-8 foot nip. Beach zone of sand and gravel. Recent erosion is indicated.

Physiographic Unit No. 594.

Figure 15. Dlb. Dunes about 35 feet high, with wave-eroded bluff 20-25 feet high. Broad beach of sand and fine gravel.

Physiographic Unit No. 607.

Figure 16. Dlb/B-4. Dunes 15-25 feet high rest on plain of lacustrine sand and gravel 12-14 feet above lake level. Fresh bluff on dunes shows wave erosion in recent years. Broad beach of sand and pebbles.

Physiographic Unit No. 48.

Figure 17. D1-r. Low wooded dunes (left background) with very broad beach mainly of sawdust and driftwood with about 20% sand. Rock reefs near water line defend beach at places. Physiographic Unit No. 329.

Figure 18. D1-B-4. Gravel bar enclosing lagoon. At left beyond view is gravel foreland or plain in front of low dunes. Physiographic Unit No. 428.

Figure 19. Fh. Vertical cliff of dolomite 35-45 feet high. Narrow beach zone of angular slabs, blocks and shingle. Physiographic Unit No. 114.

Figure 20. Fh-B-4. Cliff of shaly dolomite and limestone, 30-35 feet high. At left is low gravel foreland 6-8 feet above lake. Beach is of angular shingle and slabs. Physiographic Unit No. 249.

Figure 21. Fl. Plain of dolomite about 18 feet above water, with vertical cliff 12-15 feet high. No beach zone. Physiographic Unit No. 1149.

Fl-r

Figure 22. Plain of dolomite about 18 feet above water. Vertical cliff about 14 feet high. Narrow beach zone of cobbles and small boulders. Physiographic Unit No. 1149.

Figure 23. B-l-r-M. Beach and offshore zone of low plain of lacustrine sand and gravel. Beach zone of sand, coarse gravel, and slabs. Reefs of dolomite show through beach deposits at places. Offshore zone 50-300 yards wide is filled with reeds. Physiographic Unit No. 396.

PRESENT AND PAST CHANGES IN THE SHORE ZONE

Shore Processes — Progradation and Retrogradation

Along most of the Lake Michigan shore zone, wave and current action has either built out (prograded) or cut back (retrograded) the land. These processes have been slow or rapid, depending on a number of factors. In general, erosion seems to have been most common. Deposition or progradation occurs where a large amount of sediment is supplied to the shore by tributary streams or shore erosion nearby, or where a large amount of sediment in longshore transit is caught by some projecting point or structure. No large amounts of sediment are being brought into Lake Michigan by tributary streams. Where man has built long piers, groins, or other structures out from the shore, these have locally caught longshore drift so as to create beaches up to several hundred feet wide. At a few places the configuration of the shoreline has led to a concentration of longshore drift at certain points — notably at Point Betsie in Benzie County, and Big Sable Point in Mason County, Michigan. But at most places the shore is relatively stable or has suffered recession. The rate of such recession depends on such factors as the following:

Height of backland above mean lake level.

Materials composing backland and landface, whether weak or strong.

Abundance and coarseness of beach materials, whether moved in from elsewhere or derived from the retreating landface by erosion and assorted by wave action.

Exposure to lake storms and waves. The inner shores of bays suffer feeblor wave attack than headlands or straight stretches of shore.

Protective structures built by man.

Level of Lake Michigan. During periods of high average lake level, wave attack is several times more vigorous than during periods of low average level.

Unusual storms of great severity.

The factors which vary most strongly with respect to time are the two last named. The mean monthly level has shown extremes, since 1854, of 577.2 feet in February, 1933, and 583.8 feet in July, 1859. From 1900 to 1953 the level averaged 579.9 feet, with unusually high levels occurring in 1918, 1929, and the period 1943 to 1952. Unusually low levels occurred in 1926 and 1934. Without exception, accelerated shore erosion has taken place during times of high water, while during low water, beaches have widened and wave attack on the landface has been much less effective. Records kept since 1854 show that lake levels have fluctuated in an irregular pattern with times of high water recurring, on the average, every ten to twelve years. Past wave erosion has varied with these changes in lake levels.

The problem of present wave erosion and shore retreat is a very serious one to both municipalities and individuals. As such, it has been persistently studied by engineers and engineering organizations, including the Beach Erosion Board of the U.S. Army, Corps of Engineers. The latter organization has published the results of detailed shore studies in Milwaukee and Racine Counties, Wisconsin; the city of Kenosha; and Lake and Cook Counties, Illinois. A similar report on Berrien County, Michigan, is now ready. To these reports the reader is referred for information on engineering aspects of the shore problem.

Former Studies of Shoreline Changes

The problem of Lake Michigan shore recession under wave attack was studied as early as 1864 by Charles Whittlesey in the Milwaukee area, and 1868 and 1870 by Henry M. Bannister in Illinois. Although neither gave quantitative measurements, both authorities concluded that past wear of bluffs may have amounted to hundreds of feet and that the annual rate was several feet at

many places. In 1870 Edmund Andrews* computed that, in a period of 15 to 35

* Andrews, Edmund, "The North American Lakes Considered as Chronometers of Post-Glacial Time," Trans. Chicago Acad. Sci., Vol. II, 1870, pp. 1-24.

years preceding 1870, annual recession of the shore averaged 5.28 feet at 23 selected points between Evanston and Manitowoc. T. C. Chamberlin in 1877 published results of computations by P. R. Hoy, S. G. Knight, and himself.**

** Chamberlin, T. C., "Geology of Wisconsin," Vol. II, 1877, pp. 219-233.

Hoy found that Racine cemetery suffered an average annual loss, between 1840 and 1884, of 9.73 feet per year. Knight found that between 1836 and 1874, the average recession at 18 section and quarter-section lines in Racine County was 3.33 feet annually. Chamberlin computed that the average annual loss at 8 section lines in Milwaukee County, between 1835 and 1874, was 2.79 feet.

Frank Leverett in 1899*** published results of measurements made by Surveyor

*** Leverett, Frank, "The Illinois Glacial Lobe," U.S.G.S. Mon. XXXVIII, 1899, p. 458.

Galvin of Berrien County, Michigan, which indicated an average annual loss, at 8 points in that county during the 41 to 57 years following 1828, of 3.30 feet.

Between 1905 and 1907, the low bluff in lacustrine clay and silt at Manitowoc, Wisconsin, suffered an annual recession of more than 40 feet, according to J. W. Goldthwait.**** W. E. O'Brien found that 6 section and quarter

**** Goldthwait, James W., "Abandoned Shorelines of Eastern Wisconsin." Wis. Geol. and Nat. Hist. Surv., Bull. 17, 1907, p. 58.

section lines in Kenosha County, Wisconsin, showed an average annual loss of 6.84 feet between 1835 and 1922.* J. R. Ball found that 4 measured lines

* Ball, J. R., and Powers, W. E., Shore Recession in Southeastern Wisconsin: Trans. Ill. Acad. Science, Vol. 22, 1930, p. 438.

north of Kenosha showed an average annual recession for the period 1918-1921, a time of high water, of 12.33 feet per year.** At the same place the loss

** Ball and Powers, Idem. p. 439.

between 1921 and 1929, a period of generally low water, averaged only 0.73 feet per year.

More recent studies have confirmed the fact of substantial losses to the shore. In four segments along the Milwaukee County line, the Beach Erosion Board computed the average annual losses between 1836 and 1941 to be, from north to south, 2.5 feet, 1.6 feet, 2.8 feet, and 1.2 feet.*** The Beach

*** U. S. Army, Corps of Engineers, Beach Erosion Board, Beach Erosion Study, Lake Michigan Shore Line of Milwaukee County, Wisconsin: U.S. House of Representatives, 79th Congress, 2nd Session, 1946, Document No. 526, p. 13.

Erosion Board determined that bluff recession averaged about 2 feet per year north of the harbor in Kenosha, and about 4 feet south of the harbor, between 1872 and 1955.****

**** U.S. Army, Corps of Engineers, Beach Erosion Board, City of Kenosha, Wisconsin, Beach Erosion Control Study: House of Representatives, 84th Congress, 2nd Session, 1955, Document No. 273, p. 11

In Illinois, the past history of the shoreline from Wilmette and northward to the Wisconsin line shows contradictions because (1) part of this shore is a low lake plain of natural accretion, and (2) much of the shore here has

been developed since 1910 with protective structures which have promoted accretion, even though erosion had been dominant previously.* The low lake

* U. S. Army, Corps of Engineers, Beach Erosion Board, Illinois Shore of Lake Michigan, Beach Erosion Control Study: House of Representatives, 83d Congress, 1st Session, 1953, Document No. 28, pp. 30-31.

plain near Camp Logan and the Wisconsin line suffered erosion losses averaging 7.5 feet per year between 1872 and 1946. In Waukegan, the same lake plain, during the same period, showed an average annual accretion of 17.6 feet! Part of this gain may have been fill placed by man. Behavior of the coastline south of Waukegan shows similar contradictions, although losses of from 1 to nearly 6 feet per year occurred at certain points between 1872 and 1910. At some places, the process changed from recession to accretion after 1910, due to development of the shore.

Remeasurements to the Lake Michigan Shore at Identifiable Points

A part of the present study is an attempt to evaluate past changes in the shoreline at places other than those studied by the Beach Erosion Board. Early basic measurements were furnished by (a) the original U. S. government township surveys, dating from the 1830's for most of the Lake Michigan shore area, but with some notes dated from 1829 to 1855; and (b) surveyed plats of shore subdivisions dating mainly from 1900 to 1930, but with a few earlier and later. No surveyed plat was used of later date than 1837.

Field notes made during the original U. S. government township surveys record the distances from section and quarter posts to the "meander line" of the lake. The "meander line" was never precisely defined, but clearly it was seldom, if ever, identified with the water line. In many cases the measurements were obviously made to some point at or near the edge of the

bluff, where present. Our resurveys were carried in every case to the edge of the bluff, and thus our computed recession must be somewhat less than the actual, wherever the original meander line was inland from the bluff edge. The pattern of roads and field boundaries on aerial photos shows many section and quarter corners. All of these that could be identified within 1/2 mile to 1 mile of the lake were tabulated, and their original chained distances to the meander line of the lake were procured from copies of the original field notes filed in state offices in Madison, Wisconsin; Lansing, Michigan; and Indianapolis, Indiana. Where possible, these distances were remeasured in the field, either with a steel tape or by stadia measurement with a telescopic alidade. Tests of the latter method indicated a probable error of no more than 0.5%, a value on most lines far smaller than the change in position of the shore or meander line. In no case was an original corner or quarter post recovered, but the position of long established fence lines and other boundary indications checked closely with the chained distances given in the original survey. It is believed that most if not all points of origin used for re-measurement were correct to within 3 to 5 feet of their true position.

A considerable number of surveyed subdivision plats were obtained from county engineers and recorders of deeds. The courtesy and assistance of Messrs. H. E. Stafseth and William Osner of the Highway Commission of Ottawa County, Michigan is gratefully acknowledged. Many of these plats gave distances to the waterline rather than to bluffs or other features above the beach zone. Inasmuch as position of the waterline changes, without erosion of or accretion to the shore, by any change in water level, such measurements are less satisfactory than those to a bluff crest which can change only by further recession. In some of the older subdivision plats, it proved impossible

in the field to recover the original street pattern and other reference points. Some of the projects had been abandoned; in others, a second and different subdivision plan had been superimposed on the first. However, approximately 20 remeasurements were established from these plats and are included in Table III.

A summary of the results of remeasurements at 134 selected points along the Lake Michigan shoreline is given in Table III. For each point is listed the location, date of original survey, gain or loss in feet up to the year 1957, and average change per year in feet. Of the 134 points or stations, six showed net gain or accretion, generally small but amounting in one case to 5.86 feet per year between 1902 and 1957. Four stations showed no change during the period of record. One hundred twenty-four stations showed recession, averaging 1.47 feet per year. The greatest loss, 3.40 feet per year since 1835-36, was recorded in Kenosha County. Thirty-four stations showed an average annual loss of more than 2 feet, and 36, a loss of between 1 and 2 feet. Only 13 stations showed a total loss of more than 300 feet during the period of record. For these and similar details, the reader is referred to Table III.

The total recession and its average annual rate as determined for these 134 stations are both smaller than would be expected from most of the earlier studies reviewed under "Former Studies of Shoreline Changes" above. It is apparent that such men as Chamberlin, Hoy and Goldthwait considered only shore segments of unusually severe erosion.

Table III. Summary of Past Erosion or Accretion at 134 Selected

Summary: Number of Stations: 134.

Number showing net accretion: 6.

Average gain per year at the 6: 1.59 feet.

Number showing no change: 4.

Number showing net erosion loss: 124.

Average loss per year at the 124: 1.47 feet.

Relation of Shore Changes to Lake Levels

It is apparent that the rate of shore change, particularly erosion, has varied greatly. The factors chiefly responsible for such variation in rate of erosion are protective structures built by man, storms of unusual severity, and fluctuations in mean lake level.

Protective structures have been placed along the lake shore at many points by individuals and by municipalities, highway departments, railroads and other large organizations. The scale of such structures ranges from inexpensive groins or seawalls of boulders placed at one or two points, to massive piers and walls of driven steel piling, cement, and heavy riprap so

placed as to protect shore segments several hundred yards in length. Where such protective structures have been properly designed, sturdily built, and of a scale sufficient to protect the entire area of critical erosion, they have generally retarded or checked recession of the shore. Where they have failed in their purpose, the failure has commonly been due to faulty design, weak construction, and inadequate coverage of the shore segment undergoing erosion. A single individual can seldom cope effectively with erosion of his shore, partly because the cost of proper structures is generally beyond his means, but also because shore erosion will continue on both sides of his property, which then becomes subject to attack on 3 sides (see Figure 8). Because the problem of such shore protection has been long and successfully investigated by the U. S. Army, Corps of Engineers, and by private engineering organizations, it will not be discussed further in this report.

Unusually severe storms occur at irregular intervals and have often caused accelerated erosion of the shore. Among them are the storms of October 22 and 29, 1929; September 28, 1945; May 28-29, 1947; January 1 and March 26-28, 1948. The unusual vigor of wave attack during such storms is due partly to greatly increased wind velocity and hence wave energy and height of waves; and partly to the rise in water level associated with strong onshore winds. Such high water may exceed mean level for the period by as much as two feet. Data on actual losses to the shoreline during such storms are meager. Recession of from one to several feet during a single storm have been reported. Because quantitative data over a considerable period of time are lacking, no evaluation of the total effects of unusual storms can be made here.

It has long been known that fluctuations occur in the mean monthly and annual levels of Lake Michigan. Fluctuations of even shorter periods, often

less than one day, are also known and are attributed to changes in wind direction and barometric pressure.* The monthly fluctuations follow somewhat

* Powers, W. B., Effects of Barometric Pressure and Winds on the Level of Lake Michigan: Trans., Illinois State Acad. of Science, vol. 27, 1934, pp. 113-114.

irregularly an annual cycle involving high water in early summer and low water in winter. The annual fluctuations are related partly to rainfall variations but even more to variations in rate of evaporation. Mean annual lake levels rise and fall irregularly with peaks occurring every 10 to 12 years. Since 1864, peaks in the lake level curve have occurred in 1870, 1876, 1886, possibly 1893, 1899, 1905-8, 1918, 1929, 1943-1952. Levels were very low in 1925-26, and 1932-37. They were generally high for the decade 1943-52.

It is apparent that most shore erosion and recession occur during periods of high water. Dated photographs of bluffs, taken in past years, commonly show grassed and stable slopes during low water periods, but fresh cuts and evidences of rapid erosion during high water. Newspaper accounts of wave damage prove the same relationship. However, there are few actual measurements recorded from year to year which permit the relationship of erosion rate to lake level to be put on a quantitative basis. By statistical analysis, involving known fluctuations in lake level and varying rates of erosion along the shore, the Beach Erosion Board estimated that bluff recession in Milwaukee County averages 1.0 foot per year for a maximum lake level of 579 feet; 2.1 feet per year for 581 feet; and 3.2 feet per year for 583 feet.** Your

** Beach Erosion Board, U. S. Army Corps of Engineers, Beach Erosion Study, Lake Michigan Shore Line of Milwaukee County, Wisconsin: U. S. House of Representatives, 79th Congress, 2nd Session, Document No. 526, 1946.

author believes that those figures are conservative and that annual erosion at the 583-foot level would probably be far more than 3.2 times that at the 579-foot level. The work of J. R. Ball near Kenosha, quoted previously under "Former Studies of Shoreline "Changes," showed an average annual recession of 12.33 feet per year from 1918 to 1921, when lake level averaged about 580.6 feet; and 0.73 feet per year from 1921 to 1929, when lake level averaged about 579.3 feet. It is apparent that yearly measurements on erosion over a period of years are needed, before a quantitative relationship can be established between lake levels and erosion rates.

A human factor also enters into this problem. Long periods of low lake levels, as that between 1929 and 1943, are times of broad beaches and feeble wave attack on the shore. Groins and other protective structures are allowed to lapse into disrepair. Then when another high water period arrives, the decayed shore structures may be quickly destroyed by wave action, and the shore is left open to attack. Such was the situation in 1943, when the unexpected return to a high water level promptly caused serious damage to the shore and shore properties, which owners often did not have the means to combat immediately.

APPLICABILITY OF SHORELINE STUDIES ON LAKE MICHIGAN

TO OTHER LARGE INLAND LAKES

Comparable Large Lakes Elsewhere

Lakes comparable in size to Lake Michigan include Superior, Huron, Erie, and Ontario in the United States; Winnipeg, Athabaska, Great Slave, and Great Bear in Canada; Caspian Sea, Aral Sea, Ladoga, Balkhash, and Baikal in Eurasia; and Victoria, Rudolf, Albert, Nyasa, and Tanganyika in Africa. Although

differing greatly from Lake Michigan in outline, geological structure and history, most of these lakes possess many similarities to Lake Michigan. A few differ notably in one particular: they lie deep below surrounding mountains or elevated plateaus. Specifically, Lake Baikal lies amidst mountains, while all of the African lakes except Victoria are in valleys sunk deeply below a plateau surface. On the contrary, the others are all in plains or lowlands and their shorelines possess many similarities to ~~that~~ of Lake Michigan.

Processes similar to those on Lake Michigan are now modifying the coast zones of these other large lakes, and have done so in the past. Similar basic shore zone features have been developed, including bluffs, cliffs, dunes, bars, and nips. With appropriate modifications where necessary, the letter code used for describing the shore zone elements of Lake Michigan can be applied to all other large lakes. Most of the larger shore zone features identified on Lake Michigan can be recognized on good aerial photos of large scale; this statement applies particularly to bluffs, cliffs, dunes, low plains, and other major features. Widths of beaches can be measured from the photos; areas of active erosion can be identified by narrow beach zones and lack of vegetation on fresh bluffs; the nature of beach materials can usually be deduced from the character of the landface and backland areas and the inferred nature of shore processes. Associations of shore zone features, observed in the Lake Michigan area, can be extended to other large lake basins. Therefore the types of shore zone features on Lake Michigan, the methods developed for mapping them in code, and their observed combinations and associations, can be applied to the study of any other large lake. By such study, shore zone areas can be identified which are best suited for man's operations, of whatever character they may be.

APPENDIX I. Explanation of Graphic Symbols used on the 26 Section Maps of the Lake Michigan Shore.

APPENDIX II. Code (Letter and Numeral) Used in Field Mapping, in Table II, in Descriptions of Figures, and on the 26 Section Maps Showing Characteristics of the Shore Zone.

A. Upland with bluff.

Ah — high bluff, more than 20 feet high.

Al — low bluff, less than 20 feet high.

Materials of bluff and backland:

1. Glacial till
2. Glacial sand and gravel
3. Dune sand
4. Lacustrine sand and gravel
5. Lacustrine silt or clay

Examples: Ah-1, high upland of till, with bluff.

Al-1/4, low upland of till over lacustrine sand and gravel, with bluff.

B. Low plain, generally without nip.

Materials of plain:

- 1 to 5. Same as above
6. Stream alluvium, mainly gravel, sand mud and silt
7. Swamp
8. Bedrock

If rock ledge or reef occurs in beach zone, r is added.

Example: B-2-r, low plain of glacial sand and gravel, with reef on beach.

C. Foredunes, mostly less than 20 feet high.

Cb, if low bluff or nip is present.

C, if no bluff or nip is present.

D. Old dunes, generally wooded and mostly more than 20 feet high.

Dh — high dunes, more than 40 feet high.

Dl — low dunes, less than 40 feet high.

If bluff is present b is added.

Example: Dlb, low dunes with bluff.

M E. Sand bar or spit.

If dunes are on top, d is added.

Example: Ed, spit or bar with dunes.

F. Bedrock upland with cliff.

Fh — high cliff, more than 20 feet high.

Fl — low cliff, less than 20 feet high.

M. Reed marsh in offshore or foreshore. Generally no beach is present.

This type occurs with other basic types of coastal features.

Example: B-4-M: Low plain of lacustrine sand and gravel, with reed marsh offshore.

R. Artificial fill. This generally occurs with some other basic types of coastal features.

Example: Al-2-R, upland of glacial sand and gravel with bluff less than 20 feet high, with artificial fill along "shore."
