TRAFFICABILITY OF SOILS

SOIL CLASSIFICATION

TECHNICAL MEMORANDUM NO. 3-240
SIXTEENTH SUPPLEMENT
August 1961
(Supersedes TM 3-240, 11th Supplement)

U. S. Army Engineer Waterways Experiment Station
CORPS OF ENGINEERS
Vicksburg, Mississippi

ARMY-MRC VICKSBURG, MISS.

PREFACE

The study reported herein was made to obtain information in furtherance of Corps of Engineers Research and Development Project 8S70-05-001, "Trafficability and Mobility Research," Subproject 8S70-05-001-02, "Surface Mobility (Trafficability)."

The study was performed by engineers of the Trafficability Section, Army Mobility Research Center, Soils Division, U. S. Army Engineer Waterways Experiment Station, under the general supervision of Messrs. W. J. Turnbull and C. R. Foster and under the direct guidance of Messrs. S. J. Knight and A. A. Rula. Part of the data used in this study was collected by the U. S. Forest Service and Purdue University, under contract to the Waterways Experiment Station. The data were analyzed and the report was written by Messrs. M. P. Meyer and S. J. Knight. Mr. N. H. Smith assisted in the compilation and analysis of data.

Col. Edmund H. Lang, CE, was Director of the Waterways Experiment Station during preparation of this report. Mr. J. B. Tiffany was Technical Director.

CONTENTS

CONTENTS (CONT'D)

SUMMARY

The study described herein consisted of a statistical analysis of the principal factors that influence soil trafficability and the application of the analysis to the development of a scheme for classifying soils under generally wet conditions in a temperate climate. The scheme developed is an improvement over the one reported in the 11th Supplement in this series of reports.* This report supersedes the 11th Supplement.

The original scheme was based on data from 321 sites; in the present scheme 1310 were considered. The former scheme recognized only the Unified Soil Classification System (USCS) for identifying soils; the present scheme also recognizes the U. S. Department of Agriculture (USDA) textural classification system. The first scheme considered the trafficability of soils under average wet-season conditions and ignored topographic position and water table. This scheme differentiates between average wet-season conditions (called simply "wet-season condition") and poorest trafficability conditions in the wet season (called "high-moisture condition") and considers topographic position and water table. The first scheme classified soils into four general trafficability groups; this scheme rates the trafficability of each soil type separately.

Although the scheme presented herein for classifying soils from a trafficability standpoint is considered to have exploited available data and knowledge to a maximum extent and is, therefore, the best available scheme to date, it is admittedly limited in scope. Some of the major limitations are: (a) the scheme considers only soils in humid, temperate climates; (b) it does not consider thawing or recently thawed soils, e.g. soils during the spring breakup; and (c) it does not attempt to describe the specific effects of certain environmental factors known to be important influences on soil trafficability, such as parent material, landform, land use, second-order climatic variations, and second-order soil textural variation. Initial attempts to quantify the effects of these environmental factors were temporarily abandoned when it was determined that valid data were not sufficiently numerous for statistical soundness. Collection of additional data and further analysis will be accomplished in the future.

The classification scheme presented in this report is essentially a listing of soil types (USCS and USDA) in decreasing order of median rating

---

* Listed on back of front cover of this volume.

cone index. Means and ranges are shown for each soil type in high- and low-topography positions and at times of wet-season and high-moisture conditions. The probability of successful negotiation of a soil type by military vehicles can be ascertained by comparing vehicle cone indexes with the frequency distribution of rating cone index for the soil. Results of the various studies performed in developing the trafficability scheme are summarized as follows:

a. Under wet-season condition, USCS soils are rated in the following order from a trafficability standpoint (i.e. in order of decreasing trafficability): clean sands and gravels, sands and gravels with fines, highly plastic fine-grained soils, moderately plastic fine-grained soils, silty soils, and organic soils.

b. Under high-moisture condition, USCS soils are rated as follows: clean sands and gravels, highly plastic fine-grained soils, moderately plastic fine-grained soils, sands and gravels with fines, silty soils, and organic soils.

c. A general correlation between USCS types and USDA types for the same soils was found.

d. The USDA soil type in the 6- to 12-in. layer was the same as that in the 0- to 6-in. layer of the profile at 71% of the sites.

Two appendices, giving sources of and procedures used in obtaining the data used in the analyses, are included.

TRAFFICABILITY OF SOILS

SOIL CLASSIFICATION

PART I: INTRODUCTION

Background

1. The study reported herein is a part of an extensive investigation to develop (a) techniques and equipment that will enable reconnaissance parties to determine off-road soil conditions, and (b) a graphic means of presenting these conditions which will show field commanders the relation between vehicle mobility, soil type and moisture condition, and slope. This study consisted of a statistical analysis of the principal factors that influence soil trafficability, and the application of the analysis in developing a scheme for classifying soils under generally wet conditions in a temperate climate. The scheme developed is an improvement over that reported in the 11th Supplement in this series of reports,* also entitled Soil Classification, which it supersedes.

General Concepts

Present limitations of scheme

2. A soil trafficability classification scheme, if it is to be practicable, must first name or identify the soils according to some recognized system of soil classification, then establish trafficability limits for each soil type, and finally, if feasible, collect the various soil types into a small number of groups, each exhibiting a discrete trafficability behavior. The ideal scheme would be one that considered and evaluated all aspects of the environment (pedologic, geologic, hydrologic, physiographic, climatic, and vegetative) that affect the trafficability of the soil. The scheme reported herein, while it more nearly approaches the ideal than did the previous scheme (described in TM 3-240, 11th Supplement), considers the soil types under general space and time conditions in a temperate climate.

* Reports of this series are listed on the inside of the front cover of this volume.

Tropical soils, arctic soils, and soils during spring thaw will require separate treatment. Further refinement according to the environmental parameters mentioned previously must await the collection of additional data and further analysis.

3. Because clean sands and gravels are clearly the best soils from a trafficability standpoint they have been given a distinct place in the soil trafficability classification scheme, and have been excluded from the various statistical analyses that are presented in this report. For further information on the trafficability of sands, refer to WES TM 3-240, 15th Supplement.

Moisture references

4. Since it is generally true that every soil is trafficable when dry, and that every soil, with the possible exception of clean sand or gravel, can become untrafficable if sufficiently wet, it is necessary that some common moisture reference be employed if a classification scheme is to be meaningful. In the scheme developed herein, two general topography positions, termed "high topography" and "low topography," have been used with respect to space. Each position reflects a general water table condition of an area and thus a general moisture condition of the soil for a given time. "High topography" is assigned to a medium- to well-drained area of generally high topographic position where the water table always is more than 4 ft below the surface. "Low topography" is assigned to a poorly drained area of generally low topographic position where the water table lies 4 ft or less below the surface at some time during the year. Two common moisture references have been used with respect to time, a wet-season condition and a high-moisture condition. Wet-season condition refers to the average moisture condition of a soil during the period of the wet season. High-moisture condition refers to the time of approximately highest moisture content (lowest strength) of a soil.

5. The time and space terms are described in more detail in Part III. It can be shown statistically that the type of soil (clean sands and gravels excepted) will control the trafficability of an area under wet-season or high-moisture conditions. One soil type will exhibit a higher strength than a second type, which in turn will be more trafficable than a third, etc. Thus, relative ratings of trafficability by soil types

can be determined, and a classification scheme is feasible.

Soil classification systems

6. The soil trafficability classification scheme presented in this report may be considered a composite classification scheme because it uses two well-known systems of soil identification and is based on the moisture references mentioned in paragraph 4. The two soil classification systems used are the Unified Soil Classification System (USCS)[8*] and the U. S. Department of Agriculture (USDA) soil textural classification system. The USCS employs soil texture, plasticity, and organic content to name or type soils, whereas the USDA system is based solely on grain size. Because the USCS characterizes soils on the basis of their engineering behavior, and engineering behavior includes the reaction of soil to excavation, spreading, and rolling by construction equipment (closely analogous to trafficability operations), it is considered that the USCS-based trafficability scheme is the more reliable. However, since many areas are mapped in USDA terms or their foreign equivalents (and only a few in USCS terms), it was considered desirable to develop a scheme in USDA terms.

Purpose

7. The purpose of this study was to improve the soil trafficability classification scheme previously reported in the 11th Supplement in this series through analysis of additional data collected since development of the original scheme.

Scope

8. Data collected on coarse-grained soils with fines and on fine-grained soils during the period 1950-1958 were statistically analyzed in the development of the soil trafficability classification scheme. As noted previously, clean sands and gravels were assigned a distinct place in the scheme on the basis of their known excellent trafficability as compared to other soils; therefore, data on them were not subjected to statistical

---

* Raised numerals refer to similarly numbered items in List of References at end of text.

analysis. Data used in the analysis were obtained from 1310 sites used in six different trafficability studies, including traffic-test, field-trip, prediction-development, survey, airphoto-trafficability, and high-water-table sites.* In the traffic-test program, data were collected from 36 natural-ground sites during the spring months of 1950 through 1953 for the purpose of determining the relations between vehicles and soils. In the field-trip program, 206 sites were each visited once during the springs of 1951 and 1953 to obtain information on the remolding effects of different soils. In the prediction-development program, data were collected frequently from 128 sites at various times from 1951 through 1954 for use in development of a means for quantitatively predicting daily moisture conditions of the surface soil. Data collected in the survey program at 618 sites in 1954 and 1955 were used to check the accuracy of soil-moisture prediction based on relations developed from prediction-development site data. Airphoto-trafficability data were obtained from 262 sites during the period 1950 through 1958 by the Engineering Experiment Station, Purdue University, under contract to the Waterways Experiment Station (WES), for use in a study to develop criteria for defining the trafficability characteristics of major landform environments from aerial photography.[5] Data for the high-water-table study were collected in 1957 from 60 sites for the purpose of obtaining information on soil strength under conditions of maximum wetting. Most of these data were collected in the United States during the wet season in humid, temperate regions; however, some of the data were obtained from soils in subhumid and arid temperate regions under high-moisture conditions.

9. The following studies, directly or indirectly pertinent to the improvement of the soil trafficability classification scheme, were conducted:

a. A mean and standard deviation analysis of strength, moisture content, density, and per cent saturation for high- and low-topography sites under wet-season condition, and for low-topography sites under high-moisture condition for soils in the 6- to 12-in. layer classified in USCS and USDA terms.

b. A cumulative frequency analysis of rating cone index for

---

* These sites are discussed in detail in Appendix B.

high- and low-topography sites under wet-season condition, and for low-topography sites under high-moisture condition for soils in the 6- to 12-in. layer classified in USCS and USDA terms.

c. Study of USDA soil types classified in terms of USCS types for soils of the 6- to 12-in. layer.

d. Study of USCS soil types classified in terms of USDA types for soils of the 6- to 12-in. layer.

e. Determination of the degree of similarity between 0- to 6-in. and 6- to 12-in. layer soil types in terms of the USDA classification.

Previous Investigations

10. Much of the basic trafficability terminology and most of the site and soil data contained herein are included in the 3rd and 8th through 15th Supplements of the Trafficability of Soils series of reports listed inside the front cover of this volume, and in the series entitled Forecasting Trafficability of Soils, TM 3-331.[7] Some of the data are included in a series of reports written by personnel of the Engineering Experiment Station, Purdue University, under contract to WES during the period June 1951 to December 1957 under the general title, Application of Airphoto Pattern Analysis to Soil Trafficability Studies.[5] A summary report with the same title, written by Purdue University personnel and to be published by WES, contains most of the information and data included in the individual reports.

PART II: BASIC SOIL CLASSIFICATION SYSTEMS

11. The two soil classification systems, the USCS and the USDA, used in this study are briefly described in the following paragraphs.

Unified Soil Classification System (USCS)

12. The USCS is based on the identification of soils according to their textural, organic, and plasticity qualities, and on their grouping with respect to engineering behavior.[8] A condensation of the classification system is contained in table 1.

13. The soils are divided into coarse-grained soils, fine-grained soils, and highly organic soils. The coarse-grained soils may be subdivided into sands with fines, gravels with fines, clean sands, and clean gravels.

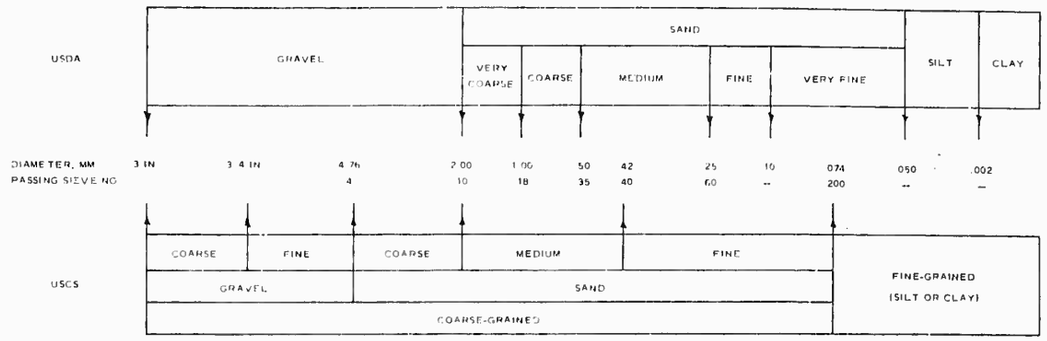
14. The soil types within the fine-grained and coarse-grained with fines groups are, for the most part, differentiated by their plasticity properties which are described in terms of moisture content limits, termed Atterberg limits. The limits, designated the liquid and plastic limits and the plasticity index, are defined in the 14th Supplement.

U. S. Department of Agriculture (USDA) Soil Classification

Textural classification system

15. The USDA system, utilized chiefly by the agronomist and soil scientist, is based on the identification of soils according to their texture. Texture is identified by the proportion of sand, silt, and clay in a sample. Limiting grain sizes corresponding to these three terms are shown in the following chart which also shows subdivisions under sand. Gravel includes sizes above 2.00 mm. The basic USCS soil names and corresponding sizes are shown in the lower half of the chart for comparison.

16. Four broad fundamental textural groups are recognized: sands, loams, silt, and clays. Soils containing more than 20% organic matter usually are classified as peat or muck if the mineral portion is silty or clayey. The sands, loams, and clays are subdivided into types based on



defined ranges of percentage of sand, silt, and clay. The textural composition of the four groups and the twelve basic types included within them are as follows:

a. Sands. Two specific types, sand (S) and loamy sand (LS), are recognized within this group.

b. Loams. The loam soils are heterogeneous mixtures of varying proportions of sand, silt, and clay. The predominant texture or textures are usually denoted by the first name or names, respectively, of the loam types, i.e. sandy loams have appreciable amounts of sand, and sandy clay loams appreciable amounts of sand and clay. Soil types within the group include loam (L), sandy loam SL), sandy clay loam (SCL), clay loam (CL), silt loam (SiL), and silty clay loam (SiCL).

c. Silt. This group is a type in itself. Comparatively few soils classify as silt.

d. Clays. The specific types in this group include sandy clay (SC), silty clay (SiC), and clay (C).

17. The type name may be modified by the textural terms "stony," "cobbly," or "gravelly," or by the grain size of sand (very coarse, coarse, medium, fine, or very fine).

18. Once the percentages of sand, silt, and clay are determined, the type name is established by reference to the textural classification triangle (fig. 1). Soils falling on a line between two types normally are denoted by the names of both types. For purposes of this study, however, such soils are gouped into the type having the greater percentage of silt or the smaller percentage of sand, i.e. the type that normally would be the more critical from a trafficability standpoint.

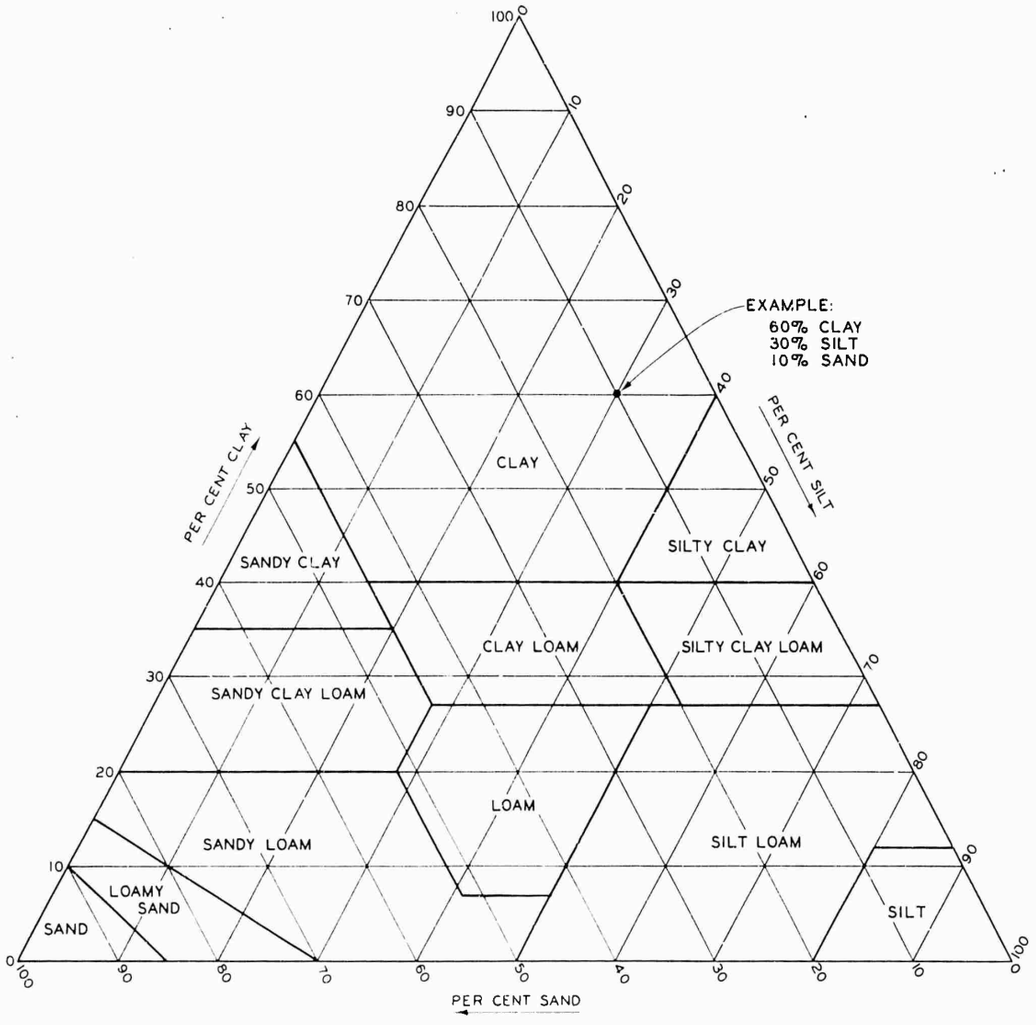


Fig. 1. USDA soil textural classification

Soil series

19. A soil series is a group of soils with similar characteristics and arrangement of soil horizons in the soil profile, except for the texture of the surface or "A" horizon. The soils within a series are developed from a particular type of parent material within a specific climatic environment, and are essentially homogeneous with respect to such features as slope, stoniness, degree of erosion, topographic position, and depth to bedrock. The series names are place names taken from the area where the soil was first defined, such as Miami, Hagerstown, Norfolk, and Houston. A soil series is normally subdivided into types based on the texture of the

surface or "A" horizon, which is the zone of organic accumulation and/or eluviation (mineral leaching). The type-textural name follows the series name, as Miami silt loam or Norfolk sand loam.

20. The Soil Conservation Service, U. S. Department of Agriculture, has been actively engaged in describing and mapping soil series areas of the United States. To date, approximately 4000 series have been distinguished and many areas, especially agricultural areas, have been mapped in units of these series. Information usually contained in the detailed description of the series includes the texture, color, structure, and range of thickness for each horizon within the profile; range in variation of soil characteristics; topography; external and internal drainage and permeability characteristics; typical and predominant vegetation; land use; and geographic distribution.

21. The wealth of environmental information implicit in a soil series name suggests that use of soil series names would provide a more accurate trafficability classification scheme than one based on texture alone. Unfortunately there was not sufficient soil series information in the data available to warrant the development of such a system at this time. Also there was no knowledge of the variation in trafficability which might be expected in a given soil series. Studies are presently being conducted by the Forest Service, USDA, in cooperation with WES, to determine the horizontal and vertical variations of soil properties and strength characteristics for four different soil series areas in the vicinity of Vicksburg, Mississippi. The results of these and future studies in other soil series areas will determine the feasibility of using soil series descriptions to interpret trafficability conditions.

PART III: TRAFFICABILITY FACTORS AND THEIR MEASUREMENT

22. Trafficability is defined as the capacity of a soil to withstand traffic by vehicles. It is an important aspect of cross-country movement which may be defined as the ability of terrain and environment to permit the movement of vehicles. The factors that influence cross-country movement are numerous. They not only include the many variables which combine to determine the strength and other physical properties of soils, but also include slope and other natural obstacles such as drainageways, scarps, dense vegetation, and microrelief features, as well as man-made obstacles such as railroad embankments, canals, etc. Investigations conducted by WES thus far have been limited to the trafficability of level and sloping soils and have not considered obstacles.

Soil Strength

Factors influencing strength

23. The principal factor affecting the trafficability of a soil is its shear strength. Physical soil properties that influence the shear strength of a soil include moisture content, grain size, grain shape, mineralogical composition, organic content, plasticity, and density. There is also evidence that environmental conditions play an important part in the existing soil strength. From laboratory studies of soils molded at a given moisture content and then soaked to produce a higher moisture content, it is known that the strength after soaking is influenced to a very large degree by the molding moisture content. Thus, the existing strength of natural soils is probably influenced by the specific conditions that prevailed during formation or deposition of the soil, and by subsequent cycles of wetting and drying, dessication by vegetation, and all the other environmental influences, such as natural cementing agents, that served to bring the soil to its present condition. The relative significance of each of these factors is difficult to evaluate since one factor may influence another in numerous combinations of interrelations.

Strength measurements

24. Cone index (CI). The shear strength of a soil is evaluated for

trafficability purposes by means of a cone penetrometer. This instrument employs a right 30-degree circular cone which has a base end area of 1/2 sq in. The force necessary to push the cone slowly through the soil is indicated by a dial that ranges from 0 to 300. The value 300 occurs under a force of 150 lb. The measured value, a dimensionless number termed cone index, is used as an index of soil strength (see 14th Supplement).

25. Remolding index (RI). When traffic is applied to a moist or wet soil in its natural condition, the soil is remolded and its strength usually is changed. Remolding tests, one for fine-grained soils and another for poorly drained, coarse-grained soils with fines, have been devised that will permit an estimate of the magnitude and direction of these strength changes. The tests yield a remolding index which expresses the proportion of original strength that will be retained under traffic. The test equipment is described in detail in the 14th Supplement; the procedures for the two remolding tests are discussed in paragraph 3, Appendix A.

26. Rating cone index (RCI) and vehicle cone index (VCI). The rating cone index is the product of the cone index and the remolding index, and expresses the probable strength of the soil under a moving vehicle. The minimum CI required for 50 passes of a specific vehicle is called its vehicle cone index. If the RCI of a soil is higher than the VCI of a particular vehicle, 50 such vehicles can be expected to travel successfully in the same straight-line path, or one vehicle can be expected to execute severe maneuvers without becoming immobilized.

Soil Bearing and Traction Capacities

27. Bearing and traction capacities are primarily functions of strength (or shearing resistance) of a soil. Bearing capacity is the ability of a soil to support a vehicle without undue settlement; traction capacity is the ability of a soil to provide sufficient resistance between the moving wheel or track of a vehicle and the soil for the necessary thrust to move the vehicle forward. The trafficability of a soil is considered adequate for a given vehicle if the soil has sufficient bearing capacity to support the vehicle and sufficient traction capacity to enable the vehicle to develop the forward thrust necessary to overcome its rolling

resistance. When the rolling resistance is equal to or greater than the forward thrust, the vehicle becomes immobilized.

Soil Slipperiness and Stickiness

28. Two other soil properties, slipperiness and stickiness, affect the operation of a vehicle. Slipperiness is a condition of deficient traction capacity in a thin surface layer of a soil which is otherwise trafficable. A vehicle immobilized solely because of slipperiness spins its wheels or tracks but neither moves forward nor sinks excessively. Stickiness is the ability of soils to cling to and build up on the running gear of vehicles. When this happens, the rolling resistance of the vehicle is increased and steering becomes more difficult. In extreme cases, stickiness can produce enough rolling resistance to "freeze" the running gear of a vehicle.

Critical Soil Layer

29. Correlations between vehicle performance and soil strength are most consistent when the strength in the critical layer is considered. For most Army vehicles, in an area with a normal soil profile (cone indexes increase or remain constant with depth) the critical layer is that between the 6- and 12-in. depths. Detailed procedures for determining the critical layer for very light or very heavy vehicles in normal and abnormal profiles are described in the 14th Supplement. The analyses and trafficability classification scheme described herein are based on soils data from the 6- to 12-in. layer.

Soil Moisture

30. The principal factor influencing the strength of a given soil is its moisture content. Any soil in a comparatively dry state may be trafficable to all military vehicles; but at a higher moisture content, its strength, and consequently trafficability, may be such that only certain vehicles can pass. At even higher moisture contents the soil may be

untrafficable for all vehicles. It is apparent that moisture conditions must be taken into account in any evaluation of the trafficability of soils and, further, that soils must be at similar or equivalent conditions of moisture in order that they can be rated fairly in comparison with each other.

31. Moisture is added to the surface soil through precipitation, a rising water table, flooding, irrigation, melting of snow, or thawing of frozen ground. Moisture is generally depleted from the surface soil by runoff, gravitational percolation, evaporation, or transpiration through plants. The rate and magnitude of moisture gain or loss and the capacity of the soil to hold water are controlled not only by the above-listed physiographic, hydrologic, and climatic environmental factors, but also by the porosity and permeability characteristics of the soil. These latter characteristics, for the most part, are determined by the plastic, organic, and textural properties of the soil that are defined in terms of the USCS and the USDA soil classification system.

Soil-moisture terms

32. The soil-moisture terms used in this report are defined as follows:

a. Field capacity. The field capacity may be defined as the amount of water held in a soil with adequate opportunity for drainage after the excess gravitational water has drained away, and after the rate of downward movement of water has materially decreased. The moisture-content value at 0.06-atmosphere tension, defined below in subparagraph e(1), is sometimes used to approximate field capacity.

b. Per cent saturation. Per cent saturation is commonly defined as the ratio, in percentage, of the volume of water in a given soil mass to the total volume of intergranular space (voids). A soil is theoretically 100% saturated when its total pore space is completely filled with water. This condition, however, seldom occurs in nature because air is trapped in the voids.

c. Field-maximum moisture content. The field maximum is the naturally recurring, average highest moisture content of a soil layer in its natural position. The field-maximum moisture contents of the 6- to 12-in. soil layer normally are greater than field capacity and approach saturation at low-topography sites, and are generally slightly greater than or at field capacity at high-topography sites.

d. Field-minimum moisture content. The field minimum is the

naturally recurring, average lowest moisture content of a soil layer in its natural position. It occurs frequently during the dry season, but is seldom reached during the wet season in humid climatic areas.

e. Moisture tension. The moisture tension is defined as the force, or tension, by which water is held to the soil surface or within interstices. The tension for a specific soil varies inversely with its moisture content. The moisture content-tension relation for a particular soil is determined by means of a laboratory tension-table device at a sequence of tension, or pressure, settings. At a given moisture content, the tension is equal to the negative or gage pressure to which free water in the instrument has been subjected in order to be in hydraulic equilibrium, through a permeable wall or membrane, with the water in the soil. The tension values considered in this report include the following:

(1) 0.06-atmosphere tension (60 cm water). The moisture content at this tension value is sometimes used either to approximate the field capacity of soils or to estimate the field-maximum soil-moisture content of sites classified as high topography wherein water tables are more than 4 ft below the surface.

(2) 0.005-atmosphere tension. The moisture contents at this tension are close to saturation moistures for fine-grained soils, and are approximately equal to field-maximum soil-moisture contents of low-topography sites where the water table is less than 1 ft below the surface.

(3) 0-atmosphere tension. The moisture contents of soil samples at 0-atmosphere tension are determined in the laboratory using the same equipment and technique employed in determining the moisture content-tension relations noted above, except that tension is not applied to the sample. For a given soil, the moisture value at 0-atmosphere tension, as would be expected, is slightly greater than the value at 0.005-atmosphere tension, and is very close to the saturation moisture content (discussed in paragraph 15, Appendix A).

Climate and season

33. Climate must be considered in any type of soil-moisture analysis. The principal elements of climate consist of precipitation, temperature, atmospheric humidity and pressure, and wind velocity. Of these, precipitation and temperature are the two most important factors controlling the gain and loss of soil moisture. Similar soils within a specific climatic area will have qualitatively similar seasonal soil-moisture conditions; and, conversely, similar soils of different climates will have

dissimilar seasonal soil-moisture conditions. Soils in humid climatic areas, for example, generally have higher moisture contents than soils in arid climatic areas because of the difference in the amount of precipitation.

34. For purposes of this study wet and dry seasons are considered, based on the qualitative moisture conditions of the soil. The wet season is defined as the period of the year when generally high soil-moisture contents prevail; it does not necessarily correspond to the period of maximum precipitation. The dry season is defined as the period of generally low soil-moisture contents, although maximum moisture contents may occur for short periods during and immediately after heavy rainfall. Moisture studies conducted at specific sites (prediction-development) in various sections of the United States for continuous periods of at least one year (discussed in paragraphs 12-23, Appendix B) have been used to develop a system for predicting the effects of meteorological factors on the trafficability of soils.[7e] The studies show, among other things, that the top 12 in. or so of soils at sites in humid temperate climatic regions attain relatively high moisture contents in the late autumn months and, as a result of low evapotranspiration losses, maintain these moisture contents with relatively little deviation through the winter and early spring months. Transpiration is negligible because most plants are dormant or dead and require very little or no water, and evaporation to the atmosphere is small because of the normally cool or cold weather. The temporal limits of the wet season vary geographically and with local and regional microclimate.

35. Thornthwaite has developed a method for determining the ground moisture conditions based on precipitation and evapotranspiration for particular climatic environments.[6] In his scheme the nonfrozen ground conditions are classified into five categories: W (wet), MM (very moist), M (moist), D (dry), and DD (very dry). In W, MM, and M conditions the soil has a water surplus and the moisture content of the root zone is greater than field capacity; in D and DD conditions the soil has a water deficiency and the moisture content of the root zone is less than field capacity. These conditions and those of frozen and snow-covered ground are shown on monthly maps of the United States in Thornthwaite's report.

In order to provide an estimate of temporal and spatial limits for wet-season conditions in this study, the information from the Thornthwaite maps has been incorporated into a single map of the United States showing the distribution and months duration of wet-season conditions (fig. 2). The W, MM, and M ground conditions occurring between November and May were assumed to be wet-season conditions with the following exception: the last month of the wet season is transitional to the dry season and some low-topography areas and most high-topography areas can be considered to be under dry-season conditions for this time. W, MM, and M ground conditions shown by Thornthwaite in months other than the period November through May were assumed to be dry-season conditions. Areas in which Thornthwaite showed no W, MM, or M conditions for any month of the year were assumed to be areas with no wet season. In the northern tier of states, months omitted from the range are periods of predominantly frozen or snow-covered ground conditions.

Space and time factors affecting soil-moisture content

36. The moisture content of a soil at a site depends significantly on the topographic position and water-table level (drainage features) and the general precipitation-evapotranspiration balance at the time the site is investigated. Take, for example, a large area of essentially the same soil type consisting of hills and drainageways or valleys. (The loessial deposits in the vicinity of Vicksburg, Mississippi, constitute such an area. Whether at the top of a ridge or at the bottom of a drainageway, examination shows that the soil in the top foot is a silt loam (SiL) in USDA terms and a lean clay (ML) in USCS terms.) Suppose that this area had sustained a heavy rainfall during the wet season, when soil-moisture and water-table levels are generally high (evapotranspiration low). Following this rainfall, a test of the trafficability conditions on a transect through the area would show that the low-lying, poorly drained sites with water tables close to the surface had very poor trafficability, that better drained low-lying areas with deeper water tables had somewhat better trafficability, and that, in fact, trafficability improved directly with improvement in topographic position and drainage characteristics, until on ridgetops trafficability was excellent. It is obvious that a

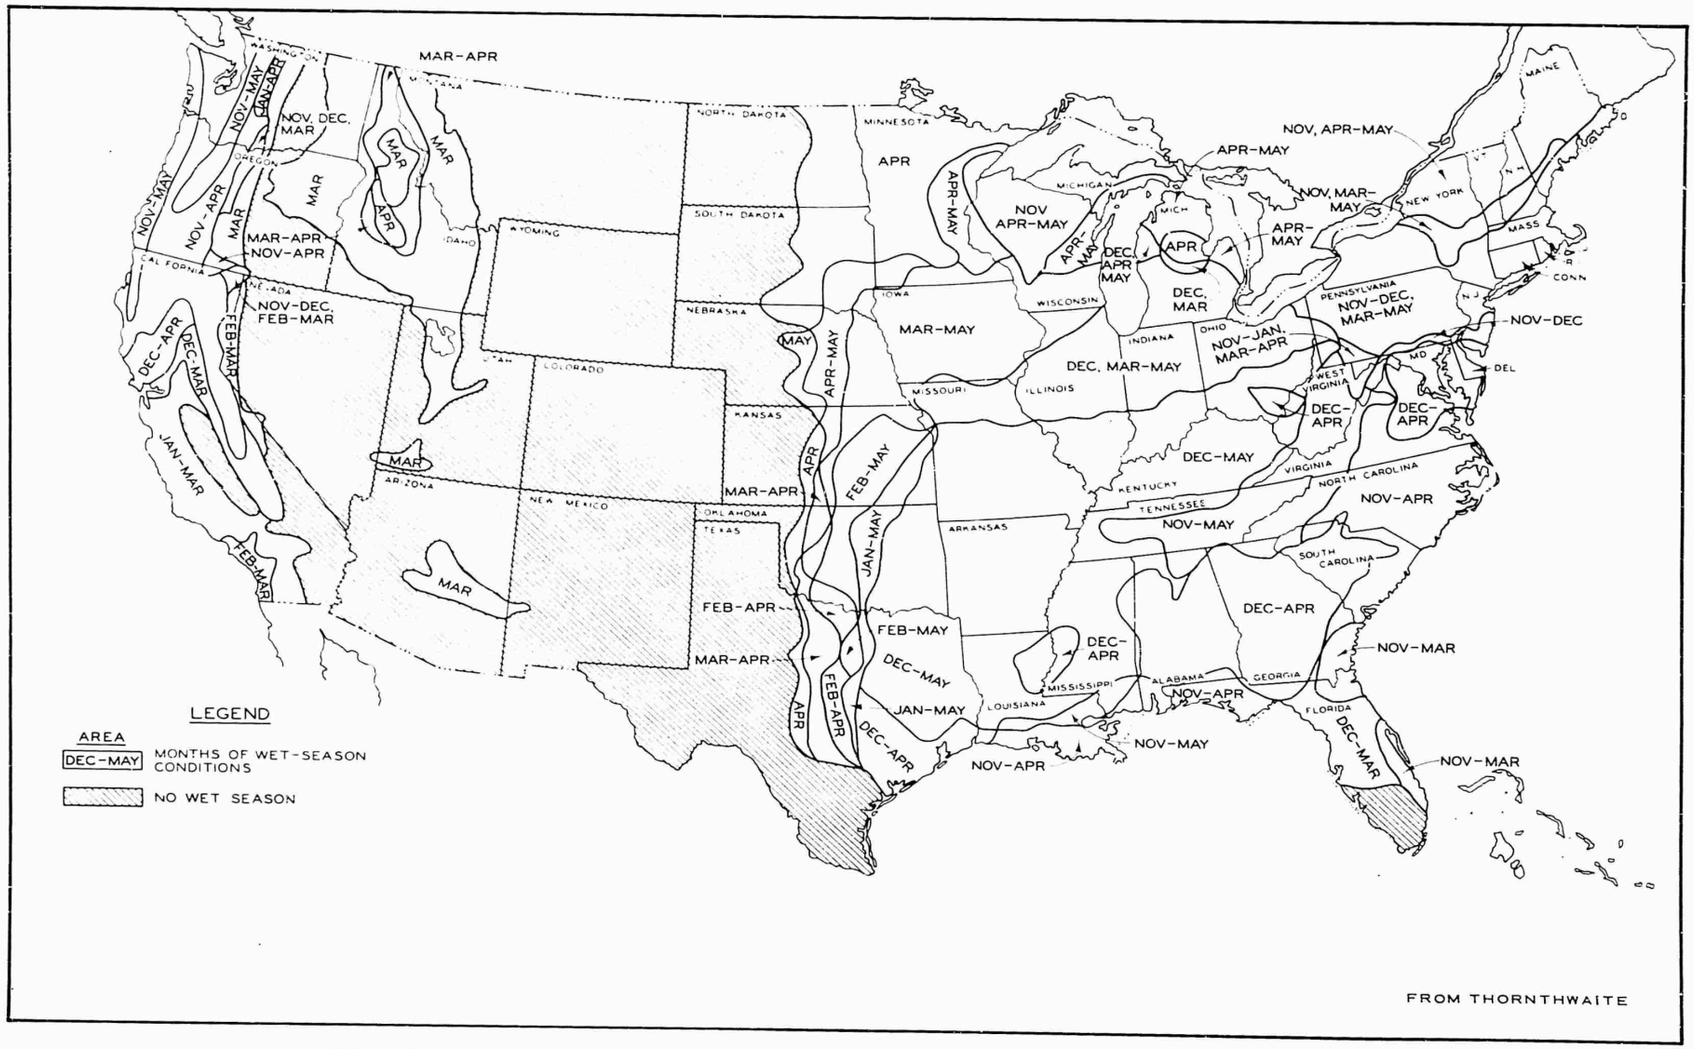

Fig. 2. Distribution and months duration of wet-season conditions

classification of the trafficability of this soil type would have to be "very poor to excellent," and would therefore be of little value from a practical standpoint. Similarly, suppose a rain fell during the dry season, when soil-moisture and water-table levels were generally low (evapotranspiration high). A few very poorly drained sites might be brought to a very poor trafficability condition and ridgetops would still enjoy excellent trafficability. Again one would have to say that trafficability varied from very poor to excellent, even though site for site, the trafficability under the latter assumption was generally much better than under the former.

37. In order to estimate the trafficability of a site more accurately, consideration must be given not only to its soil type but to its topographic position, and to its general relative moisture-content level. From a study of the data available, certain arbitrary "space" and "time" factors have been designated. These are considered essential for optimum accuracy in estimating trafficability on the basis of existing knowledge and available data. Additional data and further study may produce more explicit criteria for estimating the trafficability at a site. However, at the present time, two space factors, low and high topography, and two time factors, wet-season and high-moisture conditions, will be used. These are illustrated in fig. 3 and explained in the following paragraphs.

38. Space factors. The depth to the water table has been found to be a significant factor in determining how wet a site may become. Sites which have a water table within 4 ft of the surface become wetter in the top foot than do sites with the water table below the top 4 ft, even though all other conditions appear to be the same.

a. Low topography. A site of low topography is one at which a water table is known to exist within 4 ft of the surface, perennially or at some time during the year. Such sites usually occur as bottomlands, lower terraces, depressions, or bottoms of slopes, or occasionally as upland flats associated with impervious subsurface layers or pans. They are generally characterized by poor to fair external drainage and moderately poor to very poor internal drainage. If the water table is actually observed at depths of less than 4 ft from the surface at a site at least once, the site automatically qualifies as a low-topography site. If observed data on water-table depth are not available, sites which appear, from observation or from soil series descriptions,

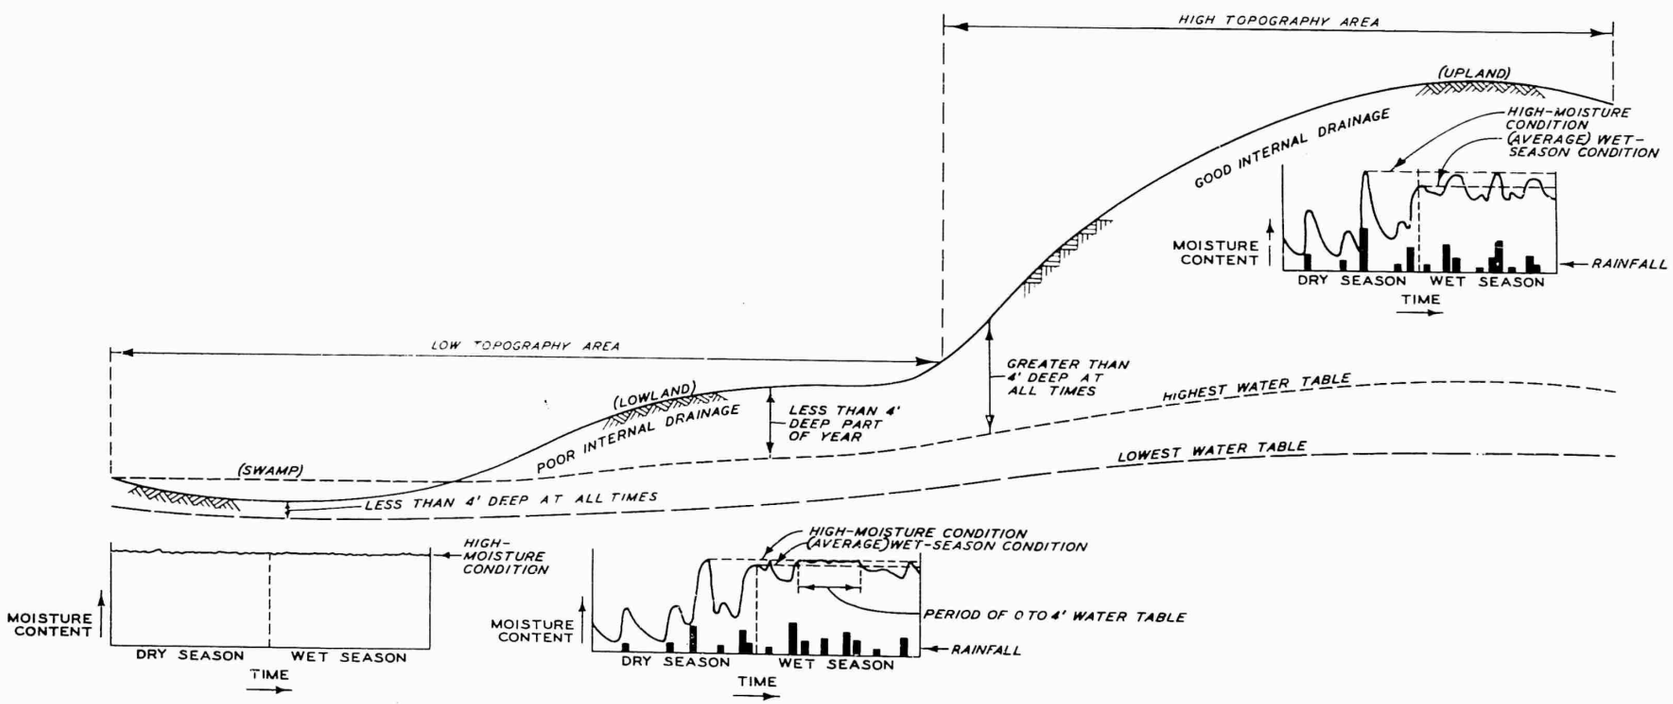

Fig. 3. Profile of a typical area showing various topography-moisture conditions during year

likely to have high water tables on the basis of their topographic position, drainage characteristics, proximity to surface water bodies, or soil coloring (gray or blue mottled soils usually indicate the presence of a consistent water table) are judged to be low-topography sites.

b. High topography. Sites of high topography have water tables at depths greater than 4 ft from the surface at all times. These sites are characterized by soils with no impervious layers or pans and moderate to good internal and external drainage. They are usually located on ridges or upper slopes. If information on water table is not available, it is usually possible to determine when a site is one of high topography through a study of the topographic position and other environmental data available.

39. Time factors. While, for this study, it would have been desirable to have examined the means and ranges of pertinent soil values measured at a time when the moisture content was at rigorous reference levels, such as field maximum or field capacity, this was not feasible because only a few sites were known to have been tested when the moisture content was at these levels. In order to realize the benefit of values derived from large masses of data, the less rigorous moisture levels, wet-season condition and high-moisture condition, were selected. These conditions, or time factors as they are called in this report, are discussed in the following subparagraphs.

a. Wet-season condition. The wet-season condition is intended to represent the average condition prevailing in soils during the wet season. In effect, it probably represents slightly wetter-than-average conditions, because data were obtained from some sites visited only once, specifically during a time of very wet moisture conditions, and because data from some of the drier sites were not utilized. The drier sites were usually visited only once or just a few times. At many of these sites, it was not possible to obtain a sample for the remolding test. Since remolding index (and therefore rating cone index) could not be determined for such sites, the other parameters, cone index, moisture content, and density, were not used for averaging. This treatment of the data permits straightforward comparisons of cone index, remolding index, rating cone index, moisture content, and density within a soil type. Exclusion of data from drier sites tended to bias the averages toward the wet end, and inclusion of data from the wetter sites strengthened this bias.

b. High-moisture condition. The high-moisture condition represents the worst trafficability condition that can occur at

sites that undergo seasonal changes. (Marshes, bogs, swamps, and other perennially wet, soft, spongy areas are prime examples of low-topography areas under high-moisture condition at all times.) Low-lying areas with fluctuating water tables and upland areas with seasonal perched water tables are typical examples of low-topography areas where high-moisture condition occurs intermittently. Low- and high-topography areas that have been subjected to moderate or heavy rainfall are normally under high-moisture condition during and immediately following the rainfall. In this study high-moisture condition at high-topography sites could not be identified from the collected data. Consequently, an analysis was not made for this topography-moisture condition and the classification scheme does not include data for this category. Only one set of high-moisture data (cone index, remolding index, rating cone index, and moisture content) was used in the analysis for a given low-topography site. At sites where high-moisture data were collected on more than one day, the set of data selected was for the day of lowest rating cone index. The moisture content for this day was usually, but not necessarily, the highest recorded at the site. The per cent saturation at high-moisture condition for all low-topography sites except those of the survey sites was based upon the moisture content of this day. The per cent saturation data for the survey sites was based on laboratory-determined moisture content at 0-atmosphere tension. In analyzing the data, a high-moisture condition was considered to have been prevalent at a low-topography site when it was known that the water table was within the top 4 ft of a fine-grained soil or within the top 2 ft of a coarse-grained soil with fines. If the precise elevation of the water table was not known a high-moisture condition was assumed to have prevailed if:

(1) The measured field moisture content was not more than 1% less than the laboratory-determined 0-tension moisture content for the site. This criterion was used for survey sites of low topography at which no water-table measurements were made.

(2) The measured moisture content was slightly less than, equal to, or greater than the field-maximum moisture content. This criterion was used for prediction-development sites of low topography at which no water-table measurements were made.

(3) The per cent saturation was greater than the per cent saturation mean of the soil type minus one standard deviation. This criterion was used for traffic-test and field-trip sites of low topography at which no water-table measurements were made and for all airphoto-trafficability sites of low topography. The

data for a few field-trip sites located next to streams and with exceptionally low rating cone index values were also included under high-moisture condition even though the per cent saturation was a few per cent below one standard deviation from the mean of the soil type. The data used in the per cent saturation analysis were derived from low-topography sites assumed to be under high-moisture condition based on conditions discussed above, or because of the site's proximity to a water body, or because it was tested during or immediately after a period of heavy rainfall. The statistical values for this assumed high-moisture condition approximate those obtained in the final analysis of per cent saturation discussed in paragraph 72.

Slope

40. Vehicles that can traverse certain soils on level surfaces often become immobilized when climbing slopes on similar soil conditions. These immobilizations can be attributed primarily to a downhill force, a function of the vehicle's weight and the angle of slope, which opposes the vehicle's forward thrust.

41. In this report slope is expressed in terms of per cent (vertical rise divided by horizontal distance multiplied by 100).

Slope index

42. The adverse effect of slope on vehicle performance can be expressed by an increase in rating cone index requirements above the vehicle's requirements for level terrain. These excess RCI points, called slope index, may be added to the vehicle cone index and the determination of "go"* or "no go" is made by comparing this value with the measured RCI. Detailed procedures for determining slope effects and for estimating the maximum slopes negotiable for various vehicle types are described in the 8th and 14th Supplements. Three slope index values, one for tracked vehicles with grousers longer than 1-1/2 in., another for tracked vehicles with grousers shorter than 1-1/2 in., and the third for wheeled vehicles, can be obtained for a given slope from the three respective curves shown

---

* In this report "go" means that 50 vehicles can pass in careful straight-line traffic or one vehicle can execute severe maneuvers without becoming immobilized.

in plate 1. If, for example, the slope is 30%, the slope indexes for the three vehicle classes would be 13, 15, and 20, respectively.

Effective rating cone index (ERCI)

43. The ERCI is a combined soil strength-slope value which rates the trafficability of a sloping soil. The index is computed by subtracting the slope index from the rating cone index. For example, if the RCI of a soil is measured to be 50 and the slope is 30%, the ERCI would be 50 minus 13 or 37 for tracked vehicles with grousers longer than 1-1/2 in.; 50 minus 15 or 35 for tracked vehicles with grousers shorter than 1-1/2 in.; and 50 minus 20 or 30 for wheeled vehicles. The determination of "go" or "no go" on sloping terrain is based on comparison of the vehicle cone index with the ERCI for the vehicle class. If the VCI is greater than the ERCI, vehicles of this type will not be able to climb the slope; if the VCI is less than the ERCI, the slope is considered negotiable. The ERCI can also be applied and, if desired, mapped in regard to level terrain. In this case, the slope index is zero for all vehicle classes and the ERCI is equal to the RCI of the soil.

PART IV: ANALYSIS OF DATA

Types of Analyses Made

44. The following studies of direct pertinence to the main purpose of this report, improvement of the soil trafficability classification scheme, are described in this part of the report.

a. A statistical study of the occurrence of strength, moisture content, density, and per cent saturation in the 6- to 12-in. layer of soils, classified in both USCS and USDA terms, under wet-season condition for low-topography, high-topography, and all sites (includes high- and low-topography sites), and under high-moisture condition for low-topography sites.

b. A cumulative frequency analysis of rating cone index in the 6- to 12-in. layer of soils, classified in both USCS and USDA terms, under wet-season condition for low- and high-topography sites and under high-moisture condition for low-topography sites.

45. In addition, three studies closely related to the classification scheme are described. The studies are:

a. Determination of the frequency of USDA soil types classified in terms of USCS types for soils of the 6- to 12-in. layer.

b. Determination of the frequency of USCS soil types classified in terms of USDA types for soils of the 6- to 12-in. layer.

c. Determination of the degree of similarity between 0- to 6-in. and 6- to 12-in. soil layers in terms of the USDA classification.

Basic Data

46. The data used in the above-listed studies were derived from six sources. The number of sites for each source and the number of sites which provided data for each of the studies are shown in the following tabulation. The sources of data are discussed in Appendix B, locations of sites are shown in fig. B1, and data are presented in tables B1 through B6.

Data Source	No. of Sites in Table	Number of Sites Used in Analysis of Mean and Standard Deviation: Wet-Season Condition: CI RI RCI*	Wet-Season Condition: Moisture Content	Wet-Season Condition: Density	High-Moisture Condition: CI RI RCI*	High-Moisture Condition: Moisture Content	High-Moisture Condition: % Saturation	Comparison of: USCS with USDA Soils	Comparison of: 0- to 6-in. with 6- to 12-in. USDA Soils
Traffic-test sites	36	34	34	30	27	27	23	27	11
Field-trip sites	206	150	178	167	103	102	99	169	167
Prediction-development sites	128	68	67	64	23	22	11	128	128
Survey sites	615	360	379	379	111	103	55	618	618
Airphoto-trafficability sites	202	9	61	57	19	16	11	194	186
High-water-table sites	60	3	4	0	36	27	30	40	30
Total	1310	654	724	697	319	297	229	1176	1140

* The rating cone index (RCI) values were also used in analysis of cumulative frequency of rating cone index.

Statistical Study of Strength, Moisture Content, and Density Under Wet-Season Condition

Procedures and presentation of data

47. This study establishes the statistical mean and standard deviation values of strength parameters (cone index, remolding index, and rating cone index), moisture content, and density for soils in the 6- to 12-in. layer under wet-season condition. Values were computed for low- and high-topography sites and all sites (high- and low-topography sites combined) for each of the soil types in the USCS and USDA systems, respectively. The data are presented in tables 2-6. The USCS soil types are arranged from top to bottom and the USDA soil types from left to right in order of decreasing mean rating cone index for all sites under wet-season condition (table 4). The same order of soil types is used for the cone index, remolding index, moisture content, and density tabulations (tables 2, 3, 5, and 6, respectively). The summary data for given soil types are also shown as histograms in plates 2-6. The first three bar graphs in the histogram for each soil type represent high topography, all sites, and low topography, under wet-season condition, respectively; the fourth bar graph represents low topography under high-moisture condition (discussed in

paragraphs 67-72). Each bar shows the range from +1 to -1 standard deviation. The mid-point of the bar is the mean value, and the number of samples (sites) used in the analysis is shown at the top of the bar.

48. The data used in these analyses were obtained from 767 sites in 41 states generally located in the humid, temperate regions of the United States. Some of the data were derived from sites located in subhumid or arid climatic areas wherein moisture contents were similar to wet-season moisture contents in the humid, temperate regions.

49. The IBM 650 computer was employed in this and in the high-moisture condition study. Two IBM data cards were used for each site. The first card tabulated the USCS and USDA types and the topography by code number, and listed the wet-season condition values for strength, moisture content, and density. The second card repeated the tabulations of USCS and USDA types and topography; noted by code number the site number, location by state, and type of study the site was used in; and listed the high-moisture condition strength and moisture-content values for each low-topography site.

50. The data were analyzed in terms of mean and standard deviation because these are probably the most widely used and most readily understood statistical measures. The mean (commonly termed arithmetic mean or average) is computed by summing the individual measurements and dividing by the total number of measurements. The standard deviation is a measure of the dispersion of the data around the mean. The standard deviation (s) for less than 30 measurements was computed by means of the formula

$$s = \sqrt{\frac{\Sigma(x - \bar{x})^2}{n - 1}}$$

where Σ = the sum of

$(x - \bar{x})$ = the deviation of an individual measurement from the mean of all measurements

n = the number of measurements

(The -1 may be omitted from the denominator of the formula if more than 30 measurements are used in the computation.) When the number of measurements for the specific condition exceeds 30, the interval defined by +1 and -1 standard deviation from the mean will usually contain approximately 68% of

the data; or assuming the data are universally valid, if three additional measurements were taken, the values of two would usually fall within this interval. Mean and standard deviation values of a condition with less than 30 measurements, and especially of a condition with less than 5 measurements, should be viewed with skepticism.

51. The histograms in plate 5 show that mean moisture contents for a given soil type are generally highest under low topography, high-moisture condition and lowest under high topography, wet-season condition, and the mean moisture content for low topography, wet-season condition is properly arranged. If data had been developed for high topography, high-moisture condition, the mean moisture content would probably lie between those for low topography, wet-season condition, and low topography, high-moisture condition. This consistent pattern for all soil types (except USCS type SC and USDA sandy clay loam (SCL)--see paragraph 63 for discussion) is presumed to be evidence in support of the proper identification of site data into the four arbitrary space-time categories used in this report.

Analysis of strength

52. Cone index. The results of the analysis of CI are given in table 2 and the summary data for each soil type-wetness condition are shown graphically in plate 2. The following tabulation lists the soil types in decreasing order of mean CI for all sites under wet-season condition.

USCS Type	Mean Cone Index	USDA Type	Mean Cone Index
SP-SM	194	LS	188
SC	178	S	184
SM-SC	175	SCL	180
SM	172	SL	159
ML	160	Si	158
CH	155	SiL	156
CL	150	SiCL	156
MH	143	CL	151
CL-ML	139	SC	148
OL	115	C	146
OH	114	SiC	142
Pt	83	L	140
		Pt	83

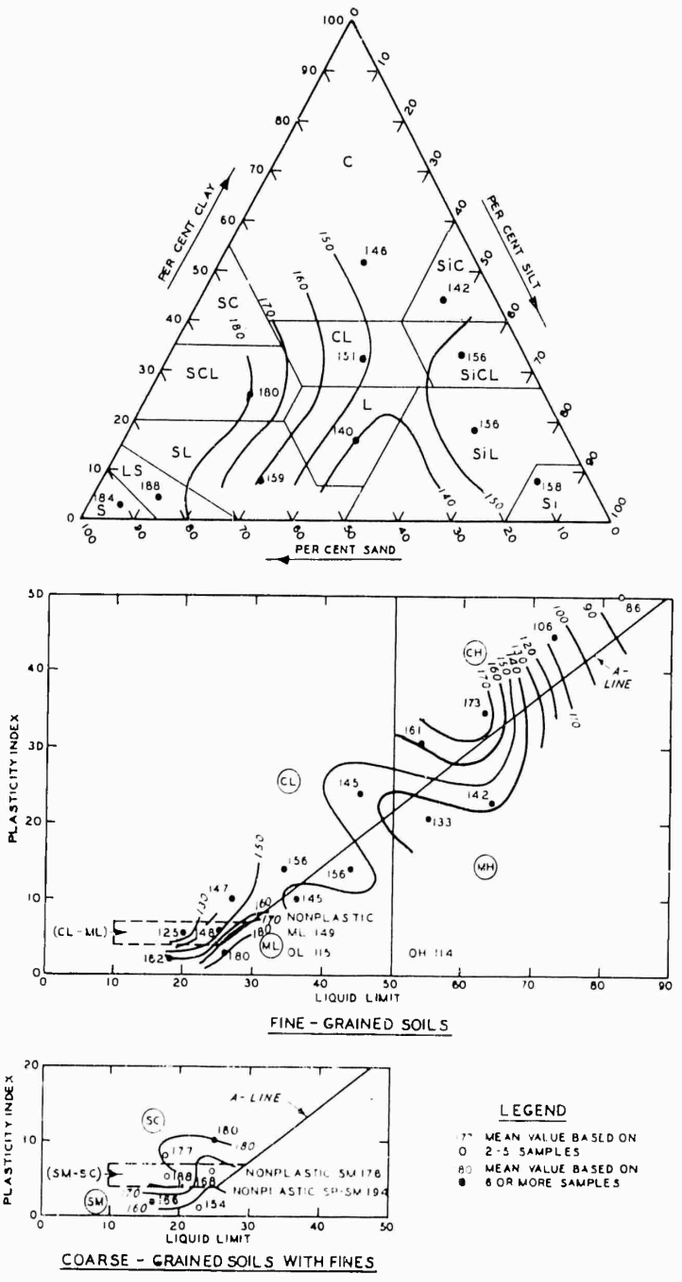

Fig. 4. Mean cone index for all sites under wet-season condition

53. On the textural triangle in fig. 4, the mean CI for a USDA soil type for all sites under wet-season condition has been plotted at the coordinate of the average sand, silt, and clay percentage derived from the data for the soil type, and lines of equal CI have been sketched. The isograms show low CI's at 40 to 50% silt with minimum values of less than 145 for soils that are predominantly mixtures of sand and silt or silt and clay. From these low values the CI increases slightly with an increase in silt content, and increases rapidly with an increase in the sand content to maximum values greater than 180. On the plasticity charts for fine-grained soils and coarse-grained soils with fines in fig. 4, the mean CI within an increment of 10 liquid limit values (10-19, 20-29, 30-39, etc.) for a USCS soil type has been plotted at the coordinate of the average liquid limit and plasticity index for the data, and lines of equal CI have been drawn. The coarse-grained soils with fines show relatively high CI's that increase with an increase in the plasticity

index of the fine-grained portion. The isograms for the fine-grained soils show: a decreasing CI with an increase in the plasticity index for soils with liquid limits less than 30; a general increase in CI with an increasing plasticity index for soils with liquid limits between 30 and 65; and a decrease in CI with an increasing liquid limit for soils with liquid limits greater than 65. The organic soils (OL, OH, Pt) have the lowest CI values (see tabulation in paragraph 52).

54. The CI of a soil at low topography is generally lower than that of the same soil at high topography (shown in table 2 and plate 2) because of higher moisture contents. An apparent reversal of this condition for USCS soil type SM-SC and USDA soil types S and CL (plate 2) can probably be attributed to a large variance of the low- or high-topography mean from the true mean due to an insufficient number of samples.

55. Remolding index. The results of the analysis of RI are given in table 3, and the summary of data is shown graphically in plate 3. The following tabulation lists the soil types in decreasing order of mean RI for all sites under wet-season condition.

USCS Type	Mean Remolding Index	USDA Type	Mean Remolding Index
SP-SM	1.61	S	1.61
SM	1.09	LS	1.24
CH	0.95	SC	1.07
SC	0.86	C	0.96
SM-SC	0.84	SiC	0.85
MH	0.73	SL	0.84
CL	0.71	SCL	0.83
ML	0.63	CL	0.81
OL	0.56	SiCL	0.79
Pt	0.56	L	0.66
OH	0.55	SiL	0.63
CL-ML	0.54	Pt	0.56
		Si	0.47

56. On the textural triangle in fig. 5 the mean RI for a USDA soil type for all sites under wet-season condition has been plotted at the coordinate of the average grain-size percentages for the soils of that type (same as in plots of cone index in fig. 4), and lines of equal RI have been sketched. RI is at a minimum when per cent silt is at a maximum and increases as per cent silt decreases, reaching values of nearly 1.00 in soils

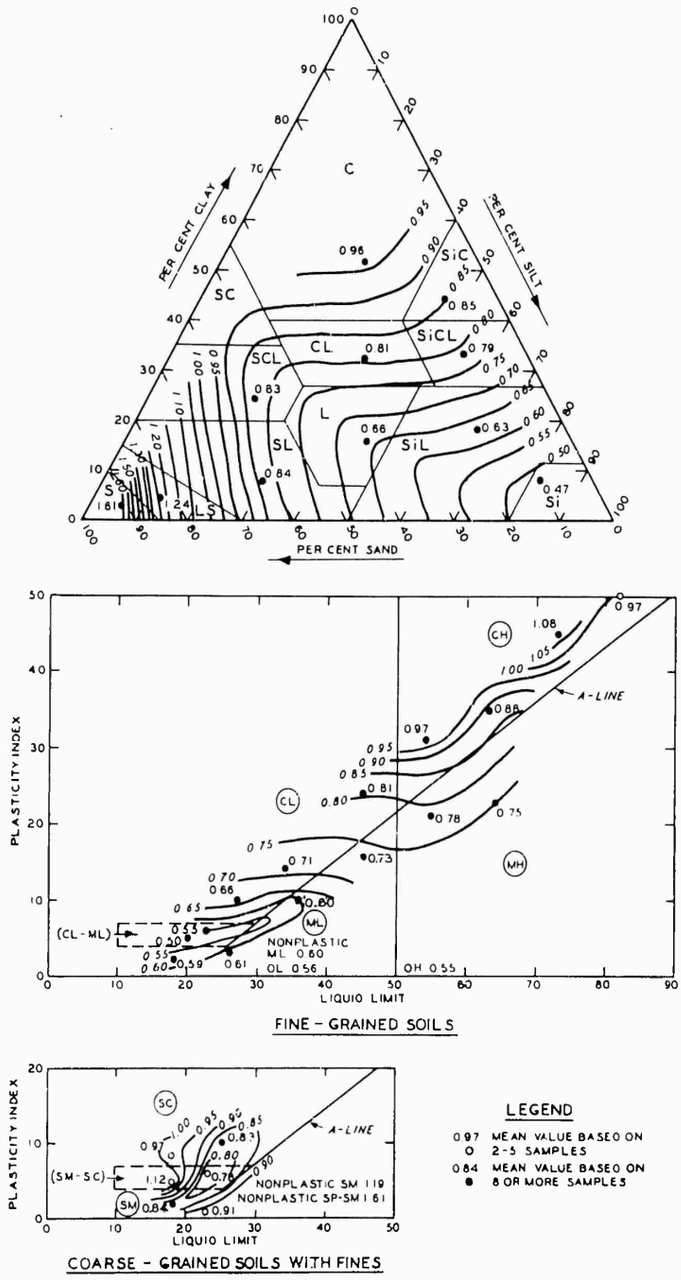

Fig. 5. Mean remolding index for all sites under wet-season condition

that are predominantly clay and well over 1.00 in soils that are predominantly sand. On the plasticity charts the mean RI for an increment of 10 liquid limit values of a soil type has been plotted at the same coordinate as for CI, and lines of equal RI have been sketched. The coarse-grained soils with fines show relatively high RI's with values of about 0.80 to 1.00 for the slightly plastic sands and appreciably over 1.00 for the nonplastic SP-SM and SM sands. The isograms for the fine-grained soils show a definite increase in RI with an increase in plasticity index above 5. Accordingly, highest RI's (close to 1.00) are indicated for the CH soils and lowest (0.50 to 0.55) for the CL-ML soils. The mean RI values for the organic soil types are similar to that for CL-ML.

57. The soil type data in table 3 and plate 3 generally show higher RI's for soils at high topography than for those at low topography. This may be attributed to lower moisture contents for soils at high topography.

58. Rating cone index. The results of the analysis of RCI are given

in table 4; the summary data are shown graphically in plate 4.

59. On the textural triangle in fig. 6 the mean RCI for a USDA soil type for all sites under wet-season condition has been plotted at the same coordinate as for CI and RI, and lines of equal RCI have been sketched. The pattern of the isograms is similar to that for RI. Minimum RCI's occur in silty soils. RCI increases with a decrease in silt content to relatively high values (greater than 120) in clayey soils and to maximum values of over 150 in sandy soils. On the plasticity charts for fine-grained soils and coarse-grained soils with fines, the mean RCI value for an increment of 10 liquid limit values of a soil type was plotted at the average liquid limit and plasticity index for the data (same coordinates as for CI and RI), and lines of equal RCI were drawn in. The pattern of the isograms, like that for RI, is of increasing strength with increasing plasticity index. Maximum RCI values for the fine-grained soils occur in the CH soils with liquid limits less than about 65, and

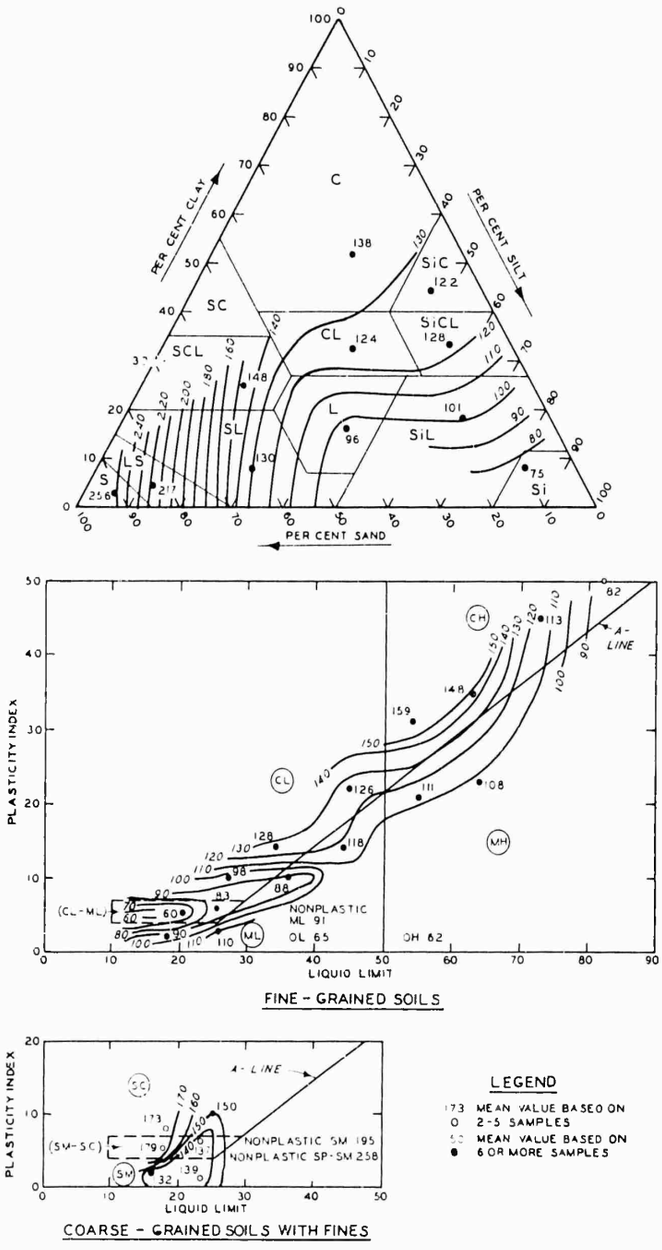

Fig. 6. Mean rating cone index for all sites under wet-season condition

minimum values in the organic soils and the CL-ML soils with liquid limits below 20. The plastic coarse-grained soils with fines (SM, SM-SC, SC) have relatively high strengths; the nonplastic SP-SM and SM soils have the highest RCI values.

60. The soil types of sites at low topography should and usually do have lower mean RCI's than sites at high topography (see table 4 or plate 4) because of normally higher moisture contents. Data that show the reverse of this condition are based on too few samples to be reliable and should be viewed with skepticism.

Analysis of moisture content

61. Results of the analysis of moisture content are given in table 5, and summary data are shown graphically in plate 5. The following tabulation lists the soil types in increasing order of mean moisture content for all sites under wet-season condition.

USCS Type	Mean Moisture Content in per cent Dry Wt	USDA Type	Mean Moisture Content in per cent Dry Wt
SP-SM	8.1	S	10.8
SM	17.0	LS	15.1
SM-SC	17.3	SCL	19.9
SC	17.5	SL	21.3
CL-ML	23.4	L	25.8
CL	25.9	CL	27.9
ML	29.0	SiL	28.7
OL	31.7	SiCL	28.8
CH	34.3	SiC	31.9
Pt	42.7	Si	32.0
MH	45.9	C	36.6
OH	65.7	SC	39.5
		Pt	42.7

62. On the textural triangle in fig. 7 the mean moisture content (to the closest unit) for a USDA soil type for all sites under wet-season condition has been plotted at the same coordinate as previously, and lines of equal moisture content have been sketched. A minimum moisture content occurs in sand. The moisture content increases at a moderate rate with an increase in silt content and at a faster rate with an increase in clay content. The nonsandy, predominantly clayey soils have the highest moisture contents. On the plasticity charts for fine-grained soils and coarse-grained soils with fines the mean moisture content for an increment of 10

liquid limit values of a soil type was plotted at the same coordinate as previously used for the strength variables, and lines of equal moisture content were sketched. The moisture contents are lowest for the coarse-grained soils with fines, with values increasing with an increase in liquid limit. A minimum mean moisture content of 8.1% may be noted for the nonplastic SP-SM sands. The values for the fine-grained soil types on the chart increase with an increasing liquid limit and a decreasing plasticity index (for a given liquid limit) from a minimum moisture content for the ML-CL soils to a maximum for the MH soils. The highest mean moisture content (65.7%) of the USCS soil types is indicated for OH soils. However, it should be pointed out that the mean moisture content for Pt soils (42.7%) is based on only one sample, and that these soils usually exhibit very high moisture contents and probably would be the type with highest mean moisture content if sufficient samples had been available for analysis.

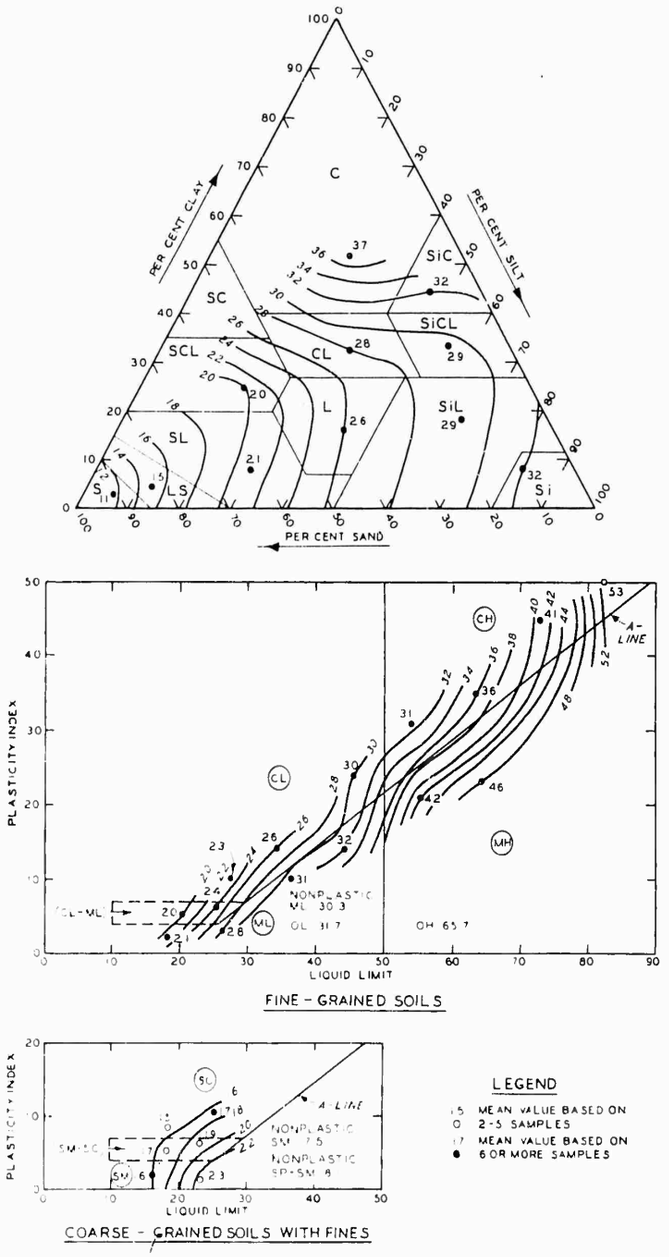

Fig. 7. Mean moisture content in per cent dry weight for all sites under wet-season condition

63. Soils of a specific type at low topography should and usually do exhibit higher moisture contents than those at high topography. Data for soils showing the reverse of this condition (table 5 and plate 5, USCS type SC and USDA sandy clay loam) were based on an insufficient number of samples, and thus may not be reliable.

Analysis of dry density

64. Density values are given in table 6 and shown graphically in plate 6. The following tabulation lists the soil types in decreasing order of mean dry density for all sites under wet-season condition.

USCS Type	Mean Dry Density in lb/cu ft	USDA Type	Mean Dry Density in lb/cu ft
SM-SC	101.1	SCL	102.2
SC	100.0	S	95.8
SP-SM	98.0	LS	93.9
SM	93.9	SL	92.9
CL-ML	93.7	CL	92.6
CL	91.3	SiCL	90.8
ML	85.7	L	90.3
CH	84.8	SiC	88.6
OL	82.3	SiL	86.9
MH	69.9	Si	85.6
OH	63.1	C	82.4
		SC	79.3

65. On the textural triangle in fig. 8 the mean dry density (to the closest unit) for a USDA soil type for all sites under wet-season condition has been plotted at the same textural coordinate as used for the strength variables, and lines of equal density have been sketched. The highest densities are indicated for the predominantly sandy soils, with maximum values of over 100 lb per cu ft shown for sands containing about 25% clay. The densities decrease moderately with an increase in silt and very rapidly with an increase in clay content above 25% to a minimum mean value of 82 lb per cu ft for the clay soil type. On the plasticity charts for fine-grained soils and coarse-grained soils with fines, the mean density value for an increment of 10 liquid limit values of a soil type was located at the same liquid limit and plasticity index coordinate as for the strength variables, and lines of equal density were sketched. The general pattern of the isograms is similar to that for moisture content, but the density

values decrease with an increasing liquid limit and a decreasing plasticity index (for a given liquid limit). Maximum densities are shown for the coarse-grained soils with fines, with peak values greater than 110 lb per cu ft indicated for SC soil types having liquid limits less than 20. Minimum mean values of less than 70 lb per cu ft occur in the MH and OH soil types. Densities of the Pt soils would undoubtedly have been the lowest, but were not measured.

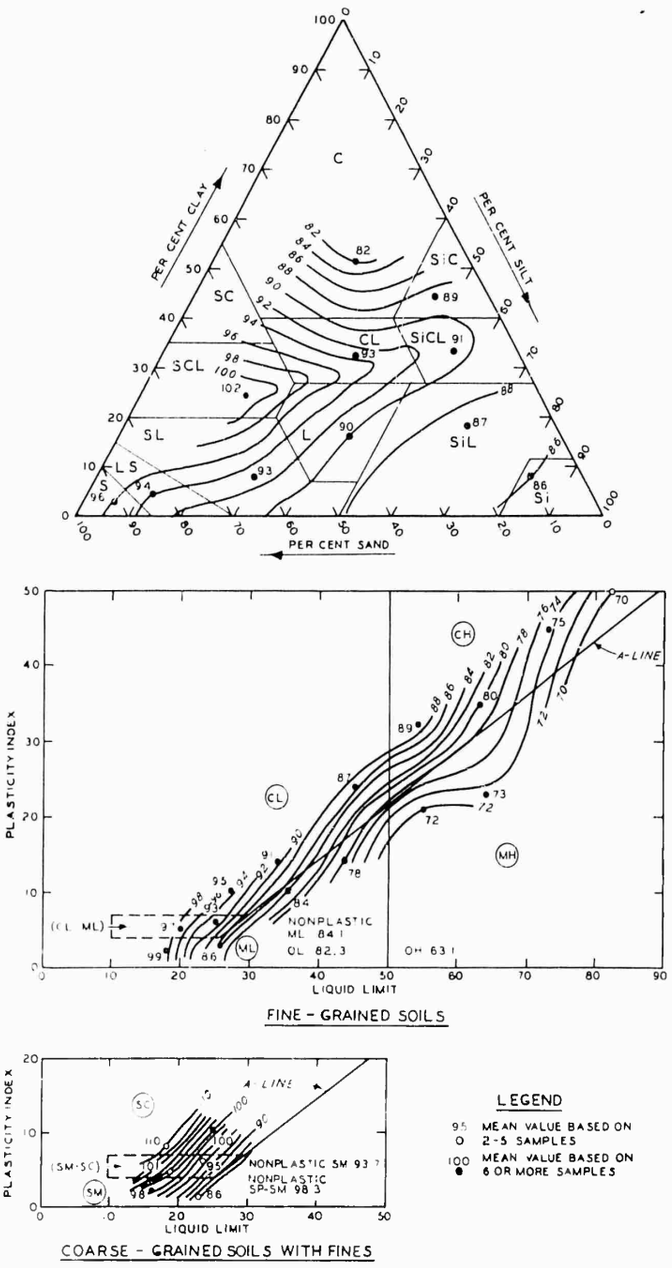

Fig. 8. Mean dry density in pounds per cubic foot for all sites under wet-season condition

66. It is interesting to note (table 6 or plate 6) that the mean density of a soil type at low topography is generally higher than that at high topography. The difference between the two values is generally greater for the nonclayey soils than for the clayey soils. The higher values may be attributed to settlement and compaction of soils due to fluctuating high water tables.

Statistical Study of Strength, Moisture Content, and Per Cent Saturation Under High-Moisture Condition

Procedures and presentation of data

67. The procedures for analysis, general source of the data (see tabulation in paragraph 46), and the statistical derivations required for this study were the same as those for the study of wet-season condition, but the data used in this analysis were measured only for low-topography sites under a condition of high moisture. As previously mentioned, high-topography sites under a condition of high moisture could not be identified from the data and therefore were not used. Mean and standard deviation values for cone index, remolding index, rating cone index, moisture content, and per cent saturation were computed for USCS and USDA soils of the 6- to 12-in. soil layer. The information is presented in table 7 in which the soils are listed in descending order of RCI as determined from the analysis. The data for CI, RI, RCI, and moisture content are also graphically shown as the fourth bar in the series of soil-type histograms in plates 2-5. The histograms permit visual comparison of the data for the various topography-moisture conditions. The data are also plotted and isograms drawn on a textural triangle and plasticity chart for CI, RI, RCI, moisture content, and per cent saturation in figs. 9-13, respectively. In these figures the mean value for the USDA soil type is plotted on the triangle at the coordinate of the average sand, silt, and clay percentage; the mean value for USCS fine-grained soils falling within an increment of 10 liquid limit values of a soil type is plotted on the plasticity chart at the coordinate of the average liquid limit and plasticity index for the data (the same procedure as followed in the wet-season condition study). There were appreciably less data to work with in this study than in the wet-season condition study. The number of samples (sites) for each USCS-USDA soil-type combination was generally less than 15 and in many cases less than five. Because values derived from a study based on such small numbers of samples are questionable, a statistical analysis of the various USCS-USDA soil-type combinations was not made.

Analysis of strength

68. Cone index. Soil strength data from 319 and 285 sites were used

in the analysis of the USCS and USDA soils, respectively. The following tabulation lists the soils in decreasing order of mean CI.

USCS Type	Mean CI	USDA Type	Mean CI
SM-SC	166	CL	140
SM	132	SCL	135
ML	126	LS	132
CH	118	SL	132
CL	118	SiL	122
MH	117	SiC	118
CL-ML	113	SiCL	117
OL	87	L	109
OH	87	C	102
Pt	83	Si	96
		Pt	83

The textural data in fig. 9 show low mean CI's for the very silty soils and very clayey (more than 50% clay) soils, and high mean CI's for the clay loam and predominantly sandy soils. The CI's on the plasticity chart generally decrease with an increasing plasticity index at a constant liquid limit. The preceding tabulation shows the organic soils to have the lowest mean CI values.

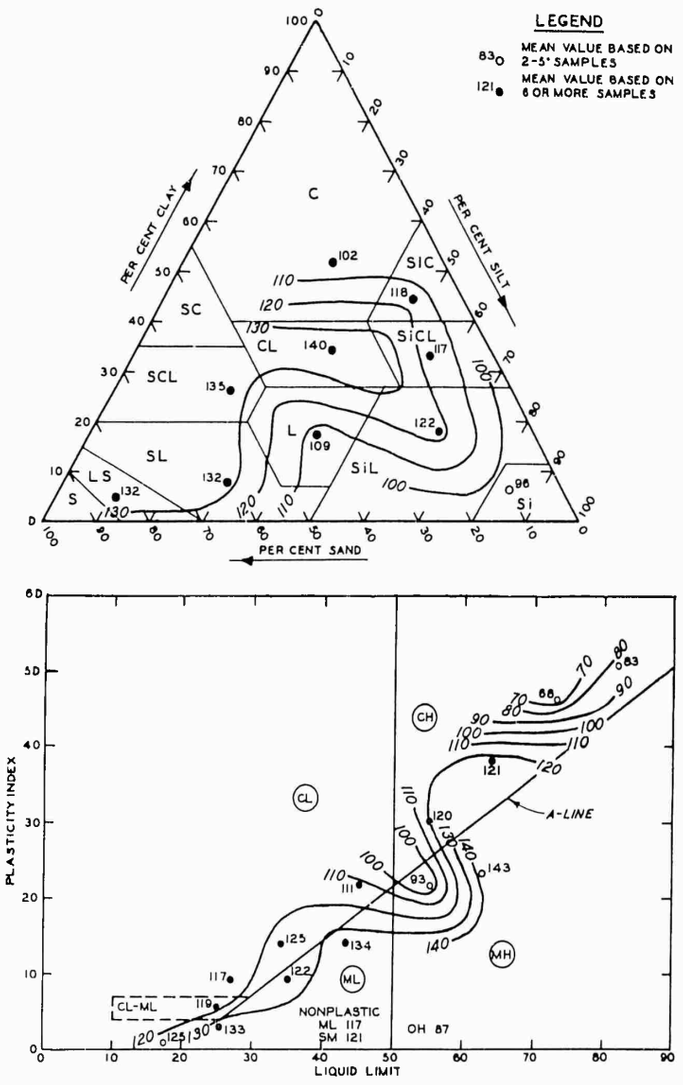

Fig. 9. Mean cone index for low topography under high-moisture condition

The data in plate 2 show that for soil types under high-moisture condition the CI decreases in approximately the same order as for soils under wet-season condition. The mean values of CI for soils at low-topography sites range from 15 to 40 points lower under high-moisture condition than under wet-season condition.

69. Remolding index. The following tabulation lists the soils in decreasing order of mean RI.

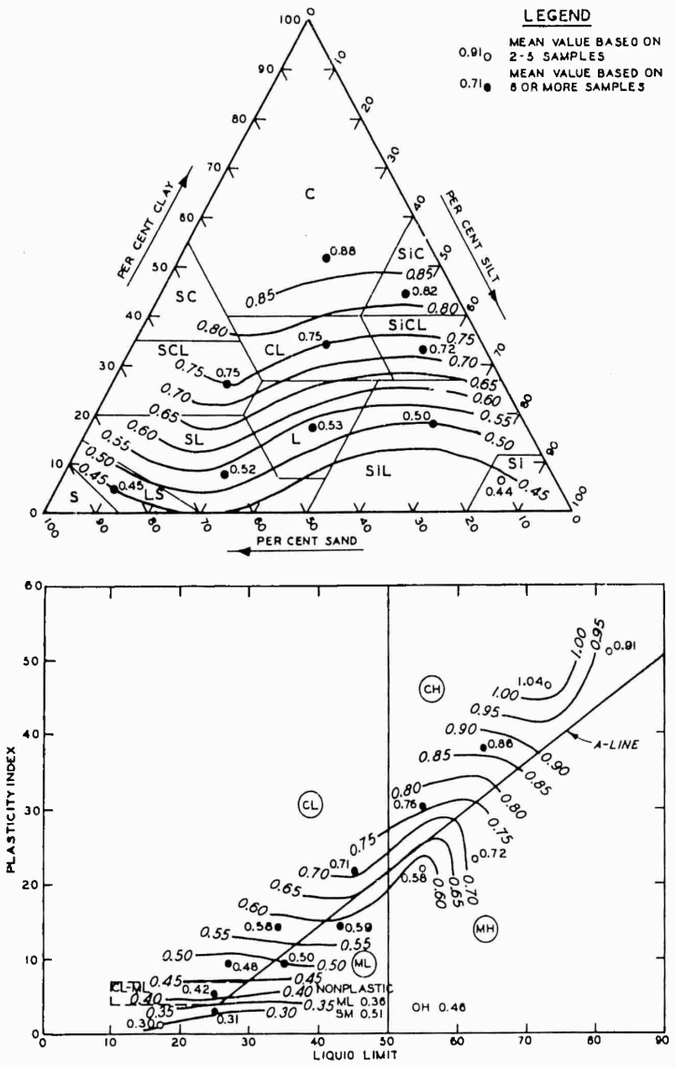

Fig. 10. Mean remolding index for low topography under high-moisture condition

USCS Type	Mean RI	USDA Type	Mean RI
CH	0.83	C	0.88
MH	0.69	SiC	0.82
CL	0.61	SCL	0.75
OL	0.56	CL	0.75
Pt	0.56	SiCL	0.72
SM-SC	0.54	Pt	0.56
SM	0.51	L	0.53
OH	0.46	SL	0.52
ML	0.43	SiL	0.50
CL-ML	0.40	LS	0.45
		Si	0.44

The isograms of mean RI in the textural triangle of fig. 10 show a constant increase in RI with an increase in percentage of clay from a minimum of 0.45 for soils with less than 10% clay to a maximum of 0.85 for soils with about 50% clay. The RI increases slightly at a given clay content with an increase in percentage of sand. The isograms on the plasticity chart show an increasing RI with an increasing plasticity index and liquid limit. At a given liquid limit the RI increases with an increase in the plasticity index. The mean RI's for the fine-grained soils of low topography under high-moisture condition, shown graphically in plate 3, range from 0.04 to 0.12 units less than those of corresponding soil and topography under wet-season condition; the means for the coarse-grained soils with fines, or sandy nonclayey soils, generally are more than 0.12 units below their wet-season means. The appreciable differences in the RI's of the coarser materials as compared to the smaller differences for the fine-grained soils can be attributed to a

larger difference in the moisture content of the coarser materials as compared to the finer materials for wet-season and high-moisture conditions, respectively.

70. Rating cone index. As mentioned previously, table 7 lists the soils in decreasing order of mean RCI. The peat and muck soil type (Pt) is listed at the bottom of the group because it probably would have had the lowest mean RCI if more samples had been available for analysis. The isograms on the textural triangle in fig. 11 show an increase in RCI with an increase in the percentage of clay from a minimum of less than 50 for silty soils with less than 10% clay to a maximum of over 100 for soils with about 40% clay. An increase in the percentage of clay above 40 results in a decrease in the RCI. The data also show a general increase in RCI at a constant clay content with an increase in the percentage of sand. The isograms on the plasticity chart show a general increase in the RCI with an increase in the plasticity index and liquid limit of the soil type. At a given liquid limit the RCI increases with an increase in plasticity index. A comparison of the mean RCI's under low topography, high-moisture condition with the means for the respective soil types under low topography,

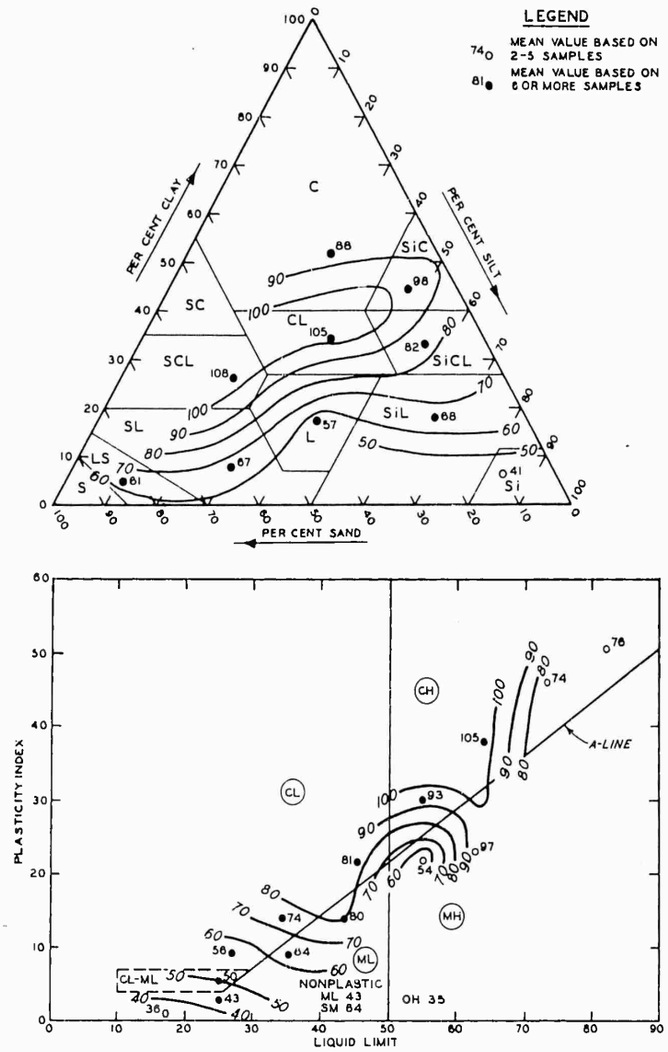

Fig. 11. Mean rating cone index for low topography under high-moisture condition

wet-season condition (plate 4) shows strengths that are between 15 and 58 RCI units lower under high-moisture condition. The differences in strength are between 15 and 40 for the fine-grained materials and between 40 and 58 for the USCS coarse-grained soils with fines and the USDA sandy nonclayey soils. The greater differences for the coarser materials agree with a similar set of strength differences for RI which, as explained in the preceding paragraph, is due to greater differences in moisture contents for the coarser materials than for the finer materials.

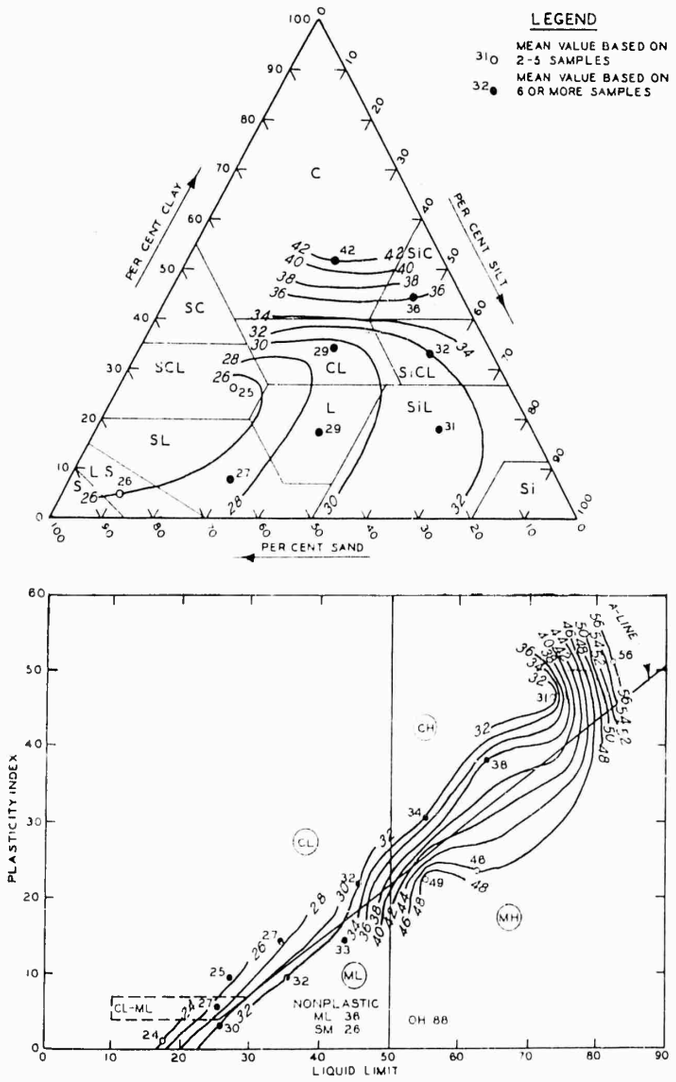

Fig. 12. Mean moisture content in per cent dry weight for low topography under high-moisture condition

Analysis of moisture content

71. The moisture-content data used in the analysis of the USCS and USDA soil types were derived from 297 and 263 sites, respectively. The soils are listed below in increasing order of mean moisture content.

USCS Type	Mean Mois Content in % Dry Wt	USDA Type	Mean Mois Content in % Dry Wt
SM-SC	23.0	SCL	24.7
CL-ML	25.7	LS	26.3
SM	26.5	SL	27.0
CL	28.5	L	28.6
ML	32.5	CL	29.2
CH	36.3	SiL	30.7
Pt	42.7	SiCL	31.6
OL	46.0	Si	34.8
MH	47.4	SiC	35.9
OH	94.5	C	42.0
		Pt	42.7

The isograms on the textural triangle in fig. 12 show lowest mean moisture contents of less than 28%

for the predominantly sandy soils. The moisture content increases slowly with a decrease in percentage of sand and rapidly with an increase in clay content above 35%. The isograms on the plasticity chart show an increase in moisture content with an increase in the liquid limit and a decrease in the plasticity index (for a given liquid limit). Lowest values are indicated for the coarse-grained soils and low-plasticity ML and CL-ML soils, and highest values are indicated for the MH and OH soils. A comparison of mean values for the soil types, plate 5, shows the moisture contents increasing in approximately the same order as for wet-season condition. The mean moisture contents of both USCS and USDA soil types under low topography, high-moisture condition range from about 4 to 6% for the coarser materials, and from about 1 to 3% for the finer materials, higher than the means for the respective soil types under low topography, wet-season condition. The greater differences for the coarser materials may be attributed to better drainage characteristics and faster rates of depletion for these soils as compared to the fine materials. It is interesting to note that even at high-moisture condition most of the MH soils and practically all of the CH soils, in situ, do not attain moisture contents greater than their liquid limit (greater than 50%); the OH soils generally have moisture contents much greater than their liquid limit.

Analysis of per cent saturation

72. The per cent saturation data used in the mean and standard deviation statistical analysis of the USCS types were obtained from 229 sites; the data from 198 of these sites were used in the analysis of the USDA soil types. Per cent saturation was not computed for the organic soils (OL, OH, and Pt) because an average specific gravity could not be assigned to these soils with any degree of confidence. Per cent saturations appreciably greater than 100%, or otherwise questionable, are indicated by an asterisk in the data tables in Appendix B and were not used in the analysis. Values of saturation slightly greater than 100% (generally between 100 and 110%) were included in the analysis even though such values are theoretically impossible. The slight excess over 100% is considered inconsequential for analysis purposes. Elimination of these data would have biased the mean values toward the low side. The tabulation on the following page lists the soils in decreasing order of mean per cent saturation.

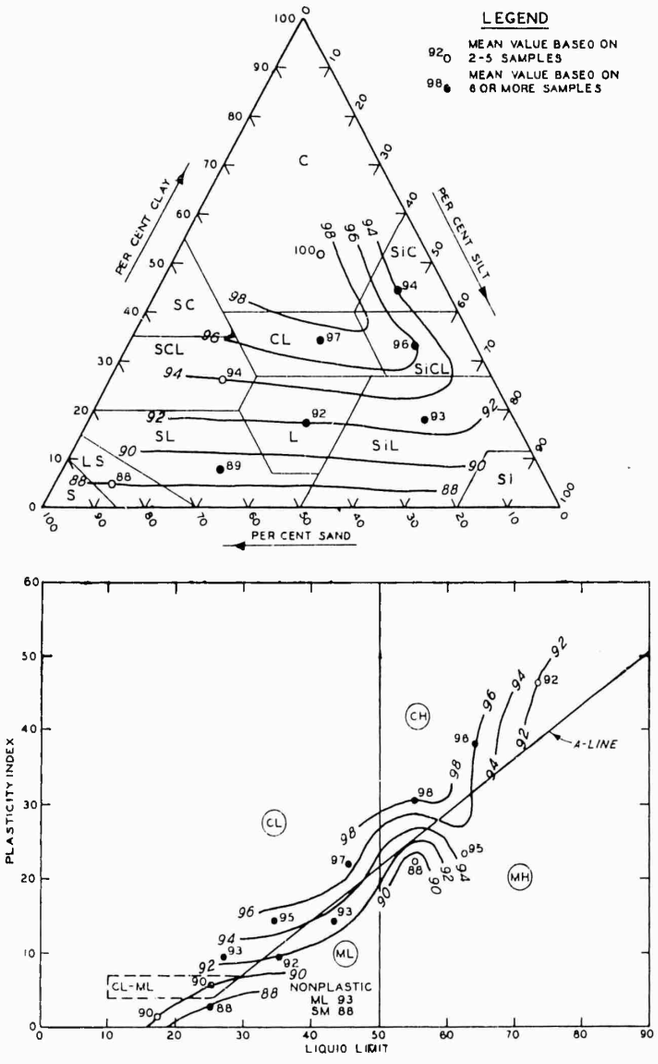

Fig. 13. Mean per cent saturation for low topography under high-moisture condition

USCS Type	Mean % Saturation	USDA Type	Mean % Saturation
CH	96.1	C	100.0
CL	93.4	CL	96.7
MH	92.0	SiCL	96.4
ML	91.6	Si	94.0
CL-ML	89.4	SCL	93.6
SM	87.1	SiC	93.5
SM-SC	77.0	SiL	92.8
		L	91.6
		SL	89.4
		LS	87.6

The isograms on the textural triangle in fig. 13 show a constant increase in per cent saturation with an increase in clay content from a minimum of 88% saturation at 5% clay to a maximum of 100% saturation at about 50% clay. The isograms on the plasticity chart show an increase in per cent saturation with an increase in plasticity index.

Cumulative Frequency Analysis of Rating Cone Index Under Wet-Season and High-Moisture Conditions

Procedures and presentation of data

73. The data used in this analysis are the same that were used in the mean and standard deviation analyses of RCI under wet-season and high-moisture conditions, respectively. The only difference between this and the previous analysis is in the statistical treatment of the data.

74. RCI's for each soil type-moisture condition were grouped into

increments of 10 RCI's from 1 to 300, i.e. 1 to 10, 11 to 20, 21 to 30, etc. The number of measurements for each increment was tallied and its per cent of the total number was computed. The percentages were added cumulatively starting with the one corresponding to the 291-to-300 increment and progressing in order of decreasing RCI. Thus the larger value of the highest RCI increment for which data were available always was 0% frequency, and the smaller value for the lowest RCI increment for which data were available was 100% frequency. The RCI at 50% frequency is the median value. This value, incidentally, generally was smaller than the mean RCI previously established for a soil type.

75. The data are plotted in cumulative frequency graphs in plates 7-10 for the USCS soil types and in plates 11-14 for the USDA soil types. Graphs for three moisture conditions are generally shown for each soil type: low topography, high-moisture condition, indicated by a solid line; and wet-season condition of low and high topography indicated by a dotted line, and a dashed line, respectively. Data were not available for sandy clay nor were data available for analysis of one or more of the wetness conditions in some of the other soil types. The number of samples (sites) used in each analysis is indicated on its graph.

76. It is noted that where an appreciable number of samples were available for analysis the three graphs drawn for each soil type seldom cross each other, and further that the general range of RCI increases from the high-moisture graph through that for low-topography wet-season to the high-topography wet-season graph. This is taken to be evidence of proper categorization of the basic field data into the three general moisture conditions.

Explanation of graphs

77. Each graph shows the manner in which RCI varied. For example, refer to the solid-line graph for CH soils in plate 7, and it can be seen that 10% of the CH soils under low topography, high-moisture condition had RCI's greater than 170, 20% had values greater than 125, and 30% had values greater than 110, etc.

Estimating probability of vehicle "go"

78. The graphs can be used for estimating the probability of "go"

for military vehicles. Soils with RCI greater than the VCI will permit 50 vehicles to pass in straight-line echelon or one vehicle to execute severe maneuvers. Thus, the cumulative frequency corresponding to the VCI indicates the probability of a vehicle's success in a given soil type under a given general moisture condition. For example, refer to the solid-line graph for ML soils in plate 9. If it is known that the soil type is ML and that the water-table conditions are such that the soil is under low topography, high-moisture condition (but specific data on strength cannot be obtained), it can be hypothesized that the M48 tank (VCI = 49) would have a 52% probability of "go."

Study of USDA Soil Types Classified in Terms of USCS Soil Types

79. This study was performed on soils of the 6- to 12-in. layer to determine the frequency of each USDA soil type occurring as a USCS soil type, and the predominant USCS soil type from the position of the soil on the USDA textural triangle (fig. 14). The information derived from the study may be used to estimate the most likely USCS soil type if the USDA type or the general textural composition of the soil is known.

Source and reliability of data

80. The soil-type information used in the analysis was based on data obtained from 1176 sites located in 44 states. The USCS type was identified from Atterberg limits and mechanical analysis (generally sieve analysis) data. The USDA type generally was identified from textural information derived from a hydrometer analysis. Grain-size distributions determined by the hydrometer method do not always yield exactly the same results as would have been obtained by the rather time-consuming pipette method, which is the official USDA method for determining soil textures. Some textural designations therefore probably are not the same as would have been obtained by the pipette method. The two methods frequently give differences in the order of 2 or 3% clay, which are enough to cause some soils to be classed as loams, for example, by one method and silt loams by another. The 0.005-mm grain size usually was the smallest measured in the hydrometer analysis. The distinction between silt and clay sizes is at 0.002 mm. The USDA class for most sites, therefore, was based on values of

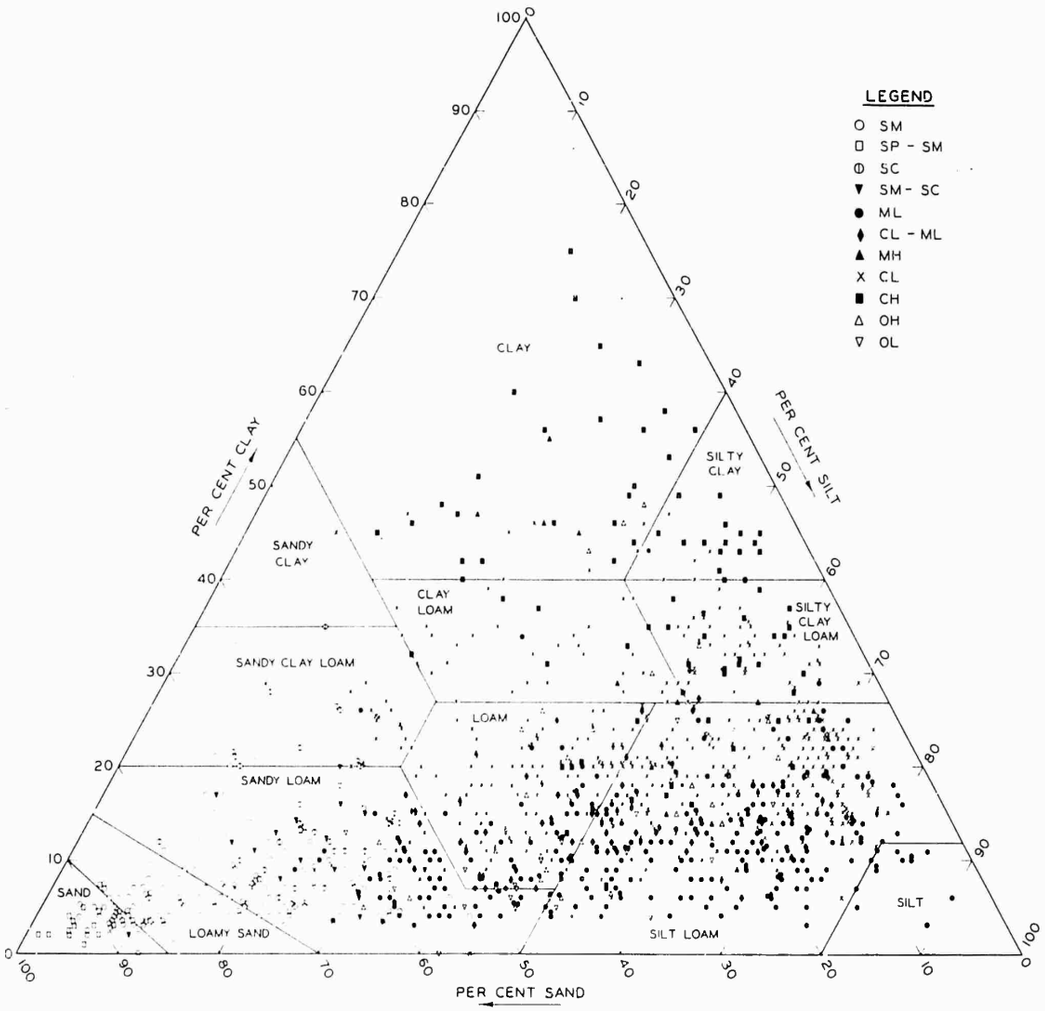

Fig. 14. Distribution of USCS soils on USDA textural triangle

per cent silt and clay extrapolated from an extension of the mechanical analysis curve to 0.002 mm. The USDA types at many of the 1951 field-trip sites, where hydrometer analyses were not run, were estimated with, it is believed, a fair degree of reliability from textural information of the profile contained in the soil series descriptions.

Results of the study

81. The results of the study are presented in table 8 and as points identified in USCS terms plotted on a USDA textural triangle, fig. 14. Fig. 15 shows USDA soil types in the textural triangle classified as predominant USCS soil types based on data shown in fig. 14.

82. Table 8. In table 8 the USCS soils are arranged from left to

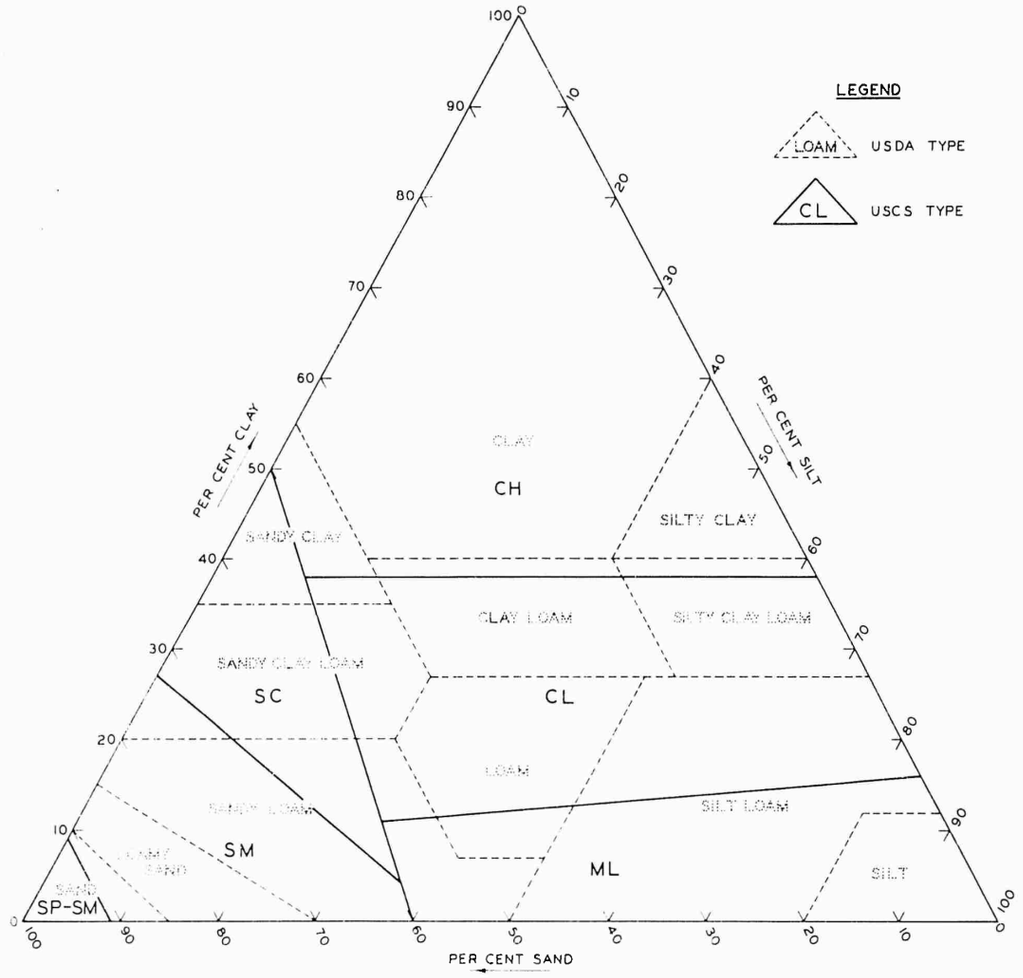

Fig. 15. Predominant USCS soil types in USDA textural triangle

right and the USDA soils from top to bottom in approximate order of decreasing grain size. The organic soils are grouped at the right and bottom positions of their respective soil classification systems. The sequence of numbers in the upper left corner of each box reads from left to right for a particular USDA soil type and represents the respective percentages of all samples of that type that classified as specific USCS soil types; e.g. of all USDA S (sand) soil samples 47% classified as SP-SM, 50% as SM, and 3% as SM-SC. The figure in the lower right corner of the box represents the number of samples of the particular USCS-USDA soil used in the analysis. The circled number represents the largest percentage of samples, and thus the predominant USCS type occurring for a given USDA type. A sample interpretation of the figures in the SiL-CL box is presented in the table.

83. Since the USCS and the USDA soil classification system both employ texture, a rough correlation between the two identifications of the same soils is to be expected. If the USDA system considered plasticity as well, the correlation might have been better than it was. In general terms, the USDA sandy soils classified as USCS coarse-grained soils with fines; and the USDA silty, clayey, and loamy soils classified as USCS fine-grained soils. More specifically, the sandy nonclayey USDA soils (S, LS, SL) usually classified as USCS coarse-grained soils with fines and were predominantly SM soils; the sandy and clayey USDA soils (SCL and SC) classified as either a coarse-grained soil with fines or fine-grained USCS soil and the USDA SCL soil was predominantly a USCS CL soil. The number of soils classified as sandy clay (two) was not sufficient to provide a reliable basis for estimating the probability of its occurrence as USCS soil types. The fine-textured, nongravelly USDA soils all classified as fine-grained USCS soils. The L (loam), SiL (silt loam), CL (clay loam), and SiCL (silty clay loam) soils were predominantly CL; the Si (silt) soils were predominantly ML; the SiC (silty clay) and C (clay) soils were predominantly CH; and Pt (peat and muck) soils classified as Pt in the USCS.

84. Textural triangle. Each point on the USDA textural triangle (fig. 14) is plotted according to the respective percentages of sand, silt, and clay in the soil sample, and the point is identified by its USCS name.

85. From an analysis of the distribution of USCS soil-type data on the textural triangle it was possible to subdivide the USDA soil types into component parts of predominant USCS types. Fig. 15 shows the distribution of predominant USCS types superimposed on the USDA textural divisions, based on the soil data in fig. 14. If the relative amount of clay or sand is known for a particular USDA soil type, the most likely USCS type can be estimated with a greater degree of confidence than if the texture is not known and the type is based upon estimates from table 8. For example, the table shows USDA silt loam soils (SiL) to be predominantly CL although only 45% of the SiL soils are so classified. The table also shows that SiL soils occur as ML 36% of the time. In the textural triangle in fig. 15 the silt loam configuration is subdivided by a line projected from 13% clay (at 50% silt) to 16% clay (at 0% sand) into sections of high-clay silt loam and low-clay silt loam. The high-clay portion has a predominance of over

50% CL soils whereas the low-clay portion has a predominance of over 50% ML soils. Further analysis of the triangle indicates the following. Loams with clay contents greater than 11 to 13% were predominantly CL soils and those with less than that percentage were primarily ML soils. Clay loams and silty clay loams were predominantly CL soils but usually were CH soils when the clay contents were greater than 38%. Depending upon the textural locations on the triangle, sandy loams were predominantly SM, SC, CL, or ML soils; sandy clay loams were predominantly SM, SC, or CL soils; and sandy clays were predominantly SC, CL, or CH soils. Silts were usually ML soils and loamy sands were almost always SM soils. Sands with less than 91% sand sizes classified as SM soils and sands with more than 91% sand sizes as SP-SM soils. Sands with more than 95% sand sizes probably would classify as SP or SW soils if data for these clean sands had been used in this study.

Study of USCS Soil Types Classified in Terms of USDA Soil Types

86. This study was performed to determine the frequency of each USCS soil type occurring as a USDA type.

Source and reliability of data

87. The soil data used in this analysis were the same as those employed in the study of USDA soil types classified in terms of USCS soil types; therefore, the source and reliability of data are the same (see paragraph 80).

Results of the study

88. The results of the study are presented in table 9. The mechanics of analysis, and the symbols and arrangement of soil types in the table are the same as those employed in the USDA-USCS comparison study.

89. The study indicated the following. All of the USCS coarse-grained soils with fines (GM, GC, SP-SM, SM, SM-SC, and SC), with the exception of GM and GC, classified as sandy USDA soils. The GM and GC soils classified as either a sandy or a fine-textured USDA soil when the USDA type was prefixed with the term gravelly, cobbly, or stony. The names of all USDA soil types classified as a GM or GC soil are not known and the per cent frequency values, noted in the table, are unreliable as

probabilities of occurrence due to the insufficient number of samples (two for GM and one for GC) used in the analysis. The SP-SM soils all classified as S (sand), the SM and SM-SC soils were predominantly SL (sandy loam), and the SC soils were predominantly LS (loamy sand). The fine-grained and organic USCS soils usually classified as fine-textured and occasionally as sandy-textured USDA soils. The ML, CL-ML, MH, CL, and OL soils were predominantly SiL (silt loam); the CH soils were predominantly C (clay); the OH soils were predominantly SiL (silt loam) or L (loam); and the Pt soils all classified as Pt (peat or muck) in the USDA system.

Study Comparing USDA Soil Types of the 0- to 6-in. and 6- to 12-in. Layers

90. The frequency of occurrence of USDA soil types in the 6- to 12-in. layer for given USDA soil types in the 0- to 6-in. layer of the soil profile was studied. The relations developed should be useful in estimating the type of soil in the 6- to 12-in. layer when USDA data for the surface soil only are available. It should be noted that the 0- to 6-in. and the 6- to 12-in. layers are depths relevant to trafficability and are not necessarily naturally occurring soil layers.

Source and reliability of data

91. The 0- to 6-in. and 6- to 12-in. USDA soil-type data used in this study were derived from 1140 sites located in approximately 44 states. The 6- to 12-in. layer data for these sites were employed in the USCS-USDA soil-type comparison studies discussed earlier; consequently, the procedures used in identifying the soil types for the 6- to 12-in. layer are the same as those discussed in paragraph 80. The textural types for about 80% of the 0- to 6-in. soil layer data were identified from values derived by means of a mechanical hydrometer analysis of the soil; the remaining 20% of the data were derived from textural-type names included in the soil series descriptions. The hydrometer analysis method of identification is, of course, the more valid method since it is based on measured values. The type name based on this textural data was used, therefore, where the soil type as identified by both methods differed.

Results of the study

92. Results of the study are shown in table 10. The soil types of the 6- to 12-in. and the 0- to 6-in. layers are arranged from left to right and from top to bottom, respectively, in order of decreasing strength as determined from the study of rating cone index values under low topography, high-moisture condition (discussed in paragraph 70). The numbers in the upper left corner of the boxes are percentages and read from left to right. Each value represents the percentage of all sites of a particular 0- to 6-in. soil type that is characterized by a specific soil in the 6- to 12-in. layer of the profile. The circled value for each 0- to 6-in. soil type designates the predominant soil of the 6- to 12-in. layer underlying the surface soil in the profile. The number in the lower right corner of the box represents the number of sites of a particular 0- to 6-in. and 6- to 12-in. soil-type combination used in the percentage analysis. The heavy-outlined boxes progressing from the upper left to the lower right in the table indicate that the soil of the 0- to 6-in. layer is the same as that of the 6- to 12-in. layer. For example, the 0- to 6-in. soil of six sites has been classified as SCL (sandy clay loam). At only one site (1/6 or 17% of all the sites) was the soil type in the 6- to 12-in. layer the same as that in the 0- to 6-in. layer, i.e. SCL throughout the profile. However, at three sites (3/6 or 50% of the SCL sites), the predominant number, the 6- to 12-in. soil layer was classified as C (clay). Thus, by reason of this analysis, if the surface soil is sandy clay loam the most likely underlying soil (with a probability of 50%) will be clay.

93. The analysis showed the soil types of the 6- to 12-in. layer to be the same as those of the 0- to 6-in. layer 71% of the time. In general, soils of the 6- to 12-in. layer are predominantly the same type as those of the 0- to 6-in. layer with the following exceptions. Clays are usually found below sandy clay loams and silty clays, and silt loams are more commonly found below silt. No data were available for the analysis of sandy clay.

PART V: SOIL TRAFFICABILITY CLASSIFICATION SCHEME AND RELATED STUDIES

94. The soil trafficability classification scheme presented in this part is essentially a listing of soil types in descending order of their median rating cone indexes under three of four general conditions of moisture: high and low topography under wet-season condition, and low topography under high-moisture condition. Information for high topography, high-moisture condition will be included in the scheme when sites under this condition are properly identified and the data from them have been analyzed. Soil types according to both the USCS and the USDA soil classification system are employed. Thus it can be considered an eightfold scheme for the classification of soils from a trafficability standpoint. The scheme considers the strength of soils in the 6- to 12-in. layer located in temperate climatic areas.

95. This part of the report summarizes the vehicle classification categories developed in an earlier study, and describes the soil trafficability classification scheme and its possible application in detail. Tables 11 and 12 supplement the classification scheme in that they provide specific data on the per cent probability of "go" for military vehicles on level and sloping terrain for each of the three general moisture conditions and the two soil classification systems.

Vehicle Categories

96. Different military vehicles require different minimum soil strengths for operation. A soil condition that is easily trafficable to one vehicle may be impassable to another. In order to make the soil trafficability classification meaningful, it was thus necessary to introduce the idea of vehicle requirements and incorporate it into a scheme for estimating the probability of vehicle "go."

97. In a previous study described in TM 3-240, 9th Supplement, Vehicle Classification, a system was developed for classifying vehicles on the basis of the minimum soil strength each required for 50

straight-line passes or one severe maneuver on level ground. This system is condensed and repeated here.

Vehicle Category	Vehicle Cone Index Range	Vehicles
1	20-29	The M29 weasel, M76 otter, and Canadian snowmobile are the only known standard vehicles in this category
2	30-49	Engineer and hi-speed tractors with comparatively wide tracks and low contact pressures
3	50-59	The tractors with average contact pressures, the tanks with comparatively low contact pressures, and some trailed vehicles with very low contact pressures
4	60-69	Most medium tanks, tractors with high contact pressures, and all-wheel-drive trucks and trailed vehicles with low contact pressures
5	70-79	Most all-wheel-drive trucks, a great number of trailed vehicles, and heavy tanks
6	80-99	A great number of all-wheel-drive and rear-wheel-drive trucks, and trailed vehicles intended primarily for highway use
7	100 or greater*	Rear-wheel-drive vehicles and others that generally are not expected to operate off roads, especially in wet soils

* Limited to maximum of 200 vehicle cone index in the trafficability classification table. Few vehicles within this category have VCI's greater than 200.

The vehicle cone indexes for individual vehicles within the categories are included in Appendix A of WES TM 3-240, 14th Supplement.

Soil Trafficability Classification Scheme, Level Terrain

98. The soil trafficability classification scheme for level terrain is presented in USCS terms in table 11 for high topography and low topography under wet-season condition and low topography under high-moisture condition. The scheme is presented in USDA terms in table 12 for the same set of moisture conditions, respectively. Information presented in the scheme for each soil type includes a general estimate of the probability of "go" on level terrain of vehicles of various categories, measurements of soil strength, and general effects of slipperiness and stickiness.

Classification of vehicle "go"

99. For the sake of simplicity of presentation the per cent probabilities of vehicle "go" have been arbitrarily classified as follows:

Excellent	greater than 90% probability of "go"
Good	76 to 90% probability of "go"
Fair	50 to 75% probability of "go"
Poor	less than 50% probability of "go"

The probability-of-"go" information is illustrated in tables 11 and 12 by a series of bar graphs, one for each soil type.

Procedure for deriving "go" information

100. The vehicle cone indexes corresponding to 50, 75, and 90% probability of "go," the limiting values of the vehicle "go" groupings, were derived from the cumulative frequency rating cone index graphs (plates 7-14). For example, from the ML soil-type graph for low topography, wet-season condition (plate 9) it can be seen that the RCI's at 50, 75, and 90% cumulative frequency are 77, 47, and 32, respectively. This means that the soil strength will be greater than 77 RCI 50 times out of 100, greater than 47 RCI 75 times out of 100, and greater than 32 RCI 90 times out of 100. This in turn indicates that vehicles with a VCI greater than 77 will have less than a 50% probability of "go" (black area of graph in table 11, classified as poor); those with a VCI ranging from 47 to 77 will have a 50 to 75% probability of "go" (diagonal-line area, classified as fair); those with a VCI ranging from 32 to 46 will have a 76 to 90% probability of "go" (stippled area, classified as good); and those with a VCI less than 32 will have greater than 90% probability of "go" (white area, classified as excellent).

Reliability of "go" information

101. The probability lines delineating the vehicle "go" groupings on the bar graphs in tables 11 and 12 are solid where the data were based on more than four samples and the information shown was considered to be reliable. The lines are broken where less than five samples were used in the analysis or the data were otherwise questionable. The positioning of these broken lines was based on an assumed rating cone index estimated from the textural, plasticity, and organic properties of the soil.

102. It should be particularly noted that the occurrence of obstacles

was not considered in the probability of "go" estimates for level or sloping terrain. Obstacle components of terrain, such as trees, hedges, boulders, and streams, that present a definite deterrent or obstruction to mobility of vehicles would certainly decrease the probability of "go."

Soil strength information

103. The range of cone index, remolding index, and rating cone index, and the mean rating cone index (discussed in Part IV) are presented again in tables 11 and 12. It may be noted that the mean RCI for a soil generally is slightly greater than its median RCI, which is the same value as the VCI at 50% probability of "go."

Soil slipperiness and stickiness information

104. The effects of slipperiness and stickiness were estimated qualitatively on the basis of experience, and noted in tables 11 and 12. Severe slipperiness will often cause the immobilization of wheeled vehicles that are not equipped with traction devices and, in combination with relatively low RCI (a few points above VCI), will often cause even chain-equipped wheeled vehicles to become immobilized. Slipperiness may adversely affect control of tracked vehicles, but will seldom be responsible for their immobilization. Soils designated as having moderate to severe stickiness will, when wet, cling to a vehicle's running gear; slight stickiness has never been found sufficiently detrimental to cause "freezing" of a vehicle's running gear and immobilization of the vehicle, except in one case where sticky soil trapped between the tracks and body of an M29C weasel caused it to become immobilized.

Probability of Vehicle "Go" on Level and Sloping Terrain

105. The per cent probabilities of vehicle "go" on level and sloping soils classified in terms of the USCS are presented in table 13 for high topography and low topography under wet-season condition, and low topography under high-moisture condition; these data on soils classified in terms of the USDA system are presented in table 14. The data for each soil type-moisture condition include the probabilities of negotiation of level terrain (0% slope) and slopes of 15, 30, and 45% by vehicles in each

of the seven vehicle categories. The probabilities were established for the median VCI within vehicle categories 1 through 6 (i.e. 25 VCI for category 1, 40 VCI for category 2, etc.) and for the minimum VCI (100) in category 7, for tracked vehicles with grousers shorter than 1-1/2 in. and wheeled vehicles, respectively. Tracked vehicles with grousers longer than 1-1/2 in. would have a slightly better probability of "go" on sloping soils than that computed for tracked vehicles with shorter grousers. For all practical purposes, however, the difference is insignificant and the probabilities of "go" listed under the "tracked" column in tables 13 and 14 may be applied to both types of tracked vehicles. The probability of "go" established for a vehicle with a median VCI of a category will closely approximate and may be used to estimate the probabilities of "go" for other vehicles within the respective category.

Procedure for deriving "go" information

106. The probability data were obtained from the cumulative frequency-rating cone index graphs presented in plates 7-14. If vehicle cone index is substituted for rating cone index and probability of "go" for cumulative frequency, an estimate of the probability of "go" on level terrain can be made for any vehicle for which a vehicle cone index has been computed (discussed in paragraph 78). In order to determine the probability of "go" for a given slope the slope index, derived from the curve of the vehicle type shown in plate 1, was added to the VCI and the probability of "go" for the soil type-moisture condition was based upon the cumulative frequency reading for this new VCI value. For example, the probabilities of "go" for tracked and wheeled vehicles of 55 VCI (median VCI of category 3), respectively, on 0, 15, 30, and 45% slopes of a silt loam soil area under low topography, high-moisture condition were derived as follows. The vehicle cone index was substituted for rating cone index in the abscissa and the probability of "go" was substituted for cumulative frequency in the ordinate of the silt loam low topography, high-moisture condition graph shown in plate 13. At 55 VCI the probability of "go," read from the graph, was 55%. This value applies to tracked and wheeled vehicles at 0% slope. The slope index at 15% slope, read from the curves of plate 1, was 7 for tracked vehicles with grousers shorter than 1-1/2 in. and 9 for

wheeled vehicles. This index was added to the VCI to provide values of 62 (55 plus 7) for the tracked vehicle and 64 (55 plus 9) for the wheeled vehicle, respectively. The probabilities of "go" for the VCI values of 62 and 64, read from the silt loam low topography, high-moisture condition graph in plate 13, were 47 and 44%, respectively. At 30% slope the slope indexes were 15 and 20, the VCI's became 70 and 75, and the resulting probabilities of "go" were 35 and 30% for the two vehicle types, respectively; at 45% slope the slope indexes were 27 and 40, the VCI's became 82 and 95, and the probabilities of "go" read from the graph were 23 and 14%, respectively. The probability of "go" can be estimated for any slope and for any vehicle for which a VCI has been computed by using data read from the proper soil type-moisture condition graph and slope index curve, and following the procedures discussed above.

Reliability of "go" information

107. The probability values for wet-season condition are undoubtedly influenced by the high-moisture low-strength bias associated with the basic data (previously discussed in paragraph 39a); thus, the actual probability of "go" would be somewhat higher than that indicated.

108. The number of samples used in the analysis of a particular soil type-moisture condition provides a rough estimate of its reliability. Those based on more than 30 samples would generally have a small plus and minus probability error, i.e. the true probability based on an infinite number of the same type of samples would not vary by more than plus or minus a small standard error of estimate. The probabilities of "go," therefore, are considered to be of good reliability. An analysis based on less than 30 samples and especially less than 15 samples, but more than 4 samples, would have a moderate standard error of estimate (estimated at ±10 to ±25% probability of "go"). Probabilities based on an analysis of this number of samples are considered to be of fair reliability and should be viewed with skepticism. Five was arbitrarily chosen as the minimum number of samples needed to provide a reasonably reliable probability value; probabilities of "go" were only estimated for the analyses based on fewer than 5 samples. The estimations were based on assumed strengths estimated from the textural, plasticity, and organic properties of the soil.

Application of Information for Estimating Trafficability Conditions

109. The information presented in the trafficability classification scheme and probability of "go" tables should be especially useful in military intelligence, military-operations planning, and vehicle-design work. The information may be applied in quantitative or qualitative terms to military problems or studies of a tactical or strategic nature.

110. Presumably the information will be used to estimate trafficability conditions for areas that, in most cases, will not be accessible for measurements. It may be reasoned that the information would not be needed for accessible areas because direct strength measurements with the cone penetrometer could be taken where and when desired. The information, however, could be used in these areas to facilitate a particular study, e.g. the speedy selection of one of several possible access routes; the selection of possible barrier areas (mine fields, etc., that normally would have good to excellent probabilities of "go"); or the selection of broad areas providing the best positions for offensive or defensive operations.

Use of trafficability classification scheme

111. The following paragraphs explain how the classification scheme can be used by means of examples.

112. Season, soil type, and topography. If the season, say wet season, the soil type, say CL, and the topography, say low topography, of an area are known, the data in table 11 for low topography, wet-season condition would be used. In this case, the probability of "go" on the CL soil would be less than 50% for vehicles with VCI's greater than 85, between 50 and 75% for vehicles with VCI's between 60 and 85, between 76 and 90% for vehicles with VCI's between 41 and 59, and greater than 90% for vehicles with VCI's less than 41.

113. Season, soil type, topography, and rainy weather or high-water-table condition. If in addition to the knowledge of the season, soil type, and topography it is known that the soil has been subjected to several days of rain, or a high water table is known to exist, the low topography, high-moisture condition data presented in table 11 (or table 12 for USDA soils)

would be used. The probability of vehicle "go" on CL soils under these conditions would be less than 50% for vehicles with VCI's greater than 67, between 50 and 75% for vehicles with VCI's between 43 and 67, between 76 and 90% for vehicles with VCI's between 31 and 42, and greater than 90% for vehicles with VCI's less than 31.

114. Probability of one or two straight-line passes for a vehicle. A rating cone index equal to 75% of the vehicle cone index usually will permit one or two straight-line passes of the vehicle. The probability of a successful operation may be derived from the classification scheme (tables 11 and 12) by projecting a line down from the VCI value multiplied by 0.75 and reading the probability at its intersection with the particular graph of soil type-wetness condition under consideration. For example, a vehicle with a VCI of 100 would have a recomputed index of 75 (100 × 0.75). The probability of its making one or two straight-line passes on a CL soil under low topography, wet-season condition (from table 11) would be 50 to 75% (estimated at 60%).

Use of probability of "go" tables

115. The following paragraphs explain how the probability tables (tables 13 and 14) may be used. The particular data to be used, like that for the soil trafficability classification scheme, will depend upon the amount and type of information known, i.e. the topography, moisture condition, and the soil type and system in which the soil is classified.

116. Probability of "go" for vehicles within specific VCI categories. The probability of "go" on sloping ground may be estimated for tracked or wheeled vehicles within VCI categories. If, for example, low topography, high-moisture condition prevails and the soil is a CL with a 15% slope, the probability of "go" for tracked vehicles in category 3 (VCI 50 to 59) would be 57% (from table 13).

117. Comparison of probabilities between two vehicle categories. The probabilities of "go" may be compared for vehicles within two different categories to estimate the advantage that vehicles in one category would have over vehicles in another. For example, under the same set of conditions as those stated in the preceding paragraph, tracked vehicles in category 5 (VCI 70 to 79) would have a 35% probability of "go" (table 13). Since the table shows the probability of "go" for vehicles in category 3 to

be 57%, the difference, 57 minus 35 or 22%, indicates the advantage in performance of vehicles in category 3.

118. Comparison of probabilities for different soil types and slopes. The probabilities of "go" for vehicles within a given category may be compared for two or more different soil types and slopes in order to determine quantitatively the advantage that one route would have over another. For example, if tracked vehicles in category 3 were being considered for use in a low-topography area under high-moisture condition (table 13), the probability of "go" along route A, an ML soil with maximum slopes of 30%, would be 35%; the probability of "go" along route B, a CH soil with maximum slopes of 15%, would be 80%. Thus, route B would have a decided advantage of 45% (80 - 35) over route A from the standpoint of soil type and slope.

PART VI: CONCLUSIONS AND RECOMMENDATIONS

Conclusions

119. On the basis of the assumption of the significance of the effects of space factors (high and low topography) and time factors (wet-season and high-moisture conditions) on the trafficability of soils, and the subsequent logical-appearing variation in mean values and ranges of pertinent parameters of soil trafficability, it is concluded that the trafficability scheme devised herein fully exploits available knowledge and data and is, therefore, a feasible scheme. The scheme has the following advantages.

a. It rates soil types (both USCS and USDA) according to their median rating cone index under high and low topography, wet-season condition, and under low topography, high-moisture condition. (Data for high topography, high-moisture condition will be added at a later date.)

b. From a consideration of cumulative frequency of occurrence of rating cone index, it permits a ready estimate of the chances of successful travel of any military vehicle (whose vehicle cone index is known) on any soil type, under three of the four general space-time moisture conditions.

120. The scheme has the following limitations.

a. It considers only soils in humid, temperate climates.

b. It does not take into account thawing or recently thawed soils.

c. It ignores the specific effects of certain environmental factors known to be significant to trafficability.

121. The conclusions that follow are based on the soil information derived from the various analyses of the basic data. For the convenience of the reader, the principal paragraphs, tables, plates, or figures supporting the conclusion are given.

a. Soil strength:

(1) A soil of a particular environment generally will have a lower strength in a low-lying position (low topography) than the same soil type in a high-lying position (high topography). (Refer to paragraphs 54, 57, and 60 and plates 2, 3, and 4.)

(2) Under a given space-time moisture condition, the initial strength (cone index) is highest for the coarse-grained soils (USCS coarse-grained soils with fines and USDA sandy soils), moderate for the fine-grained soils, and lowest for the organic soils. (Refer to paragraphs 52 and 68 and plate 2.)

(3) The silty USCS coarse-grained soils with fines (SP-SM, SM) and USDA very sandy soils (S, LS) of high topography will generally show an increase in strength after repetitive traffic (indicated by a remolding index greater than one) during times of wet-season condition. These same soils, especially the SM and loamy sand types, in low topography will lose about 50% of their initial strength under repetitive traffic during times of wet-season and high-moisture conditions. (Refer to plate 3.)

(4) The remolding index of a soil decreases with a decrease in the plasticity or clay content and a decrease in the sand content of the soil type. The organic soils have the lowest remolding indexes. (Refer to paragraph 56 and fig. 5, and to paragraph 69 and fig. 10.) The slightly plastic to nonplastic silty soils and organic soils under low topography, high-moisture condition retain about 40 to 55% of their original strength, and the highly plastic soils retain about 70 to 90% of their original strength after remolding. (Refer to paragraph 69.)

(5) The strength of a remolded soil (rating cone index) under wet-season condition is highest for coarse-grained soil, moderate for plastic soil, low for predominantly silty fine-grained soil, and lowest for organic soil (refer to paragraph 59, fig. 6, and plate 4); the strength sequence of these soil types is the same under high-moisture condition except that silty coarse-grained soils are characterized by relatively low strengths slightly greater than those of silty fine-grained soils (refer to plate 4).

(6) The mean rating cone indexes for the soil types in low-topography areas range from about 15 to 58 units lower under high-moisture condition than the respective strengths under wet-season condition. The differences in strength between the two conditions range from 15 to 40 for the fine-grained materials and from 40 to 58 for the coarser soils. (Refer to paragraph 70 and plate 4.)

b. Soil-moisture content:

(1) The moisture content of a soil is influenced by its texture, plasticity, and organic content; the organic

and highly plastic or clayey soils have the highest mean moisture contents, and the coarse-grained non-plastic soils the lowest. (Refer to paragraph 62 and fig. [illegible] and to paragraph 71 and fig. 12.)

(2) The mean moisture contents of soils of low topography range from about 4 to 6% for the coarser materials, and from about 1 to 3% for the finer materials, higher under high-moisture condition than the mean soil-moisture contents for the respective soil types under wet-season condition. (Refer to paragraph 71 and plate 5.)

(3) Soils seldom attain 100% saturation. The mean per cent saturations under low topography, high-moisture condition range from about 87 to 90% for coarse-grained silty soils, 90 to 93% for fine-grained silty soils, and 93 to 97% for moderately to highly plastic soils. (Refer to paragraph 72.)

c. Density:

(1) The dry densities of soils appear to decrease with an increasing silt content and an increasing clay content above 25%, and with an increasing liquid limit and decreasing plasticity index (for a given liquid limit) of the soil type. Organic soils have the lowest densities. (Refer to paragraph 65 and fig. 8.)

(2) Soils of low-lying (low topography) positions usually have higher densities than those of the same soil type situated on high-lying (high topography) positions. (Refer to paragraph 66 and plate 6.)

d. Soil-type identification:

(1) The USCS coarse-grained soils with fines generally classify as USDA sandy soils, and the USCS fine-grained soils are comparable to the USDA silty, clayey, and loamy soils (refer to paragraph 83). The USDA clay loams, silty clay loams, and high-clay-content loams and silt loams are predominantly CL when classified in USCS terms; the silts and low-clay-content loams and silt loams are predominantly ML; and the silty clays and clays are primarily CH. (Refer to paragraph 85 and fig. 15.)

(2) Soils (USDA) of the 6- to 12-in. layer are the same as those in the 0- to 6-in. layer of the profile 71 times out of 100. (Refer to paragraph 93 and table 10.)

Recommendations

122. The recommendations that follow are made on the basis of

consideration of the general reliability of the test data and analysis information, the limitations of the scope of the analysis, and the conclusions drawn from the study.

a. Soil data on GM, GC, SP-SM, and SC soils at moisture conditions (wet-season and/or high-moisture) for which no rating cone index information is available should be collected in a planned test program for use in improving and refining the trafficability classification scheme and providing additional significant information on the probability of "go."

b. Additional soil field data, especially rating cone index information, should be collected on soil type-moisture conditions with less than 30 test observations for use in checking the validity and improving the reliability of probability of "go" information. These data should include data for CH soils of high topography, and data for SC, SM-SC, MH, OL, OH, and Pt soils of low and high topography under wet-season condition, and under high-moisture condition, respectively.

c. An analysis of rating cone index and probability of vehicle "go" should be made for the high-moisture condition of USCS and USDA soils of high topography. This study will require a preliminary analysis to establish criteria for reliably determining conditions of high moisture. Additional samples will probably be required to supplement usable data already collected.

d. Studies of the type reported herein should be made on soils located in humid, tropical climates, in arctic climates, and in areas of freeze-thaw.

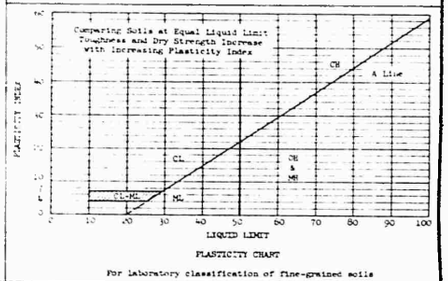
UNIFIED SOIL CLASSIFICATION
(Including Identification and Description)

Major Divisions			Group Symbols	Typical Names	Field Identification Procedures (Excluding particles larger than 3 in. and basing fractions on estimated weights)	Information Required for Describing Soils	Laboratory Classification Criteria
Coarse-grained soils: More than half of material is larger than No. 200 sieve size.	Gravels: More than half of coarse fraction is larger than No. 4 sieve size.	Clean gravels (Little or no fines)	GW	Well-graded gravels, gravel-sand mixtures, little or no fines.	Wide range in grain size and substantial amounts of all intermediate particle sizes.	For undisturbed soils add information on stratification, degree of compactness, cementation, moisture conditions, and drainage characteristics.	$C_u = \frac{D_{60}}{D_{10}}$ Greater than 4 $C_c = \frac{(D_{30})^2}{D_{10} \times D_{60}}$ Between 1 and 3 Not meeting all gradation requirements for GW
			GP	Poorly-graded gravels, gravel-sand mixtures, little or no fines.	Predominantly one size or a range of sizes with some intermediate sizes missing.		
		Gravels with fines (Appreciable amount of fines)	GM	Silty gravels, gravel-sand-silt mixtures.	Non-plastic fines or fines with low plasticity (ML below).	Give typical name; indicate approximate percentages of sand and gravel, maximum size, angularity, surface condition, and hardness of the coarse grains; local or geologic name and other pertinent descriptive information; and symbol in parentheses.	Atterberg limits below "A" line or PI less than 4 / Above "A" line with PI between 4 and 7 are borderline cases requiring use of dual symbols.
			GC	Clayey gravels, gravel-sand-clay mixtures.	Plastic fines (for identification procedures see CL below).		Atterberg limits above "A" line with PI greater than 7
	Sands: More than half of coarse fraction is smaller than No. 4 sieve size.	Clean sands (Little or no fines)	SW	Well-graded sands, gravelly sands, little or no fines.	Wide range in grain sizes and substantial amounts of all intermediate particle sizes.	Example: Silty sand, gravelly; about 20% hard, angular gravel particles 1/2 in. maximum size; rounded and subangular sand grains, coarse to fine, about 15% non-plastic fines with low dry strength; well compacted and moist in place; alluvial sand; (SM).	$C_u = \frac{D_{60}}{D_{10}}$ Greater than 6 $C_c = \frac{(D_{30})^2}{D_{10} \times D_{60}}$ Between 1 and 3 Not meeting all gradation requirements for SW
			SP	Poorly-graded sands, gravelly sands, little or no fines.	Predominantly one size or a range of sizes with some intermediate sizes missing.		
		Sands with fines (Appreciable amount of fines)	SM	Silty sands, sand-silt mixtures.	Non-plastic fines or fines with low plasticity (ML below).		Atterberg limits below "A" line or PI less than 4 / Above "A" line with PI between 4 and 7 are borderline cases requiring use of dual symbols.
			SC	Clayey sands, sand-clay mixtures.	Plastic fines (for identification procedures see CL below).		Atterberg limits above "A" line with PI greater than 7
Fine-grained soils: More than half of material is smaller than No. 200 sieve size.	Silts and Clays: Liquid limit less than 50		ML	Inorganic silts and very fine sands, rock flour, silty or clayey fine sands or clayey silts with slight plasticity.	Medium to slow / None to low / Slight to medium	For undisturbed soils add information on structure, stratification, consistency in undisturbed and remolded states, moisture and drainage conditions.	Determine percentages of gravel and sand from grain size curve. Depending on percentage of fines (fraction smaller than No. 200 sieve size) coarse-grained soils are classified as follows: Less than 5% = GW, GP, SW, SP. More than 12% = GM, GC, SM, SC. 5% to 12% = Borderline cases requiring use of dual symbols.
			CL	Inorganic clays of low to medium plasticity, gravelly clays, sandy clays, silty clays, lean clays.	Medium to high / None to very slow / Slight to medium	Give typical name; indicate degree and character of plasticity, amount and maximum size of coarse grains; color in wet condition, odor, if any, local or geologic name, and other pertinent descriptive information, and symbol in parentheses.	
			OL	Organic silts and organic silty clays of low plasticity.	Slight to medium / Slow to none / Slight		
	Silts and Clays: Liquid limit greater than 50		MH	Inorganic silts, micaceous or diatomaceous fine sandy or silty soils, elastic silts.	Slight to medium / Slow to none / Slight to medium		
			CH	Inorganic clays of high plasticity, fat clays.	High to very high / None / High		
			OH	Organic clays of medium to high plasticity, organic silts.	Medium to high / None to very slow / Slight to medium	Example: Clayey silt, brown, slightly plastic, small percentage of fine sand, numerous vertical root holes; firm and dry in place, loess, (ML).	
Highly Organic Soils			Pt	Peat and other highly organic soils.	Readily identified by color, odor, spongy feel and frequently by fibrous texture.		



PLASTICITY CHART

For laboratory classification of fine-grained soils

(1) Boundary classifications: Soils possessing characteristics of two groups are designated by combinations of group symbols. For example GW-GC, well-graded gravel-sand mixture with clay binder. (2) All sieve sizes on this chart are U. S. standard.

FIELD IDENTIFICATION PROCEDURES FOR FINE-GRAINED SOILS OR FRACTIONS

These procedures are to be performed on the minus No. 40 sieve size particles, approximately 1/64 in. For field classification purposes, screening is not intended, simply remove by hand the coarse particles that interfere with the tests.

Dilatancy (Reaction to shaking)

After removing particles larger than the No. 40 sieve size, prepare a pat of moist soil with a volume of about one cubic inch. Add enough water if necessary to make the soil soft but not sticky.

Place the pat in the open palm of one hand and shake horizontally, striking the hand vigorously against the other several times. A positive reaction consists of the appearance of water on the surface of the pat which changes to a livery consistency and becomes glossy. When the sample is squeezed between the fingers, the water and gloss disappear from the surface, the pat stiffens, and finally it cracks or crumbles. The rapidity of appearance of water during shaking and of its disappearance during squeezing assist in identifying the character of the fines in a soil.

Very fine clean sands give the quickest and most distinct reaction, whereas a plastic clay has no reaction. Inorganic silts, such as a typical rock flour, show a moderately quick reaction.

Dry Strength (crushing characteristics)

After removing particles larger than the No. 40 sieve size, mold a pat of soil to the consistency of putty, adding water if necessary. Allow the pat to dry completely by oven, sun, or air-drying, and then test for strength by breaking and crumbling between the fingers. This strength is a measure of the character and quantity of the colloidal fraction contained in the soil. The dry strength increases with the plasticity.

High dry strength is characteristic for clays of the CH group. A typical inorganic silt possesses only very slight dry strength. Silty fine sands and silts have about the same slight dry strength, but can be distinguished by the feel when powdering the dried specimen. Fine sand feels gritty whereas a typical silt has the smooth feel of flour.

Toughness. (Consistency near plastic limit)

After particles larger than the No. 40 sieve size are removed, a specimen of soil about one-half inch cube in size, is molded to the consistency of putty. If too dry, water must be added and if sticky, the specimen should be spread out in a thin layer and allowed to lose some moisture by evaporation. Then the specimen is rolled out by hand on a smooth surface or between the palms into a thread about one-eighth inch in diameter. The thread is then folded and rerolled repeatedly. During this manipulation the moisture content is gradually reduced and the specimen stiffens, finally loses its plasticity, and crumbles when the plastic limit is reached.

After the thread crumbles, the pieces should be lumped together and a slight kneading action continued until the lump crumbles.

The tougher the thread near the plastic limit and the stiffer the lump when it finally crumbles, the more potent is the colloidal clay fraction in the soil. Weakness of the thread at the plastic limit and quick loss of coherence of the lump below the plastic limit indicate either inorganic clay of low plasticity, or materials such as kaolin-type clays and organic clays which occur below the A-line. Highly organic clays have a very weak and spongy feel at the plastic limit.

(CL)200A

n Number of samples.
* Less than 1%.
† Prefixed with the term gravelly, sandy, or stony for SM or SC soil types.

Sample Interpretation

SiL: CL 45 (circled); 215

45% of all SiL samples were CL. The circle indicates that a greater number of SiL samples occurred as CL than as any other USCS type. 215 samples were classified as SiL and CL.

Total samples 1176

1 Number of samples.

* Less than 1%.

† Combined with the term generally, trace, e.g. up to 5% = M, 5 to 10% = MI type.

‡ Weight percentages.

Example: [illustration] 1-10

Of all the samples which are GM, the most frequent occurrence of the weight percentage of the material passing the No. 200 sieve is between 5% and 10%.

Pt	%				13							12		75		100	
	n				1							1		6			8
Total																	1140
Number of sites with same type of soil in 0- to 6-in. layer that is in 6- to 12-in. layer																	711
Percentage of occurrence in the 6- to 12-in. layer that is same as that of the 0- to 12-in. layer																	71%

Number of sites

Less than 1%.

Sites with same soil type in 0- to 6-in. and 6- to 12-in. layers

Interpretation Example

Of the six sites with SCL (sandy clay loam) in the 0- to 6-in. layer, one had the same soil type (FCl), one had Cl, three or 50% had C, and one had SiCl in the underlying 6- to 12-in. layer of the soil profile. The 50% under C, 6- to 12-in. layer, is encircled because C is the most frequent USDA soil type occurring below SCL.

PROBABILITY OF VEHICLE "GO" ON LEVEL TERRAIN

Excellent	Greater than 90%	Good reliability, based on analysis of data	
Good	76 to 90%	Fair reliability, based on judgement	
Fair	50 to 75%		
Poor	Less than 50%		

Note: Vehicle category and cone index range are given in paragraph 97.

* Based on +1 and -1 standard deviation from the mean.

** Applies only to wheeled vehicles without traction devices.

† Estimated from textural, plasticity, and organic properties of soil under given moisture condition.

†† Based on analysis of less than five samples.

‡ A vehicle with a vehicle cone index of 60 would have a 50-75% chance of "go" on an ML soil of low topography, wet-season condition.

* Probability of "go" based on median vehicle cone index within vehicle categories 1-6 and minimum vehicle cone index for category 7.

** Probability of "go" for vehicles in category 7 equal to or less than the given value.

† Soils with estimated probabilities.

†† Sample interpretation: A tracked vehicle with a vehicle cone index in the range 60-69 has a 62% probability of "go" on a CL soil at 15% slope under low topography,

Table 13

* Probability of "go" based on median vehicle cone index within vehicle categories 1-6 and minimum vehicle cone index for category 7.

** Probability of "go" for vehicles in category 7 equal to or less than the given value.

† Soils with estimated probabilities.

†† Sample interpretation: A tracked vehicle with a vehicle cone index in the range 60-69 has a 55% probability of "go" on an SiL soil at 15% slope

APPENDIX A: GENERAL PROCEDURES FOR OBTAINING AND TABULATING PERTINENT DATA

1. The following paragraphs discuss the general procedures used for obtaining and tabulating the data in this report.

Strength Data

Cone index

2. In Waterways Experiment Station trafficability studies several CI profiles usually were determined. Each profile consisted of a reading at the surface and at 3-in. increments to the maximum depth of penetration (30 in., or less if a reading greater than 300 was encountered). The readings for each depth were averaged and the pertinent averages were used to determine an over-all average for the critical layer. For example, the average CI for the 6- to 12-in. layer was determined from the average values for the 6-, 9-, and 12-in. depths, respectively. The rules for averaging CI when values greater than 300 are encountered were generally followed in the tabulation of data, and are as follows:

a. The first 300+ value encountered in a penetration is considered a measured value of 300 provided the material being tested is not rock.

b. Where there is evidence of a strength increase below the point at which a 300+ value is obtained and the material is not rock, values of 300 are assigned to the respective depths below the 300+ reading.

c. The 300+ values for rock are disregarded in the determination of average CI for a depth.

d. If two-thirds or more of the readings for a particular depth are maximum (300) values, the average for that depth is considered to be 300.

e. If more than one-tenth of the readings within a layer are 300, a plus sign is assigned to the average for the layer. The sign, however, is disregarded in the analysis of the data.

Remolding index

3. Remolding index test procedures for fine-grained soils and coarse-grained soils with fines are as follows:

a. Fine-grained soils. A soil sample taken with a trafficability sampler is extruded into a remolding cylinder mounted on a base. The sample is then pushed to the bottom of the remolding cylinder with a drop hammer. CI's are read at the surface and at 1-in. increments to a depth of 4 in. with a 0.5-sq-in. cone penetrometer. One hundred blows of a 2-1/2-lb hammer, dropped 12 in., are then applied and CI's are obtained in the remolded soil. The RI is determined by dividing the sum of the five CI readings made after remolding by the sum of the five readings made before remolding.

b. Coarse-grained soils with fines. The RI test for these soils is conducted in the same manner as for fine-grained soils, with two exceptions. The CI readings are obtained with a 0.2-sq-in. cone instead of the 0.5-sq-in. cone used on the fine-grained soils, and the sample is remolded by dropping the cylinder and metal base with the sample inside 25 times onto a wooden base from a height of 6 in. The annular space between the cylinder and metal base is sealed to prevent drainage.

4. Rules used in the computation of the RI are as follows:

a. A CI of 300 is assigned each depth that could not be penetrated because of the firmness of the sample.

b. The before- and after-remolding CI readings must be of equal number and taken at corresponding depths. If one of the readings has been omitted from the tabulation, the corresponding reading for that depth is excluded from the computation.

c. A CI of 300 is used in the computation only when it pairs with a smaller value obtained either before or after remolding at the corresponding depth.

d. The test is valid when the before- and after-remolding readings at two or more depths are less than 300 for one or both of the paired readings. The test is void when surface readings only are below 300.

5. Generally, two or more remolding tests are run at a site to provide a valid average RI for the soil. Two tests are considered sufficient, provided the RI's do not differ by more than 0.12. However, in some areas of highly variable soils, a third, and occasionally a fourth, test is required in order to provide at least two values within the permissible 0.12 variation. Values that do not fall within this limit are omitted from the computation of average RI. If, however, the index for the third or fourth test falls between the indexes for the first two tests, or if there is no

close agreement between values, the indexes for all the tests are used to determine an average.

Soil Classification

Unified Soil Classification System

6. Although the USCS soil types included in this study can be identified in the field with a fair degree of accuracy, all were identified by their Atterberg limits and grain-size distribution as determined by laboratory procedures.* Usually one or two samples within a 6-in. layer were obtained with a trafficability sampler for Atterberg limits and mechanical analysis determinations. Where two or more samples were taken at a site the data for each Atterberg limits and mechanical analysis test were averaged.

USDA textural classification system

7. Laboratory techniques and procedures were used to identify the soils within the 6- to 12-in. layer in regard to USDA textural names. Identification of soils within the 0- to 6-in. or surface layer was based either on laboratory procedures or on the textural nomenclature accompanying the soil series name obtained from USDA soil maps. The same samples obtained with a trafficability sampler for USCS soil identification purposes were used to establish the USDA textural name. Where more than one sample was obtained at a site, a mechanical analysis was run on each and the textural name was identified, based on averaged values of the three textural sizes. In all except a few soils, the gravel content was insignificant; consequently, the term gravelly generally was not applied to the textural name. The specific sand sizes were also excluded from the textural description.

USDA soil series

8. The soil series names were included in the site-data tables for

---

* The liquid limits of the nonplastic soils of the survey sites were determined by a modified procedure,[9]** which is presently being studied at the Waterways Experiment Station to determine its possible utility. The inclusion in this report of data obtained by means of the modified method in no way indicates that it is approved for official use.

** Raised numbers refer to similarly numbered references listed at end of main report.

information purposes where such information was available from USDA soil maps or from regional soil correlators or surveyors of the Soil Conservation Service. The names derived from maps were obtained from maps in existence at the time the data were collected, and in some cases may be different from series names obtained from recently revised descriptions or maps of the area.

Soil-Moisture Data

In-place moisture content

9. In this report, all determinations of natural field moisture content and laboratory tension moisture content are expressed as a percentage of the dry weight of the soil. Field soil-moisture contents were obtained by gravimetric or electrical-resistance methods. Instruments used for gravimetric sampling were the modified King tube (Veihmeyer tube),[13] the open-sided (Oakfield) sampler,[3] and the Hvorslev trafficability sampler (see TM 3-240, 3rd Supplement). The moisture content was computed as follows:

$$\text{moisture content} = \frac{\text{weight of water in sample}}{\text{oven-dry weight of soil in sample}} \times 100$$

Fiberglas electrical-resistance units were used to determine the soil-moisture contents at most of the prediction-development sites (discussed in paragraph 16, Appendix B). The moisture-resistance relation for each unit was determined from a calibration curve of resistance in ohms versus moisture content determined from modified King-tube gravimetric samples taken throughout the complete range of moistures for the site. Details of the units, their installation, and the problems involved in their calibration and use are discussed in several reports.[3,7c,11,12]

Per cent saturation

10. Per cent saturation of a soil may be expressed by the equation:

$$\text{per cent saturation} = \frac{\text{moisture content, \% dry weight, of soil}}{\text{moisture content, \% dry weight, of soil at 100\% saturation}} \times 100$$

where

moisture content, % dry weight, of soil at 100% saturation

$$= \left(\frac{\text{unit weight of water (62.4 lb/cu ft)}}{\text{dry density of the soil (lb/cu ft)}} - \frac{1}{\text{specific gravity}} \right) \times 100$$

The per cent saturation of nonorganic, 6- to 12-in. layer, field samples and laboratory tension moisture soil samples was determined within 1% of the computed value from density-moisture content curves developed from the equation above. Two sets of curves were employed. One set, based on a specific gravity of 2.70, was used for CH soils; the other set, based on a specific gravity of 2.65, was used for the remaining USCS soils, with the exception of the organic soil types. These two specific gravities are assumed averages for the respective soil types, based on discussions with WES personnel engaged in laboratory soil studies. The values for most of the data used in this report probably do not vary by more than ± 0.05 units from the assumed soil-type average. A 0.05 variation in specific gravity for a soil with an average density and high moisture content results in approximately a 2 to 3% variation in per cent saturation. Thus, the true per cent saturation for the majority of nonorganic soils included in this study would vary from 0 to 2% or perhaps as much as 3% from the estimated per cent saturation. The specific gravities of organic soils (OL, OH, Pt) vary appreciably with organic content; consequently, no attempt was made to estimate per cent saturation for these soils.

Field-maximum and field-minimum moisture contents

11. The field-maximum and field-minimum values for the 6- to 12-in. soil layer of the prediction-development sites (table B3) were obtained from records of moisture contents usually obtained at least once a week over a period of one or more years. The field-minimum values are included in the data tables for information purposes only. The field-maximum and field-minimum values for each site define the limits of its moisture range.

Laboratory moisture content

12. Moisture contents of 6- to 12-in. layer soil samples taken with a modified San Dimas or drive-type sampler[1] were determined for various

tensions in the laboratory. These data were used in the development of soil moisture-prediction relations.

13. 0.06-atmosphere tension (60 cm water). Moisture-content data for this tension are included for information purposes in the prediction-development, survey, and high-water-table site tables (B3, B4, and B6, respectively).

14. 0.005-atmosphere tension. Moisture contents for this tension are included in the prediction-development site data, table B3. This tension moisture value and the value of the average highest moisture content obtained on field samples from the 6- to 12-in. layer were compared for individual sites to determine whether the soil, in situ, approached saturation conditions. This information was utilized in the analysis.

15. 0-atmosphere tension. The soil sample at this tension approaches but usually does not attain saturation, even though soaked in water for periods ranging from 24 hours (coarse-grained soil) to 72 hours (fine-grained soil), due mainly to the partial entrapment of air within the interstices. A small amount of water probably drains out in the process of transferring the sample from the water-filled pan to the container that is weighed, although every effort is made to keep drainage to a minimum. The loss is probably greater in the coarse-grained soils. The 0-tension moisture contents were determined for soils of the survey and high-water-table sites, and these values are shown in tables B4 and B6, respectively. The 0-tension value for each high-water-table site was compared with the field moisture content. The field moistures presumably were at maximum since the free-water elevations at the sites lay within or, in most cases, above the 6- to 12-in. soil layer. The study showed the 0-tension laboratory moistures to be about 1% greater than the field-maximum moistures. This information was applied to moisture-content data of the low-topography survey sites. If the largest measured field moisture content at a site was not more than 1% less than the 0-tension value, then the moisture content of the soil was assumed to be at field-maximum and under high-moisture condition.

Density

16. The densities of soils in the 6- to 12-in. layer are included in

the site-data tables (tables B1-B6). For most sites, the density value is an average of two or more determinations made on samples of a specific volume obtained with the trafficability sampler or modified San Dimas sampler. In many cases these samples also were used for field moisture or laboratory tension moisture determinations.

Site Environmental Factors

17. The vegetation, land use, landform, topographic position, and drainage of a site or area may directly or indirectly affect its trafficability conditions. Where such information could be ascertained for a site from soil series or general terrain descriptions, or where the information was noted in previous site-study reports, a brief, generalized description of these features is included in the data tables. The descriptions of vegetation, land use, and landform are presented for information purposes only. It was beyond the scope of this report to analyze these features in terms of their effect on conditions of soil moisture or soil strength, or as an obstacle to vehicular traffic. The topographic position, and surface (external) and internal drainage characteristics of a site were considered only as they influenced the perched or permanent water-table depth at the site, and thus its topography class.

Vegetation

18. The vegetal cover is classified in eight general categories:

a. Bare
b. Herbaceous
c. Herbaceous with some trees
d. Brush
e. Hardwood forest
f. Mixed pine-hardwood
g. Conifer forest
h. Cultivated row crop

The type or species of trees or crops, such as loblolly pine, elm, oak, wheat, corn, or flax, is often included in the vegetal description of the site.

Land use

19. Land use is classified in the following general categories:

a. Undisturbed

b. Logged

c. Grazed

d. Cultivated

e. Cultivated, idle

f. Cultivated, grazed

g. Hay

h. Lawn

The category that characterized the land use at the time of testing was used to describe the site.

Landform

20. The following tabulation is a key to the landform symbols used in the tables. The classification system is based upon decisions reached at a conference held by the Corps of Engineers in January 1953 at the Waterways Experiment Station, and revised in February 1957:

I. GLACIAL

- A. Nonsoil
- B. Ice
- C. Lacustrine
- D. Drift
  - 1. Outwash
  - 2. Till plain
    - a. Old-layered
    - b. Young-plastic
    - c. Young-granular
  - 3. Moraine
  - 4. Esker
  - 5. Kame terrace

II. WATER DEPOSITED

- A. Delta
  - 1. Natural levee
  - 2. Swamp

II. WATER DEPOSITED (CONT'D)

- B. Flood plain - active
  - 1. Undifferentiated alluvium
  - 2. Natural levee
    - a. Crevasse
  - 3. Swamp
  - 4. Point bar
    - a. Ridge
    - b. Swale
- C. Terrace
  - 1. Alluvial
  - 2. Lacustrine
  - 3. Marine
- D. Alluvial Fan
- E. Coastal Plain
  - 1. Beach
  - 2. Marsh
  - 3. Dune
  - 4. Undifferentiated
- F. Desert Plain
- G. Lacustrine
- H. Bajada
- I. Playa

III. AEOLIAN

- A. Loess
  - 1. Hill
  - 2. Flat
- B. Sand

IV. RESIDUAL

- A. Sedimentary Rock
  - 1. Limestone
  - 2. Shale
  - 3. Sandstone
  - 4. Limestone and shale
  - 5. Sandstone and shale
  - 6. Chalk
- B. Igneous and Metamorphic Rock
  - 1. Basalt
  - 2. Metamorphic
  - 3. Intrusive

IV. RESIDUAL (CONT'D)

- C. Unconsolidated Sediment
  - 1. Clay
  - 2. Sand
  - 3. Undifferentiated

V. MISCELLANEOUS

- A. Evaporite
- B. Pyroclastic
- C. Organic
  - 1. Muskeg
  - 2. Peat
  - 3. Swamp
- D. Laterite
- E. Varved clay
- F. Colluvial

21. This landform classification with some modification has been used in the reports, Application of Airphoto Pattern Analysis to Soil Trafficability Studies,[5] as a major component in the study of wet- and dry-season soil trafficability conditions. The reports contain a discussion and analysis of soil trafficability factors and a general seasonal evaluation of cross-country vehicular movement for each major landform type.

Surface (external) and internal drainage

22. The surface and internal drainage conditions of a site are described in the following terms:

a. Good

b. Medium or moderate

c. Poor

Topographic position

23. The topographic position of a site is indicated as upland, terrace, or bottomland, with additional information such as ridge, slope, flat, or depression included. The categories considered are as follows:

a. Upland ridge

b. Upland upper slope

c. Terrace slope

d. Upland lower slope

e. Upland flat

f. Terrace flat

g. Bottomland flat

h. Upland depression

i. Bottomland depression

APPENDIX B: SOURCES OF, AND DETAILED PROCEDURES USED IN OBTAINING DATA

1. The soil and site data presented in tables B1-B6 were used in the analyses and form the basis for the trafficability classification scheme. The data were obtained in six different trafficability programs conducted during the period 1950-1958 at 1310 sites located in 44 states. Each table includes all or part of the data on texture, Atterberg limits, USDA and USCS soil type, strength (CI, RI, and RCI), moisture content, moisture tension, per cent saturation, and density of fine-grained soils and coarse-grained soils with fines within the 6- to 12-in. layer, and the USDA textural soil type of the 0- to 6-in. layer. The moisture and strength data generally are values obtained only during the wet season from sites located in the humid, temperate climatic regions of the United States or are values from sites located in subhumid or arid climatic areas with moistures approximating wet-season conditions. The location and the number of sites with strength data for each study source within a county of a state are shown on a map of the United States, fig. B1. The sites are located in 41 states. Other information (where known) for a site, presented in the tables, includes county and state location, soil series and type, topography class, depth to water table, topographic position, slope, surface and internal drainage, vegetation, land use, and landform.

2. The paragraphs that follow are grouped according to the six major sources of site data and contain a detailed discussion of soil sampling tools, frequency of visits to a site and number of measurements taken during each visit, basis for selecting data under wet-season and high-moisture conditions, number and geographical distribution of sites, and other important features of the test program relevant to the data for each of the sources.

Traffic-Test Site Data

3. The traffic-test soil and site data, table B1, were obtained from 142 tests conducted at 36 natural-ground sites in the central (Indiana, Kentucky), southeastern (Alabama, Mississippi, North Carolina), and northeastern (New York, New Hampshire, Vermont) sections of the United States

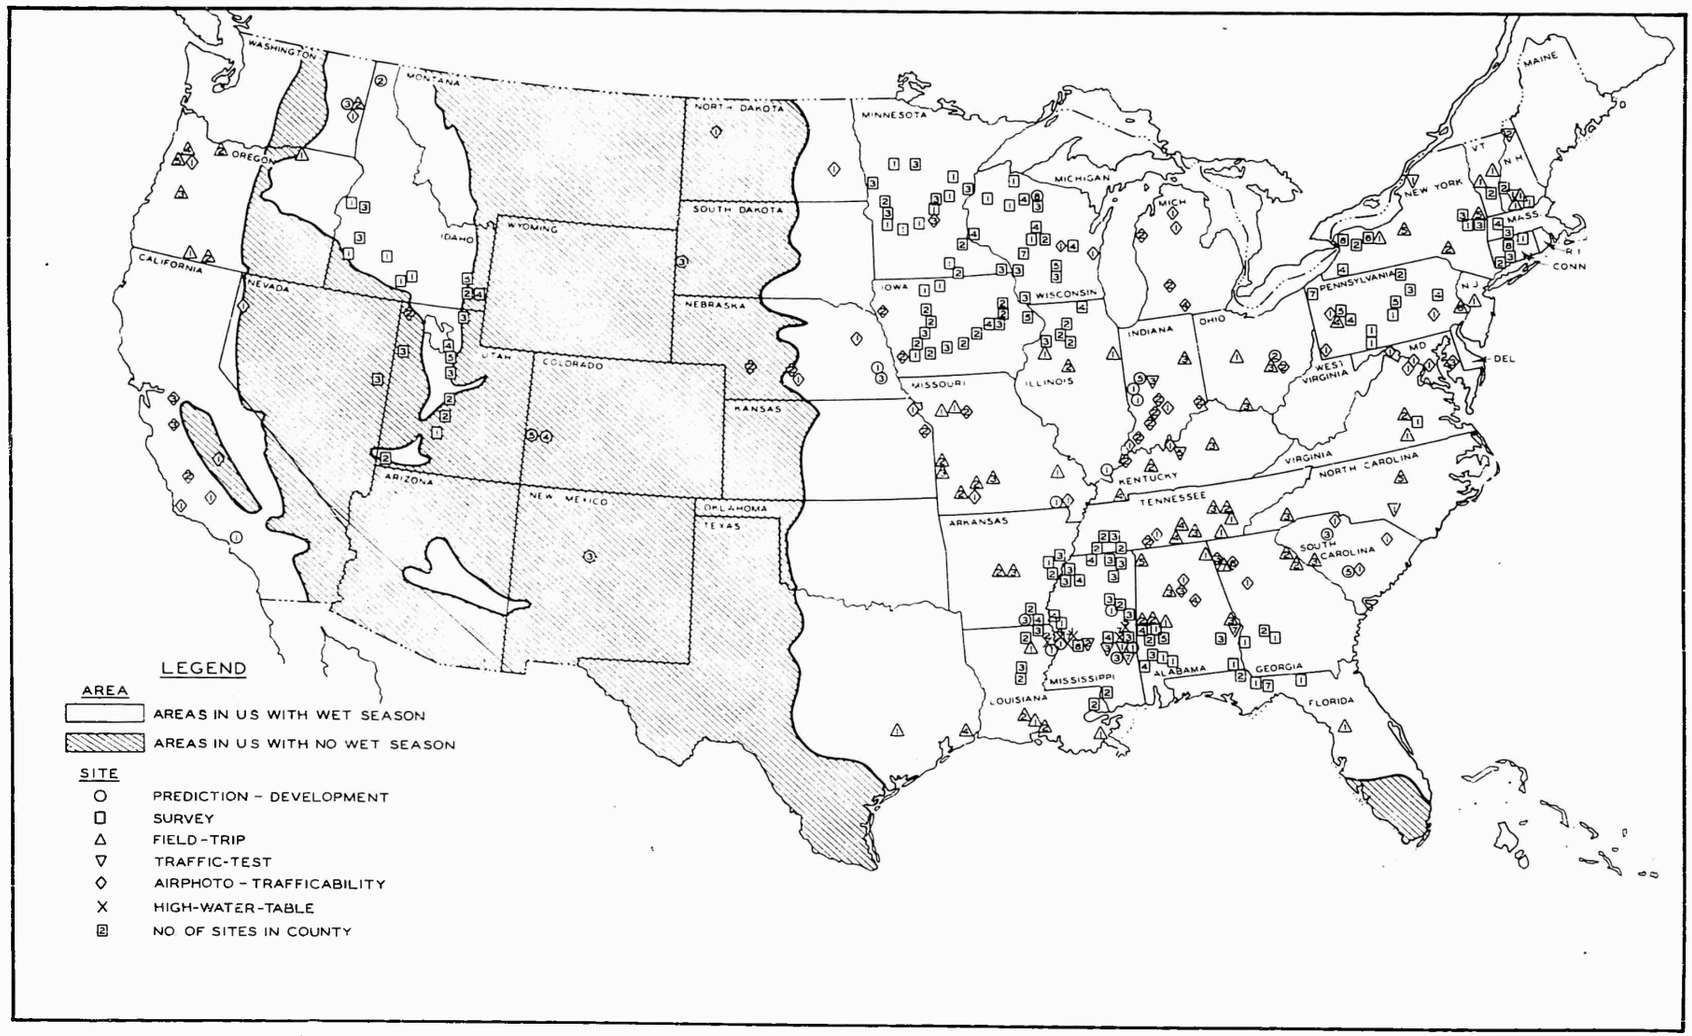

Fig. B1. Locations of strength-data test sites

during the spring months of 1950 through 1953. A complete discussion of the test program and a detailed tabulation of the data obtained in each test are contained in several reports, the 10th, 12th, and 13th Supplements of the TM 3-240 series. Most of these data were used in the development of the original trafficability soil classification scheme (11th Supplement).

Soil data

4. Cone index measurements were usually taken at 4-ft intervals along predetermined center lines of both tracks of a test vehicle's 100-ft-long test lane. Measurements at depths of 6, 9, and 12 in. were averaged to determine the average CI for the 6- to 12-in. layer. At least four RI tests, two or more tests at each of two stations located on opposite ends of the left and right side of the lane, were made and the resulting values were averaged. The average RI value for the 6- to 12-in. layer was multiplied by the average CI value to provide a reliable average RCI for the test lane. Usually four or more samples, taken with a trafficability sampler at the same two stations as were used for RI tests, were obtained for moisture-content and density measurements. The values for each measurement were averaged for the 6- to 12-in. layer. One sample, required for mechanical analysis and Atterberg limits determinations, usually was taken in the central part of a uniform soil area of several test lanes. Occasionally, a sample was taken in the center of each of the several lanes.

5. In some traffic-test areas, an appreciable number of vehicle tests, each with its own data, were run within short distances of each other. If each test was considered a site and included in the data analysis, undue emphasis would be given to those areas with abundant tests. In order to eliminate this bias, soil data from two or more test lanes within a small area and with the same USCS-USDA soil types were combined and averaged for each soil variable, respectively. For analysis purposes, this small area of uniform soil was considered a site, and the averaged test-data were included in the tables under the heading "Wet-Season Condition." The data from only one test lane at a site, however, were included in the tabulation of high-moisture condition, provided of course that this condition existed during the time of testing. If more than one test lane was at high moisture, data from the lane with the lowest RCI were used. A condition of high moisture was assumed for a test if the water table was within

4 ft of the surface for fine-grained soils, or within 2 ft of the surface for coarse-grained soils with fines, or, if no water-table data were available, when the per cent saturation was close to or at an estimated maximum for the soil type.

Site data

6. The geographic locations and topographic positions of the test lanes and the period of testing were usually selected on a basis of poor soil trafficability conditions. The sites were generally low-lying and subject to high water tables (all classified as low topography). Consequently, the wet-season data are biased toward somewhat higher moistures and lower strengths than normal for the area. Data relative to topographic position, drainage, vegetation, land use, and landform were obtained from general descriptions of the sites included in the reports referenced in paragraph 3 and from generalized information included in the soil series descriptions.

Field-Trip Site Data

7. During the early wet-season months of 1951, WES field parties visited various sections of the country accumulating strength, moisture, density, mechanical analysis, and Atterberg limits data for approximately 100 soils. The sites selected for these tests were those believed to be potentially critical from the trafficability standpoint. Additional tests of the same type were made in early 1953 on soils of about 125 sites believed to be typical of large areas of the United States. These two sets of test data were important contributions to the original soil trafficability classification study (see 11th Supplement). The 1951 and 1953 site data and soil data for the 6- to 12-in. layer obtained at 206 sites in 22 states of the southern, central, eastern, and northwestern sections of the United States are included in table B2.

Soil data

8. An average CI value for the 6- to 12-in. soil layer for each of the sites visited in 1951 was obtained from CI readings at 6- and 12-in. depths at 10 different spots within the site; an average CI value for each of the sites visited in 1953 was obtained from CI readings at 6-, 9-, and

12-in. depths at four spots within the site. Two or more RI tests were run according to standard procedures and the values were averaged. Data from silty or clayey sand soils (SM, SC, SM-SC) of sites visited in 1951 are not included in the tables because the remolding test for fine-grained soils rather than the remolding test for coarse-grained soils with fines was used to determine the RI's. The latter test was not developed until 1953. The moisture-content and density values, respectively, of the 6- to 12-in. layer were averaged from values of measurements on usually two or occasionally three samples obtained with a trafficability sampler. One or more samples were obtained for Atterberg limits and mechanical analysis tests from which the USCS and many of the USDA soil types were determined. The USDA textural sizes were not measured for most of the 1951 field-trip sites. Identification of the 6- to 12-in. layer USDA soil type for these sites was based on the textural type of the series description, where it was actually noted (or there was reason to believe) that the type extended to a depth of at least 12 in.

9. Strength, moisture-content, and density data (not questionable), with corresponding RCI values, included in the table under "Wet-Season Condition" were used in the analysis for this condition. Data included in the analysis of high-moisture condition were selected from low-topography sites with high water tables or with field moisture contents close to or at an estimated maximum per cent saturation.

Site data

10. The classification of topographic position, slope, drainage, vegetation, land use, and landform of the site was based on general information obtained at the time of the test, or on generalized data contained in the soil series descriptions. The topography class, high or low, was estimated from the general site description, the topographic position and drainage characteristics of the site, and the proximity of the site to ponds, streams, or other surface water bodies.

11. These sites, as previously mentioned, were normally chosen for testing because of their critical trafficability conditions. The data for wet-season condition, therefore, are biased toward somewhat higher moistures and lower strengths than normal.

Prediction-Development Site Data

12. The field data were obtained from two major sources: the sites used by the Waterways Experiment Station and cooperating agencies (termed University sites) and the sites of the Vicksburg Research Center of the U. S. Forest Service and cooperating agencies (termed Extension sites). The Forest Service worked with the WES in establishing the sites for the primary purpose of studying the effects of meteorological factors on the soil-moisture regime. The preliminary objective of the study was to develop means for quantitatively predicting daily soil-moisture contents of the surface soil. The ultimate objective of the study program is to develop a system for predicting strength and consequently trafficability of the critical soil layer. The studies conducted thus far show, among other things, that the moisture contents of soils in humid, temperate climatic regions will attain maximum values (field-maximum) in the wet season and, as a result of low evapotranspiration loss, will maintain these values with relatively small deviations throughout the wet season.

13. The data shown in table B3 were collected in the wet-season months of 1951 through 1954 from 128 sites scattered in 23 states throughout the various physiographic and climatic provinces of the United States. Detailed tabulations of soil and site information, most of which is contained in table B3, and a complete discussion of the study program are included in a series of WES reports.[7a-7d*] The data from some of the sites were used in the development of the original soil classification scheme (11th Supplement).

Soil data

14. Data from the WES and University sites were collected from a 40-ft-square sampling area, divided into 25 approximately 8-ft-square plots. Samples or direct measurements of the soil on any one day were usually taken in four randomly selected plots. Data from the Vicksburg Research Center and Extension sites were obtained from a 6- by 12-ft test area, divided into 72 1-ft-square plots. Samples or direct measurements on any one day were usually taken in two randomly selected plots.

---

* Raised numbers refer to similarly numbered references listed at end of main report.

15. Twelve CI spot measurements, three in each of the four selected 8-ft plots, or six spot measurements, three in each of the two selected 1-ft plots, were averaged for the 6- to 12-in. layer on any one day. The RI of the 6- to 12-in. layer on a given day was averaged from two tests performed in two of the four 8-ft plots or in each of the two 1-ft plots where CI's were measured. The RCI for a specific day was obtained in the usual manner. An attempt was made to obtain strength measurements concurrently with moisture measurements. CI and especially RI data, however, could not be obtained as frequently as moisture data, and at some sites could not be obtained at all during the wet-season period of study, due to the firmness of the soil, erratic penetration readings, or other test difficulties.

16. Moisture contents usually were measured daily or one to five times per week at most sites, and monthly at some of the sites, during a test period ranging from one to two years. Measurements were made by means of gravimetric or electrical-resistance methods. Four gravimetric samples of the 6- to 12-in. layer obtained with a trafficability sampler from each of four 8-ft plots, or eight samples, four from the 6- to 9-in. layer and four from the 9- to 12-in. layer, obtained with a modified King tube or Oakfield sampler from two spots in each of two 1-ft plots, were averaged at a site for a given day. The electrical-resistance technique for measuring moisture content was used at most Vicksburg Research Center and Extension sites. The procedures are briefly discussed in paragraph 9, Appendix A. Details of the units, their installation, and the problems involved in their calibration and use are discussed in several reports.[3,7c,11,12]

17. The number of tests, and the range and average values of moisture content, CI, RI, and RCI, respectively, for the wet season are included in the table for each site where such information was available. Only moisture-content and CI data obtained on the same day as RI data were averaged and used in the various analyses for wet-season condition.

18. The dry density of soils at the WES and University sites was often measured at the same time as, and from the same samples used in the measurement of moisture content. The density of soils from the Vicksburg Research Center and Extension sites usually was determined from two 2-in. cores taken with the San Dimas or drive-type sampler when the soil was

moist. Occasionally the dry density was determined from blocks of soil cut to a known volume. The average value included in the table for each site is the average of all of the 6- to 12-in. layer values measured in the various plots during the period of study.

19. The USDA and USCS soil types for each site were determined from mechanical analysis and Atterberg limits of usually one 6- to 12-in. layer soil sample; occasionally the type was based on an average of two values obtained from analysis of samples of the 6- to 9-in. and 9- to 12-in. soil layers. The sample for the 3- or 6-in. increment was a composite of two or more samples obtained from randomly selected plots. The 0- to 6-in. layer USDA type was in most cases identified from a textural analysis of the same number of samples as used in the identification of the 6- to 12-in. layer.

20. Organic contents were determined by means of the modified Walkey rapid dichromate oxidation method[4] at the Mississippi Agricultural Experiment Station. The loss-on-ignition method following modified procedures of the Association of Agricultural Chemists[2] was used for samples when the organic content was over 5% as determined by the Walkey method.

21. The 2-in.-diameter samples obtained with the San Dimas sampler and used for density determinations were also used to determine the moisture contents at 0.005- and 0.06-atmosphere tensions. The field-maximum and field-minimum moisture contents for each site were determined from a study of the site's complete soil-moisture record. The per cent saturations of nonorganic soils at field maximum were computed for sites of low topography using the average dry density value for the site.

22. A high-moisture condition was assumed to exist at a low-topography site on a given day if (a) the water table was within 4 ft of the surface for fine-grained soils or within 2 ft of the surface for coarse-grained soils with fines, or (b) if no water-table data were available, the per cent saturation of the soil at a moisture content of lowest RCI was slightly less than, equal to, or greater than the computed per cent saturation at the field-maximum moisture content. Moisture-content, per cent saturation, CI, RI, and RCI data for the day of lowest RCI at low-topography sites under high-moisture condition were tabulated and included in the analyses. Per cent saturation was computed using the moisture content and density (noted in the table under "High-Moisture Condition") that

were determined from the same sample or samples. Thus, the inherent variation of density and moisture from spot to spot and the interrelation of the two variables at each spot are considered, and the value of per cent saturation is valid. A per cent saturation based on a moisture content from one sample and a density value from another would not be valid.

Site data

23. The descriptions of topographic position, slope, surface and internal drainage, vegetation, land use, and landform, included in table B3, were transposed from data tables included in two previous WES reports.[7c,7d] The descriptions originally were based on detailed information obtained from observations in the field during the period of study. Sites with an original wetness index category[7c,7d] of 1 or 2 were classified as high topography and those with a wetness index of 3 or 4 were classified as low topography.

Survey Site Data

24. Data collected at the survey sites were used to check the accuracy of soil-moisture predictions that were based on tentative average soil-moisture relations developed from prediction-development site data. The field study was conducted from June 1954 to July 1955 by the Vicksburg Research Center, U. S. Forest Service, in four areas of the United States designated as the Southern, Northeast, Lake States, and Intermountain Regions.

25. The data used in the analyses are presented in table B4. The information generally was collected during the wet-season months of October 1954 through May 1955, the specific months varying with the particular region. A total of 618 sites located in 20 states were used: 178 sites in Alabama, Arkansas, Florida, Georgia, Louisiana, Mississippi, and Tennessee of the Southern Region; 135 sites in Connecticut, Massachusetts, New Hampshire, New York, Pennsylvania, and Vermont of the Northeast Region; 161 sites in Illinois, Iowa, Minnesota, and Wisconsin of the Lake States Region; and 144 sites in Idaho, Nevada, and Utah of the Intermountain Region. A complete discussion of the test program and detailed tabulations of data for each test are contained in WES TM 3-331, Report No. 5.[7e]

26. Sites were established on major soil groups located within 5 miles of a regular weather station and were tentatively selected on the basis of state soil-association maps or county soil-survey maps, and detailed highway maps. Each site of about one-tenth acre in size was located within 100 yd of an accessible road, was uniform with respect to soil and cover conditions, and was not in cultivation at the time of selection.

Soil data

27. Each site was divided into three plots for sampling purposes. Samples for moisture-content determinations normally were taken at 6-in. increments at three randomly selected points, one within each plot. The samples for each layer were composited to provide one sample and, thus, one moisture value for a specific day. At least eight visits, at about monthly intervals, were made to the site. The wet-season average moisture content for each site, included in table B4, is one, or an average of two or three 6- to 12-in. layer values obtained only on days in the wet season when RI tests were run.

28. On all test visits six CI readings were taken at two points (1 ft apart, at each of the three moisture sampling locations) and averaged for a particular layer. In coarse-textured and stony soils, an "airfield" penetrometer with a 0.2-sq-in. cone was used when the regular instrument with a 0.5-sq-in. cone would not penetrate the soil. The wet-season average CI data in the table is a single value or an average of all 6- to 12-in. layer CI measurements taken on the same days as wet-season RI tests. Remolding tests were attempted on at least two visits to the site, usually when the soil was wet. However, the firmness or stoniness of the soil often prevented sampling or resulted in nonvalid measurements. Thus, RI data are not shown for some of the sites. At sites for which data are shown, two tests on a given day were run at points between plots and averaged. The average RI value for the wet season is one, or an average of two or three, of the average daily values determined during test visits in the wet season. The wet-season average RCI is the average of all RCI values computed for days in the wet season. Wet-season average moisture-content and CI values for a site were not included in the tables if no data were obtained for remolding and rating cone indexes.

29. Bulk samples of 6-in. layers were taken at six locations, two in

each plot, and composited to provide one sample for mechanical analysis, Atterberg limits, and organic-content determinations. The liquid limits of nonplastic soils and a few soils with low plasticity could not be determined by the standard procedure, and consequently a modified procedure was used to determine liquid limits of these materials.[9] Organic-matter determinations were made using the modified Walkey rapid dichromate oxidation test. The texture, plasticity, and organic-content values of the 6- to 12-in. layer, and the USDA and USCS soil types based on these values are presented in the table for each site.

30. Measurements of density and of moisture content at 0- and 0.06-atmosphere tension were made on 2-in.-diameter cores obtained with the modified San Dimas or drive-type sampler when the soil was moist. The data presented in the table are an average of four values obtained from cores of the 6- to 9-in. and 9- to 12-in. layers taken at two central points between plots.

31. Questionable values in table B4 are indicated by an asterisk and were not used in the analyses. Moisture contents at 0-atmosphere tension were questioned if the value was appreciably less than the wet-season average field moisture content or if the value was consistently less than the wet-season moisture values for specific days. Per cent saturation values at 0-tension moistures are indicated by an asterisk if the moisture content or density was questioned or if the value was appreciably greater than 100% saturation (generally greater than 110%). Values of saturation slightly greater than 100% (generally between 100 to 110%) are not indicated by an asterisk even though such values are theoretically impossible. The slight excess over 100% is considered inconsequential for analysis purposes. The excess may be attributed to the inadequacy of the assigned average specific gravity or to minor instrumental or human error in deriving moisture-content or dry density values used in the computation. Per cent saturation values at 0-tension moistures are not presented for sites of the Northeast Region. Computed values for this region were in most cases greater than 100%, thus suggesting that the average specific gravity should be higher than the value used, or that a consistent error in sampling or in measuring provided density or moisture values that were consistently too high.

32. A high-moisture condition was assumed to exist at a

low-topography site for a particular day if (a) the water table was within 4 ft of the surface for fine-grained soils or 2 ft for coarse-grained soils with fines, or (b) where water-table data were not available, the field moisture content was not more than 1% less than the 0-tension moisture content. The data included in the table are for the day of lowest RCI under high-moisture condition. In a few cases data were presented for this condition even though the data did not meet the criteria specified above; however, the RCI for the day was lower than that for another day under high-moisture condition. It should be pointed out that the moisture content for this condition is not necessarily the highest value obtained at the site.

Site data

33. Site environmental data presented in table B4 include the classification or description of topographic position, slope, surface and internal drainage, vegetation, land use, and landform. This information was obtained from the tables of WES TM 3-331, Report No. 5,[7e] and was originally derived from direct observations at the site during the period of testing.

34. Soil series were identified by regional soil correlators or surveyors of the Soil Conservation Service, or the names were derived from county soil maps or farm plan maps supplied by the Soil Conservation Service.

35. The moisture conditions of the site were originally classified as wetness index 1, 2, 3, or 4, based on the minimum water-table depth and moisture penetration conditions as determined from the climate, topographic position, drainage characteristics, and, where available, measured depths to the water table. For purposes of this study, sites with a wetness index of 1 or 2 were classified as high topography and those with a wetness index of 3 or 4 were classified as low topography.

Airphoto-Trafficability Site Data

36. These data were collected from sites established during the period 1950 through 1958 by the Engineering Experiment Station, Purdue Uni rsity, under contract to the Waterways Experiment Station. The information was used in a study to develop criteria for defining the

trafficability characteristics of major landform environments from aerial photographs based on existing airphoto interpretation techniques.

37. The data, presented in table B5, were collected in the wet season from 262 sites located in 29 states. A detailed presentation of the trafficability data and characteristic airphoto patterns for the various landform-parent material combinations are contained in eight photo key reference books.[5] A condensation of the information and an analysis of the data based on landform-soil type associations are included in a summary report (not yet published).

Soil data

38. The CI, RI, and RCI data presented in table B5 are average values for the 6- to 12-in. layer obtained on a specific day in the wet season. CI values were not included in the table for sites where the soil was too firm to obtain a sample for an RI test.

39. The moisture content and dry density were measured to the closest one-tenth unit from one sample of the 6- to 12-in. layer obtained with the Hvorslev trafficability sampler. Most of the early basic field information, however, was lost. The moisture and density data presented in the table for most of the sites, therefore, are values interpolated to the closest unit from graphs of data contained in the reference books. The computed per cent saturation may vary to some extent (generally within a $\pm$5% range) from its true value due to the approximation of the moisture-content and density values used in the computation.

40. Soils were sampled for Atterberg limits and textural determinations by horizons within the soil profile. The values for each of the horizons within the 6- to 12-in. layer were proportioned according to its relative thickness in the layer to provide the data included in the table. The textural data were based on either a sieve (No. 200) analysis of soils visually classified as coarse grained, or on a hydrometer analysis of soils visually classified as fine grained. At sites where the per cent fines (minus No. 200 sieve sizes) was not determined, the distinction between a coarse- and fine-grained USCS soil type was based, with a fair degree of reliability, upon an interpolated 0.074-mm value obtained from the hydrometer analysis curve. The USDA type, of course, could not be ascertained for sites for which sand, silt, and clay percentages were not known.

41. Sites classified as low topography with soil estimated to be at high-moisture condition for the particular day the data were taken are noted by an X mark in the table. A high-moisture condition was assumed if the per cent saturation was greater than minus one standard deviation from the mean for the soil type or if, at sites with questionable or no values of per cent saturation, the RCI was low and the detailed description of the site suggested a very wet soil at the time of testing.

Site data

42. The classification of topographic position and landform was based on relatively detailed descriptions obtained when the site was visited and included in the reference reports. The surface and internal drainage characteristics were based on information contained in the soil series descriptions. The description of vegetation and classification of land use were interpreted from aerial or ground photographs or from descriptions of the site. A dashed line for a particular factor in the table indicates that the factor classification or description could not be ascertained.

43. The topography classification of the site was based on the topographic position, external and internal drainage characteristics, and detailed site description information contained in the reference report.

44. The soil series or series association (composed of two or three soil series) represents the best available information obtained from Soil Conservation Service soil maps in existence at the time of the test.

High-Water-Table Site Data

45. The high-water-table sites were established in 1957 by the Vicksburg Research Center, U. S. Forest Service, in cooperation with the Waterways Experiment Station for the purpose of obtaining information on the various soil variables, especially strength, under conditions of maximum wetting. Fifty-eight sites with water tables within 6 in. of the surface and two sites with water tables at a depth of 8 in., located in several counties of central Mississippi and one parish of Louisiana, were studied.[10]

46. The high-water-table site data used in this report are presented

in table B6. Since the data are obviously not typical of average soil strengths and moisture contents in the wet season, i.e. wet-season condition, they were used only in the analysis of soils under high-moisture condition.

Soil data

47. Sites often were established in the same general area within short distances of each other. If all the sites were included in the analysis the uniform soils of areas with several sites would be excessively weighted. In order to eliminate this regional bias, sites located in the same area with the same soil series and USDA-USCS type were grouped together in the table and only the site with the lowest RCI, indicated by an X mark in the table, was used in the analysis.

48. The CI and RI data are average values obtained on the day of the test visit. The RCI is the product of the CI and RI.

49. The dry density and field moisture content, respectively, were averaged from measurements on 6- to 9-in. and 9- to 12-in. layer cores obtained with a modified San Dimas sampler. The 0- and 0.06-tension moisture values were derived in the laboratory from measurements of the same cores of soil. Per cent saturations were computed for 0-tension and field moisture contents, respectively.

50. The Atterberg limits and per cent of each texture, from which the USDA and USCS soil types were determined, were derived from a mechanical analysis of a 6- to 12-in. layer soil sample.

Site data

51. Site environmental data were omitted from table B6 because the information available was not sufficient to classify each of the factors properly. Since the water tables at all sites were within 4 ft of the surface, all sites classified as low topography. The soil series information was obtained from county soil maps of the area.

Table B1

Traffic Test Data

Site No.	Test No.	Location State	Location County	USDA Soil Map Identification Soil Series	0- to 6-in. USDA Type	Topography Class	Soil Data, 6- to 12-in. * Questionable value, not used in analysis.

U. S. Army Engineer Waterways Experiment Station, CE, Vicksburg, Miss. TRAFFICABILITY OF SOILS, SOIL CLASSIFICATION, by M. P. Meyer and S. J. Knight. August 1961, viii, 65 pp and 2 appendices - illus - tables. (Technical Memorandum No. 3-240, 16th Supplement), Subproject 8S70-05-001-02

Unclassified report

A statistical analysis was made of soil strength (cone index, remolding index, and rating cone index), soil moisture, dry density, and per cent saturation for soils classified according to the Unified Soil Classification System (USCS) and U. S. Department of Agriculture (USDA) classification system. Data were obtained during wet-season periods from more than 1300 sites located principally in humid, temperate regions of the United States. Soils of high- and low-topography positions were analyzed for average and high-moisture conditions in the wet season. The information was used to improve an existing scheme for classifying soils according to their trafficability. A comparison of USCS and USDA soil types was made for the 6- to 12-in. layer of soils, and a study was made to compare the type of soil in the 0- to 6-in. layer with the type in the 6- to 12-in. layer of the profile, in USDA terms. Two appendices describe data sources and test procedures. This report supersedes Technical Memorandum No. 3-240, 11th Supplement.
