1. Preparing Institution: The Pennsylvania State University
2. Title of Report: The Influence of Body Characteristics on Human Temperature Responses to High Altitude Cold.
3. Principal Investigator: Paul T. Baker, Ph.D.
4. Number of pages, illustrations, and date: 28 pages, November 1, 1963
5. Contract Number: DA-49-193-MD-2260
6. Supported by: U. S. Army Medical Research and Development Command
Department of the Army
Washington, D. C.

In order to determine the possible role of body characteristics in man's ability to adapt and acclimatize to high altitude cold the physical characteristics of four groups of individuals were correlated to their body temperature responses when exposed to an ambient temperature of 14° C. for two hours at an altitude of 3760 meters. The body characteristics chosen for analysis were, age, standing height, sitting height, weight, % body fat, fat free weight and sum of skinfold. The four groups were U.S. Whites, University of Cuzco White and Indian students and native Indian villagers.

The results showed significant association between body characteristics and body temperatures in all groups. Fat acted as insulation in all groups and fat free weight had very significant positive effects on total body heat content. The total body heat content of native Indian villagers was more significantly affected by age than in other groups and fat-free weight in this group had a strong effect on peripheral body temperatures. The result agrees with the suggestion made in the previous progress report that native Indian villagers have a higher metabolic response to cold stress.

Note: Copies of this report are filed with Armed Services Technical Information Agency, Arlington Hall Station, Arlington 12, Va., and may be obtained from that agency by qualified investigators working under Government contract.

1. Introduction

Studies over the past ten years have shown that when individuals are exposed to moderate total body cooling, much of the individual variability in response may be based on individual variation in body structure and composition (Buskirk et al. 1963). Since population isolates of man are often dramatically different in body size and composition, many of the differences that have been reported for population isolates may be accounted for by these differences in body structure (Buskirk et al., 1963, Baker and others, 1963a). Despite the fact that body structure has a significant effect on temperature responses during body cooling it cannot be assumed that it has a similar effect on all groups. In a study of American Negroes and Whites it was found that body fat seemed to provide less insulation for American Negroes than it did for U.S. Whites (Baker, 1959). Theoretically other body characteristics such as age, surface area, and the mass of active tissue should also affect temperature responses during body cooling. However studies of these problems have so far produced meager results (Baker, 1960, Bernstein et al., 1956).

2. Methods

Sample. In the present report, the data from the four groups of men used for studying adaptation to high altitude cold in the Andes have been analyzed to determine for each group the relationship between body characteristics and temperature responses during two hours of cooling at 14°C. A complete description of the four samples is given in the Annual Progress Report, dated July 1, 1963 (Baker, 1963). Briefly, these samples consisted

of 24 native Highland Peruvian Indians living in traditional manner, 12 University of Cuzco students of Indian derivation, 12 University of Cuzco students of White derivation, and 5 U.S. Whites who had spent three to six months in the highlands of Peru. Table 1 gives the physical characteristics of the four populations.

S. Sf. = Sum of Skinfolds

The two University of Cuzco populations were carefully matched by selection for body characteristics and as a consequence there are no

significant differences in the means of the measurements of the two populations. However, standard deviations vary slightly particularly that of standing height. The Chinchero Indian population and the U.S. White population are different from each other and from the two student populations in most characteristics. While none of these populations is large enough to be considered representative of their respective larger population groups, the differences between them reflect the directions of the difference between the populations. Thus, the native Indian population is the shortest of the groups and the lightest in body weight; it is also the lowest in body fat. The U.S. White population is substantially taller, heavier and fatter than the Cuzco student population. Despite the very small size of the U.S. White sample they are quite close to estimates of body size and composition obtained on a U.S. White population of comparable age (Brozek & Henschel, 1961).

Testing Conditions. All groups were exposed nude while lying on canvas cots for two hours in an ambient temperature of approximately 14°C. Exact details of temperature conditions are presented in the previous report of July 1, 1963. However, it should be reiterated that conditions in the dressing room prior to the actual cooling exposure were not constant and produced significant cold stress so that thermal equilibrium cannot be assumed in these groups at the beginning of the study.

Of the body temperature measurements collected during the cold exposure, four measurements were selected for analysis in relation to body structure. These were: (1) rectal temperature, (2) mean weighted skin temperature, (3) hand temperature, and (4) toe temperature. Rectal and mean weighted skin temperature have been included because they represent the best two measures of the overall thermal characteristics of the individual. Hand

and toe temperature were included because in group comparisons, higher intergroup variability was encountered. They are also indicators of peripheral heat flow. In the analysis, physical characteristics have not been combined into indices, such as surface area, because such combinations are statistically less valid characterizations of the body than the raw measurements. No attempt was made to integrate rectal and skin temperatures into estimates of thermal insulation and/or total body heat content using published formulas because it is felt that individual structural differences are significant in true insulation and total body heat content. The calculation of such values by formulas derived from U.S. White groups would therefore confuse the interpretation of the results (Buskirk et al., 1963, Baker, 1958).

3. Results

In the previous analysis for group differences it was found that the two University populations did not significantly differ from each other in any of the temperature measurements used for this analysis. The White and Chinero Indian groups did differ from each other and from the University populations. Despite the lack of significant differences between the two University groups they have not been combined for this analysis since the similarity in average response does not necessarily signify a similarity in the role of body structure characteristics in cooling responses. For example, in the previously cited study of Negro-White differences in response to moderate total body cooling, the two groups did not significantly differ from each other in average response. Nevertheless,

in that study the analysis of structure in relation to temperature indicated a significant difference in the insulation provided by body fat in the two groups.

The relationship between the physical characteristics and the temperature responses in the four groups was measured by the Pearson product-moment r. The correlation coefficients for each of the time intervals at which temperature measurements were made is shown in Appendix A. High order correlations were found between physical characteristics and rectal and mean weighted skin temperatures in the U.S. White groups. However, the very small size of this sample prevented the majority of these correlations from being statistically significant. If the correlation patterns for all time intervals are considered, significant correlations exist between fat and mean weighted skin temperature with nearly comparable correlations between fat and rectal temperature. The relationship between fat-free weight and rectal temperature is also high throughout the test period. At the end of two hours this relationship provides the most highly significant correlations. The correlations found in the White group agree with the results of other studies in that they show body fat to be negatively correlated with skin temperature while it is positively correlated with rectal temperature. At the beginning of the cooling period, standing height and sitting height were highly correlated to toe and hand temperature in a negative direction. However, the correlations fall considerably below significant levels at succeeding time intervals.

For the two University student populations, correlations are generally of a much lower order than was found for U.S. Whites. Although there appear to be some consistent patterns, such as a positive relationship between fat and rectal temperature and a negative relationship between fat and mean weighted

skin temperature, there are no significant r's. More significant correlations emerge from the relationship between body structure, and toe and hand temperature. The two groups do not appear to be similar in this regard. By the end of the cooling period, the Cuzco Whites show consistently significant association between measures of fat-free weight and body fat with toe temperature. The Cuzco Indian group, however, fails to show any positive association and instead shows at the very end of the cooling period a highly significant correlation between age and toe temperature. Hand temperature r's are lower, although in the Cuzco White sample there is consistent and significant association between the measures of body fat and hand temperature. Again these are positive associations indicating the higher the body fat, the higher the hand temperature. These patterns do not emerge in the Cuzco Indian group.

Because of the larger sample size, the Chinchero group is the most suitable of the four groups for correlation and regression analysis. Thus, although correlations are substantially lower than they are in the U.S. White groups, there are more statistically significant correlation coefficients. In contrast to the U.S. White group, body composition has a low order of correlation with rectal and mean weighted skin temperature. The only significant pattern seems to be a positive association between the sum of skinfolds and the rectal temperature. In that this is a positive association, the results conform to findings on U.S. Whites. On the other hand, a highly significant negative relationship between age and both rectal and mean weighted skin temperature develops over the two hours of cooling. No such association with age is found in the U.S. White group.

In summary, the simple correlations suggest that the U.S. Whites respond to high altitude cooling with the same relationship between body structure and temperature as has been found by other investigators in controlled laboratory experiments at low altitudes. The two University populations do not seem to be identical to each other in the relationship of body structure to temperature responses, nor do they appear to be identical to either of the other two groups. The Chinchero Indian group shows a substantially different pattern, with age the dominant factor and body composition apparently of less significance to overall body cooling. However, the groups are not comparable to each other in body structure except for the two University populations and the analysis of simple correlations does not necessarily show the accurate pattern since the measures of body structure are interrelated. Therefore, an analysis based on multiple correlation with parsimony was undertaken.

The multiple correlation with parsimony technique is simply a standard multiple correlation with a subsequent series of single variable eliminations from consideration of many independent variables to a final indication of the prime predicting variable. By this method it is possible to determine which of the body structure factors is most significant in relation to an individual body temperature. Multiple correlation with parsimony was used to relate the physical characteristics of each group to each of the temperature measurements. Table 2 summarizes the results of this analysis for time interval 120, i.e. the last measurement of temperatures during the study.

Table 2

Multiple correlation with parsimony analysis of body characteristics in relation to body temperatures after 120 minutes of cooling at 14° C.

% B.P. = Percent Fat, F.F.W. = Fat Free Weight, S.Sf. = Sum of Skinfold thickness.

The notation of "all characteristics" refers to all the body characteristics shown in Appendix A. The selection of the second item labeled "most significant variables" is based on a somewhat subjective criterion. The small sample sizes made impossible the selection of the border line between significant drops in R values by rigorous statistical tests. Therefore, the judgments were arbitrarily made by inspection. The very high R values shown for the U. S. White sample should probably not be accepted as proof of perfect association. An increase in the number of variables automatically adjusts multiple correlation R s to a higher value and when as many characteristics as were used in this study are submitted to multiple correlation, R values will reach a very high value in small samples. Nevertheless, the results do suggest a very high degree of association between physical characteristics and body temperature responses in the U.S. Whites.

Correlations of body characteristics to temperature in the other three groups are of a lower order. However, substantially R values are obtained in most cases and the consideration more than one characteristic at a time improves prediction considerably in most instances. Considering the small sample size involved in each of the groups with the exception of Chincho, the major value of the multiple correlation with parsimony probably lies not in the derived R values but in the indication of which body characteristics are the prime predictors of the body temperatures. Table 3 summarizes for each of the body temperature measurements the prime predicting body characteristic and the next most important contributing characteristic.

Age, St.H = Standing Height, St.H = Sitting Height, BW = Weight, % BF = Percent Fat, FFW = Fat Free Weight, SSF = Sum of Skinfolds

Even when considering simple prime predictors the limitations imposed by the small sample size should not be neglected. Therefore, only the consistent and over-all trends should probably be considered and minor shifts of prime predictors from one time period to another may be considered statistical artifacts. The results of this analysis indicate some variation from the conclusions which were derived on the basis of simple correlations. In some instances the findings from the simple correlations were reinforced. For example, in the U. S. White sample fat-free weight and skin folds remain highly significant in relation to mean weighted skin and rectal temperature. The two University student populations do not show consistent differences in the prime contributors when body characteristics are related to rectal or mean weighted skin temperature by this method. However some differences between the student groups remain. Age appears to be the prime predictor for toe temperature in the Indian students while body weight is more significant in the White group. Whether there is a significance to this difference or whether it is simply the product of random variation cannot be determined until larger groups from the same populations are studied. Within the Chinchero Indian group multiple correlation again shows age to be a prime factor in the measure of total body heat. Of secondary importance to mean weighted skin temperature and rectal temperature are measures of body fat. On the other hand, toe and hand temperatures do not seem to be as significantly affected by age and measures of fatness. Instead, total body size is of greater significance to these body temperatures.

Regression Analysis Although the U.S. White sample is small, the high correlations and conformance of findings to previous studies

of the relationship of body fat to body temperatures during cooling, make the further analysis of the relationship of body structure to temperatures useful. Regressions of body fat and fat-free weight to rectal temperature and mean weighted skin temperature are shown in Table 4.

Table 4

Regressions for predicting rectal and mean weighted skin temperatures from percent of fat in the body and fat-free weight.

120	Rectal Temp. = $.257x + 96.17$	Rectal Temp. = $.137x + 89.90$

Mean Weighted Skin Temperature

Time	% Body Fat regression	F.F.W. regression in Kgs.
0	M.W.S.T. = $-.385x + 86.64$	M.W.S.T. = $-.115x + 89.73$
20	M.W.S.T. = $-.512x + 87.50$	M.W.S.T. = $-.121x + 89.66$
40	M.W.S.T. = $-.521x + 87.20$	M.W.S.T. = $-.106x + 88.41$
60	M.W.S.T. = $-.489x + 86.57$	M.W.S.T. = $-.107x + 88.17$
80	M.W.S.T. = $-.579x + 87.72$	M.W.S.T. = $-.115x + 88.99$
100	M.W.S.T. = $-.526x + 87.45$	M.W.S.T. = $-.168x + 88.63$
120	M.W.S.T. = $-.433x + 86.38$	M.W.S.T. = $-.110x + 88.66$

Both fat-free weight and body fat show positive slope association with rectal temperature. These slopes are fairly steep indicating a strong effect of these variables upon rectal temperature. Over the cooling period, from the initial reading to the final reading, there is an increase in the steepness of the slope. This is not consistent from one time period to the other but it appears that over the total time

period there has been an increase in slope. This would suggest that both fat-free weight and body fat increase in their significance in association to rectal temperature as the body is further cooled by cold exposure. The regressions between body fat and fat-free weight with mean weighted skin temperature show the opposite slope, that is, the higher the body fat and the higher the fat-free weight, the lower the skin temperature. This agrees with previous findings that fat acts as insulation. The negative relationship between fat-free weight and skin temperature may be a valid finding or may simply be a product of the high correlation between body fat and fat-free weight in this small sample. The slopes show a tendency to become steeper as the cooling time increases, again suggesting that at least body fat has an increasing significance to skin temperature with the passage of time in the cold.

The two University student populations were not submitted to regression analysis not only because of small sample size but also because there is no comparable material on larger populations.

Only in the Cinchero group is the sample size sufficiently large to provide reasonable regression slope estimates. The simple correlations and the multiple correlations suggest that the fat-free weight and the percent of body fat are the two most significant body characteristics in relationship to the temperature of the toe. Regressions for these two variables are presented in Table 5.

Table 5:

Regressions for predicting toe temperature
from fat-free weight and % body fat.

Chincheró Indians

Time	F.F.W. Regression in K.	% Body Fat Regression
0	Toe Temp. = $.69x + 30.96^{\circ} \text{ F.}$	Toe Temp. = $-.82x + 72.43^{\circ} \text{ F.}$
20	Toe Temp. = $.61x + 33.74^{\circ} \text{ F.}$	Toe Temp. = $-.98x + 72.44^{\circ} \text{ F.}$
40	Toe Temp. = $.52x + 27.44^{\circ} \text{ F.}$	Toe Temp. = $-1.05x + 72.11^{\circ} \text{ F.}$
60	Toe Temp. = $.47x + 38.86^{\circ} \text{ F.}$	Toe Temp. = $-.83x + 69.24^{\circ} \text{ F.}$
80	Toe Temp. = $.39x + 42.81^{\circ} \text{ F.}$	Toe Temp. = $-.66x + 67.78^{\circ} \text{ F.}$
100	Toe Temp. = $.32x + 45.60^{\circ} \text{ F.}$	Toe Temp. = $-.46x + 65.44^{\circ} \text{ F.}$
120	Toe Temp. = $.26x + 48.14^{\circ} \text{ F.}$	Toe Temp. = $-.33x + 64.14^{\circ} \text{ F.}$

The regression of fat-free weight to toe temperature is a positive one indicating that the larger the mass of the fat-free body, the higher the toe temperatures. The slope of the regression decreases through the cooling period indicating that with the passage of time in the cold, the fat-free weight gradually loses its significance to toe temperature. This does not mean however that there is no association remaining at the end of the cooling period. Indeed the correlation remains significant throughout. However, the toe temperature of the largest man shows a greater drop from initial to final readings than the toe temperature of the smaller man. The relationship between body fat and toe temperature is negative indicating that the larger the amount of body fat the lower the toe temperature. The slopes of the regression do not show a consistent trend during the cooling. Instead for the first forty minutes the slope of the regression increases, thereafter it decreases.

Regressions for hand temperature based on body weight and sitting height are presented in Table 6. These characteristics were chosen because of the correlation they bear to hand temperature and the importance shown by multiple correlation with persinacy.

Table 6

Time	Body Weight Regression in Kg.	Sitting Height in Cm.
0	Hand Temp. = $.30x + 64.50^{\circ} F$	Hand Temp. = $.68x + 29.70^{\circ} F$
20	Hand Temp. = $.25x + 64.02$	Hand Temp. = $.41x + 44.70$
40	Hand Temp. = $.17x + 69.93$	Hand Temp. = $.37x + 45.69$
60	Hand Temp. = $.14x + 67.59$	Hand Temp. = $.39x + 43.03$
80	Hand Temp. = $.20x + 64.42$	Hand Temp. = $.46x + 37.39$
100	Hand Temp. = $.25x + 61.37$	Hand Temp. = $.35x + 46.19$
120	Hand Temp. = $.21x + 62.71$	Hand Temp. = $.55x + 42.84$

The body weight and sitting height regressions to hand temperature are both positive, indicating greater body weight and higher sitting height are both associated with higher hand temperatures. In neither case does there appear to be a consistent change in the slope of the regression during the cooling period.

Rectal temperature prediction is made on the basis of age and sum of skin folds. Table 7 presents these regressions. Age shows a negative regression slope to rectal temperature, i.e. the older the individual the lower the rectal temperature.

Table 7

Regressions for predicting rectal temperature
from age and sum of skin folds.

Chinchoro Indians

Time	Age in years	Sum of Skin folds in Mc.
0	Rectal Temp. = $-.0099x + 99.25^{\circ} \text{ F}$	Rectal Temp. = $.018x + 98.29^{\circ} \text{ F}$
20	Rectal Temp. = $-.013x + 99.25$	Rectal Temp. = $.020x + 98.13$
40	Rectal Temp. = $-.016x + 99.25$	Rectal Temp. = $.019x + 98.09$
60	Rectal Temp. = $-.018x + 99.14$	Rectal Temp. = $.021x + 97.82$
80	Rectal Temp. = $-.019x + 99.07$	Rectal Temp. = $.024x + 97.59$
100	Rectal Temp. = $-.020x + 99.10$	Rectal Temp. = $.026x + 97.35$
120	Rectal Temp. = $-.023x + 99.05$	Rectal Temp. = $.025x + 97.37$

Sum of skin folds has a positive regression slope, showing the higher the sum of skin folds the higher the rectal temperature. Age shows a consistent trend over the cooling period with the slope of the regression becoming steeper as body heat is lost. This suggests that age has an increasingly important role in rectal temperature with the length of time the person is cooled. Despite some variation during the first three time periods of measurements there appears to be an overall rise in the steepness of the slope when relating skin folds to rectal temperature also suggesting that the importance of the fat thickness increases with the length of time of cooling.

In Table 8 mean weighted skin temperature prediction is shown on the basis of age. No other variable showed consistent significant correlation to mean weighted skin temperature. The association is negative indicating that the older the individual the lower the mean weighted skin temperature.

Table 8

Regression for predicting mean
weighted skin temperature from age

Chincheró Indians	
Time	Age in years
0	H.W.S.T. = $-.012x + 86.33$
20	H.W.S.T. = $-.020x + 85.95$
40	H.W.S.T. = $-.015x + 85.22$
60	H.W.S.T. = $-.011x + 84.71$
80	H.W.S.T. = $-.017x + 84.89$
100	H.W.S.T. = $-.025x + 85.01$
120	H.W.S.T. = $-.027x + 84.97$

During the first hour of cooling no consistent change of the slope of the regression appears, but during the second hour of cooling the regression slope increases in its steepness, again suggesting that age has increasing importance in the mean weighted skin temperature with the extension of body cooling.

Discussion and Conclusions

The analysis of body characteristics in relation to temperature responses in the four groups of this study has shown that in high altitude cold exposure, body fat is significant to the rate of cooling, and as has been shown at lower altitudes for U. S. Whites it acts as insulation. Despite the smallness of the U. S. White sample the data also suggest that the mass of the fat-free body should be considered as a significant factor in the rate and degree of body cooling.

In the analysis, significant differences between the U. S. White and the Chinchero Indian groups were found. Age was the prime factor in the Indian groups in relation to overall indices of body cooling, while fat and fat-free weight were of prime importance for the Whites. Nevertheless, this should not be interpreted as necessarily signifying a functional difference between the populations. The age range in the U. S. White sample was much more limited than the age range in the Indian sample and the body fat range was much greater in the U. S. White sample than it was in the Indian group. It is therefore possible that the differences in the selection of prime predictors and in the significance of correlations was an artifact of sampling and not a real difference in the populations.

The careful matching of the two University of Cuzco student populations should make the data obtained from their study helpful in choosing between the alternatives of sampling and real group differences. The results of the student comparisons suggest that the White and Indian may not respond identically, and body characteristics may not have the same relationship to cooling responses in the two groups. However, firm conclusions do not seem warranted, because of the small sample sizes and the restricted range of age and fatness in these populations.

Within twenty minutes after the beginning of the cooling exposure, the toe temperatures of the U. S. Whites reached almost ambient temperature and they remained at this level throughout the test period. The lack of variability within the group made any significant correlation between toe temperatures and body characteristics impossible. Toe temperatures for the student groups are also low, though not as low as

the U. S. Whites. Only the Chinchero Indian group maintained toe temperatures substantially above ambient temperatures. As shown by regression analysis, the maintenance of toe temperature was not universal for the Chinchero individuals. The small, thin Chinchero man had a toe temperature as low as the U. S. Whites and only the heavier and fatter individuals maintained elevated reading.

These results support the suggestion that the Chinchero Indians have a higher metabolic response to cold exposure. Since fat free weight is the prime factor in prediction it might be deduced that the greater mass of metabolically active tissue produces more heat and this is reflected in greater heat flow to the extremities.

The results of the hand temperature analysis can be interpreted as supporting this suggestion. However, the group differences are not so clearly defined, perhaps because more arm movement than leg movement was permitted during the test.

The overall body temperature measurements of rectal and mean weighted skin temperature also suggest such an interpretation since the negative relationships between age and these measures may reflect the declining ability of the body with age to support maximal heat production.
