SYNOPSIS

Texas Instruments Incorporated has been engaged in studies of seismicity and related fields for approximately three years. The purpose of this study was to obtain a quantitative estimate of the low-magnitude seismicity which constitutes noise in a seismic monitoring system used for the detection and identification of nuclear explosions. This research effort, which began in May, 1961 under Contract AF 19(604)-8517, was sponsored by the Air Force Cambridge Research Laboratories (AFCRL) as part of the Advanced Research Projects Agency (ARPA) Project VELA UNIFORM.

Since the inception of this effort, many contributions have been made toward the understanding of seismicity and seismology in general. In this Final Report little purpose would be served by repeating verbatim what has been published in previous Semiannual or Special Reports; however, for readers interested in such detail, an annotated bibliography is provided in Appendix B.

The primary objective of this report is to evaluate and document seismic activity that occurred in 1963. The following is a synopsis of major results of this effort.

A. SEISMICITY

1. General

It is apparent from the 1960 and 1963 studies that several gaps appeared in the worldwide coverage of earthquakes. The capabilities of some of the standard stations were limited to such extent that there was insufficient areal coverage. In several regions of the earth it is doubtful that many earthquakes of magnitude 4.5 (m_b) were recorded by a sufficient number of stations to permit complete evaluation, while many events of magnitude less than 4 likely went undetected.

Additional factors must be considered in identifying events which have occurred in known seismic areas. Relatively remote, sparsely populated areas where earthquakes of magnitude 3 or 4 may occur should be treated as highly suspicious areas with regard to clandestine testing of nuclear devices. All the northwestern quarter of China is, in this sense, a suspicious area; indeed, it was in this area that the Communist Chinese detonated their first nuclear device. The European and Central Asian seismic zones of the USSR are relatively densely populated and are near many stations outside the USSR; however, along the border between the USSR, China and Mongolia lie areas of poorly defined seismicity. An event of magnitude less than 4 anywhere in this region may be expected. Relatively few

stations outside the USSR and China or within their political influences are capable of recording events of magnitude 4 within the adjacent Chinese territory. The same may be said of the Northeastern Siberia area within the Arctic seismic belt.

Kamchatka must not be overlooked as a potential test site; while closer than the other areas to good stations outside the USSR, it is still quite distant from sensitive stations in Japan, Alaska and Canada. The high recurrence frequency of earthquakes in the magnitude-4 range compounds the problem of identification of nuclear explosions since criteria for discrimination must be applied to a large number of events.

2. Magnitude

The following observations are apparent from the study of magnitudes:

a. Magnitudes as presently calculated require several corrections which are not very well determined. For example, empirical studies indicate a large variation of amplitude with azimuth.

b. Magnitudes determined from P-waves are influenced by instrument type. For teleseisms, short-period instruments generally yield magnitudes about one unit less than long-period instruments.

c. Magnitudes calculated for events at shadow-zone distances frequently are much too high in comparison with those calculated for events at teleseismic distances. The implication is that the A_2 curve has values too high for some regions of the earth.

d. The apparently anomalous relationship between the m_b scale, recently adopted by the USC&GS and AFTAC, and the widely used Richter scale, M , may be explained by the different rules for measuring P-amplitudes by instrument band-pass characteristics and by possible shadow-zone effects. At approximately 16 degrees Δ and greater the relationship between m_b and M_S becomes approximately $M_S = m_b + 0.8$.

B. NOISE STUDIES

1. Visual Methods

Digitized noise spectra were compared with visual evaluation of the noise. It was concluded that a visual evaluation will yield a measure of the average peak amplitudes as seen by the observer and cannot be directly related to the amplitude or energy density content of the noise record.

Therefore, visual analysis should be limited to estimating expected noise which will be the most obvious and possibly the most disturbing to the observer, e.g., small high-frequency oscillations.

Conclusions from visual interpretation of noise based on 1960 and 1963 data were difficult due to the scarcity of information. The study indicated, however, that (1) areas of low microseisms over continents and high microseisms over oceans showed seasonal variation, (2) two- to ten-second microseisms are strongest in the winter months and are probably generated by oceanic storms, and (3) storm-generated microseisms are strongly attenuated at continental margins.

2. Polarity Method

Experiments have revealed that the most practical method of obtaining relative noise-power density spectra from film recordings is by polarity processing. Distortion of the spectra can be predicted and corrective procedures applied when using the polarity method. This method has been demonstrated to be both theoretically sound and experimentally verifiable.

From a study of noise spectra obtained from 1963 recordings it was observed that near 1 cps the slope (db/octave) on the average changed from approximately 25 db/octave to 90 db/octave or 45 db/octave. The steeper noise spectral slope may be associated with local movement of fronts; whereas the intermediate slope may be associated with storms.

C. EARTHQUAKE STUDIES.

Several fault-plane solutions were attempted using the P-polarity method. Although these events show few P-polarities which are inconsistent with the solution, little confidence can be placed in any tentative solution as all solutions contain some nodal figures which were arbitrarily drawn; the data will allow other configurations. Use of S-data has permitted the exclusion of some possibilities in fault-plane orientation as well as exclusion of certain mechanism types.

Attenuation patterns in the vicinity of nodal lines were evaluated for a few events. The calculated magnitude in the vicinity of the nodal surface in one example was found to be about one unit lower than that in a location far removed from the nodal surface.

Two distinctly different polarity and attenuation patterns were found in studying a suite of Kurile Islands shocks; however, similar polarity patterns yielded similar attenuation patterns. It has been suggested that identification of the polarity patterns from attenuation data recorded at a

limited number of stations may be practical. Before this can be accomplished, however, much more research must be conducted to resolve problems concerning regional travel times and phase attenuations.

WORLDWIDE SEISMICITY, 1963

SECTION I

DEFINITION AND SUMMARY

A. OBJECTIVES

Annual numbers of earthquakes which might be confused with nuclear explosions are of great importance to VELA UNIFORM. Providing additional data for estimating such numbers is the primary objective of this study.

Prior to the publication of the report on worldwide seismicity in 1960, little was known of seismic activity below $M_S = 6.0$ on a worldwide basis. That report succeeded in extending knowledge of seismicity down to $M_S = 5.0$. However, the 1960 report showed, as was generally known, that seismic activity is subject to sometimes extreme variations from year to year. Hence, the apparent necessity for a more extended seismicity study resulted in this 1963 study.

Using nearly the same methods developed and standardized in the 1960 study, the following objectives were set:

- Documentation of seismic activity during 1963
- Comparison with seismicity in 1960 and other years
- Definition of areas having unusual activity in 1963
- Estimation of seismic activity in magnitude ranges and geographical areas of primary interest to VELA UNIFORM

In addition to studies performed in the 1960 effort, magnitudes on the USC&GS scale (m_b) were calculated. Thus, 1963 seismicity data are available for the same time period, same events and from the same suite of stations based upon both the old and the new magnitude scales, and the results are compared.

It was also necessary to ascertain the capabilities of the suite of stations to record seismic activity. These capabilities were determined from the calculation of theoretical limits of perceptibility and the results obtained were used in estimating the lowest magnitude for which worldwide data may be considered complete.

B. METHODS

Little change has been effected in the methods employed in the 1960 study. (The major change has been mentioned, i.e., the addition of the m_b calculation.) Data reduced from the USC&GS Standard Stations and three of the Canadian seismograph stations are summarized in Table I. All amplitudes are $\frac{\text{peak-trough}}{2}$.

TABLE I
PHASES ANALYZED FOR 1963 DATA

Phase	Definitions and Remarks	Measured On:
PU	Maximum A/T in first few cycles of P	SPZ only
P	Maximum A/T in P group	SPZ, LPZ
PP	Maximum A/T, when P not observed	SPZ, LPZ
S	Maximum A/T	All components
R	Maximum A of surface waves, $T = 20$	LPZ, SPZ
L	Maximum A of surface waves, $T = 20$	LPN& E, SPN& E
MZ	Maximum A& T of surface waves, $17 \leq T \leq 23, T \neq 20$	LPZ, SPZ
MH	Maximum A& T of surface waves, $17 \leq T \leq 23, T \neq 20$	LPN& E, SPN& E

These data are recorded on analysis sheets from which IBM data cards are punched. One header card containing information about the event and one or more phase cards containing trace measurements are punched for each station event. These cards serve as input to a five-stage computer program employing an IBM 1401 for the first and last stages and an IBM 7094 for the remaining stages.

The first stage of the program is a pre-edit routine which checks all cards for completeness and disallowed entries and transfers the correct data to magnetic tape. Data in the input tapes are listed by station. In the second stage of the program, trace measurements are converted to ground motion in microns using a library of response curves for the instruments at each station. In the next stage, magnitudes are computed and a set of statistics are developed for each magnitude method and each station. Magnitudes calculated and methods employed are shown in Table II. Statistics

TABLE II

MAGNITUDE CALCULATION DATA

METHOD	EQUATION	INPUT	RESTRICTIONS	SOURCE
USC&GS m_b	$m_b = \log \frac{A}{T} + A_2$	$\frac{A}{T}$ for P _u phase in μ/sec A_2 = depth-distance factors for P phase	$2^\circ \leq \Delta \leq 110^\circ, h = 0$ $5^\circ \leq \Delta \leq 110^\circ, 0 \leq h \leq 700 \text{ km}$	USC&GS (1963)
Max. P	$M = 1.59 \left(\log \frac{A}{T} - 2.5 + A_2 \right)$	$\frac{A}{T}$ for P phase in μ/sec A_2 = depth-distance factors for P phase	$1^\circ \leq \Delta \leq 110^\circ, h \leq 200 \text{ km}$ $5^\circ \leq \Delta \leq 110^\circ, h > 200 \text{ km}$	Richter (1958)
PP	$M = 1.59 \left(\log \frac{A}{T} - 2.5 + A_4 \right)$	$\frac{A}{T}$ for PP phase in μ/sec A_4 = depth-distance factors for PP phase	$25^\circ \leq \Delta \leq 180^\circ$	Richter (1958)
S	$M = 1.59 \left(\log \frac{A}{T} - 2.5 + A_3 \right)$	$\frac{A}{T}$ for SH phase in μ/sec , A is vector amplitude if recorded on both components of horizontal set (SPN&E, LPN&E) A_3 = depth-distance factors for SH	$10^\circ \leq \Delta \leq 110^\circ, h \leq 175 \text{ km}$ $1^\circ \leq \Delta \leq 110^\circ, h > 175 \text{ km}$	Richter (1958)
Vertical component surface waves, $T = 20$	$M = 0.8 (\log A_{20} - \log B + 0.0082 h + M_R)$ $M = 0.5 (\log A_{20} - \log B + 0.0082 h + M_R)$ $M = 0.5 (\log A_{20} - \log B + 0.85 + M_R)$	A_{20} in μ for R phase $\log B = f(\Delta)$ M_R = path correction	$20^\circ \leq \Delta \leq 180^\circ, h \leq 40 \text{ km}$ $20^\circ \leq \Delta \leq 180^\circ, 40 < h \leq 100 \text{ km}$ $20^\circ \leq \Delta \leq 180^\circ, 100 < h \leq 300 \text{ km}$	Bath (1952)
Horizontal component surface waves, $T = 20$	$M = \log A_{20} - \log B$	A in μ for L phase, A is vector amplitude if recorded on both horizontal components of matched set.	$20^\circ \leq \Delta \leq 180^\circ, h \leq 35 \text{ km}$	Richter (1958)
Vertical component surface waves, $17 \leq T \leq 23$, $T \neq 20$	Same as R except $\log A_{20} = \log A_T + \frac{1}{2} \log \frac{20}{T} + 24.13$ $(K_T - K_{20}) \Delta$	A_T for MZ in μ , and T in sec $\log B = f(\Delta)$ K_T, K_{20} = extinction coefficients for T and T = 20	Same as R	Bath (1952)
Horizontal component surface waves, $17 \leq T \leq 23$, $T \neq 20$	Same as L except $\log A_{20} = \log A_T + \frac{1}{2} \log \frac{20}{T} + 24.13$ $(K_T - K_{20}) \Delta$	Vector amplitude of MH or single amp for MH in μ , T in sec $\log B = f(\Delta)$ K_T, K_{20} = extinction coefficients for T and T = 20	Same as L	Bath (1952)

accumulated for each method of magnitude determination are:

ALPHA	Average difference between calculated and published magnitudes
BETA	Standard deviation of ALPHA
GAMMA	Maximum algebraic value of ALPHA
SIGMA	Minimum algebraic value of ALPHA
ETA	Number of times each method has been compared to published values

The values of ALPHA are corrections which are added to each magnitude for $\Delta > 16^\circ$ except for m_b . In the case of m_b , the uncorrected value is retained and another m_b is derived which has the correction applied at all distances. Weights based upon these statistics are assigned each method. In general, these weights are unity except where the statistics show general unreliability of the method. Also, surface-wave magnitudes computed from short-period instrument data are weighted less due to the decreased reliability of instrument response data at longer periods.

Using these weights and corrections, magnitudes for each event at each station are averaged in the fourth stage as follows:

$\overline{M}_P$	=	mean of corrected short- and long-period maximum P-magnitudes, or if P not recorded,
$\overline{M}_{PP}$	=	mean of correct short- and long-period PP magnitudes.
$\overline{M}_{SH}$	=	mean of long- and short-period SH magnitudes,
$\overline{M}_{LR}$	=	weighted average of corrected surface wave magnitudes.

The values of the USC&GS unified magnitude (m_b) are kept separate from these magnitudes throughout the program. The final magnitudes calculated for each event at each station consist of $\overline{M}_S$, (the mean of $\overline{M}_P$, $\overline{M}_{SH}$ and $\overline{M}_{LR}$), m_b and corrected m_b .

In the final stage of the program all values of $\overline{M}_S$, m_b and corrected m_b are averaged for the same events. These are the calculated magnitudes shown in the event list found in Appendix A.

In this report, seismicity is defined as the annual number of earthquakes per unit area, in the magnitude ranges $5.0 \leq M_S < 6.0$. The unit area chosen is approximately the size of a five-degree grid on the earth's surface at the equator (about 3×10^5 square kilometers). The procedure followed is to divide the earth along each five degrees of longitude, starting at the prime meridian, and in latitude, north and south of the equator at 5, 10, 15, 20, 25, 30.5, 36, 42, 49, 57, and 67 degrees. The number of earthquakes in the magnitude ranges $5.0 \leq M_S < 6.0$ which lie in each of the nearly equal 1728 unit areas are counted. On the seismicity map the number counted is placed within the unit area and contours drawn to delineate different levels of seismicity.

Various epicenter maps, showing the geographical distribution of earthquakes in 1963, are drawn. Two maps are drawn for earthquakes of magnitude $M_S \geq 4.0$ — one for shallow and normal depth foci and another for intermediate and deep earthquakes. A similar set of two maps are drawn for events of $m_b \geq 4.0$. Magnitude ranges indicated are 4.0 to 5.0, 5.0 to 6.0 and greater than 6.0 for both M_S and m_b . Deep focus earthquakes are differentiated from intermediate by showing intermediate depth events as open circles and deep as closed circles.

C. SUMMARY OF OBSERVATIONS

Data were reduced and processed from the records of 72 seismograph stations in 1963. All but three of the stations were part of the USC&GS Worldwide Standard Station Network. The other three stations were part of the Canadian seismograph station network and were located in the Canadian Arctic.

Based upon the investigations undertaken in this study, plus search of available bulletins for additional epicenter locations, it was determined that about 11,600 events were recorded during 1963. About 4800 events are listed in Appendix A representing the known epicenter locations in 1963. Worldwide data are considered complete above magnitude 5.0 (m_b and M_S). Numbers of shocks $M_S \geq 5.0$ were:

	Shallow ($h \leq 70$ km)	Intermediate (70 km $< h < 300$ km)	Deep ($h > 300$ km)
$5.0 < M_S < 6.0$	1000	239	95
$6.0 \leq M_S < 7.0$	158	26	11
$7.0 \leq M_S < 7\text{-}3/4$	8	1	1
$M_S \geq 7\text{-}3/4$	<u>0</u>	<u>1</u>	<u>0</u>
Total	1166	267	107

These data give relationships between number and magnitude as follows:

- (1) Shallow — $\log N = 8.00 - 0.96 M_S$,
- (2) Intermediate — $\log N = 8.14 - 1.11 M_S$, and
- (3) Deep — $\log N = 6.70 - 0.92 M_S$.

The circum-Pacific belt accounted for about 76, 85 and 93 percent of shallow, intermediate and deep focus activity ($M_S \geq 5.0$) in 1963.

The remainder of the deep focus shocks were located in the Sunda arc. Most of the activity outside the circum-Pacific belt was located in the Alpide, although the oceanic ridges and rises were rather well defined by shallow seismic activity.

The southern Kurile Islands were the most active single area in 1963, although the Kermadec-Tonga Islands area had the greatest amount of intermediate and deep-focus shocks. Besides the Kurile-Kamchatka area, activity in the USSR was located east of the Caspian Sea along the border with Iran, in the Caucasus Mountains and in Central Asia near the Hindu Kush.

Activity in southern Chile was lower than in 1960 by a considerable margin, after less than three years following the onset of the great earthquake swarm of 1960.

D. PRINCIPAL CONCLUSIONS

In 1963 the numbers of shallow earthquakes $M_S \geq 6.0$ were about the same as the mean annual numbers given by Gutenberg and Richter (1954) while more shocks in the range $5.0 < M_S < 6.0$ were recorded than predicted by Gutenberg and Richter. In comparison to 1960, seismic activity was quite low, mostly due to the reduction in activity in southern Chile.

However, in most regions fewer shallow shocks were observed in 1963 than in 1960. Two exceptions were the Kurile and Aleutian Islands, particularly the former.

Activity at depths deeper than normal was considerably increased over 1960. Part of this increase may be only apparent since hypocenter determination has been improved over that in 1960 due to the greater number of high-quality stations and use of electronic computer capabilities in processing seismic data.

Analysis of 1963 seismicity, plus reference to the 1960 study and other works in seismicity, enable a worldwide system of fault traces to be sketched. These tectonic features outline continental and oceanic stable areas.

Comparison of statistics based on M_S and m_b shows apparent inconsistencies from region to region, related to the proximity of seismograph stations to active zones. Somewhere between 15 and 20 degrees distance, the relationship between m_b and M_S becomes approximately $M_S = m_b + 0.8$. At distances less than about 15 degrees, a different relationship (one very near Richter's $m = 0.63 M_S + 2.5$) seems to hold.

Lack of consistent results in relating the two scales and in comparing m_b data from region to region, compounds the problem of estimating the numbers of shallow shocks which might be confused with nuclear explosions in the USSR and China. Estimates of annual numbers of expected shallow earthquakes $4.0 \leq M_S < 5.0$ can be made, however. These estimates are: Kuriles and Kamchatka — 1500; other USSR activity — 50; China — 100. The estimated worldwide shallow earthquakes ($4.0 \leq M_S < 5.0$) was 9000.

E. RECOMMENDATIONS

Seismicity studies should be continued, with emphasis placed on the accumulation of statistics on smaller shocks ($M_S < 6.0$). The work of Gutenberg and Richter (1954) essentially established the trends in the geographical distribution of seismic activity. However, their studies were based on data for large shocks only, and activity in the magnitude range of interest to VELA UNIFORM was inferred from statistics of much larger magnitudes. The studies of 1960 and 1963 seismicity extended the range of knowledge down to $M_S = 5.0$ and showed that the estimates of Gutenberg and Richter for annual numbers of earthquakes in the range $5.0 \leq M_S < 6.0$ were probably too low. Only the accumulation of more statistics can substantiate this conclusion.

Use of the unified magnitude scale m_b , based upon the maximum amplitude of P or P_n within the first few cycles, began with VELA UNIFORM stations in 1962 and became widespread only with the adoption of the scale in early 1963 by the USC&GS. Considerable difficulty was encountered in relating the new scale to the Richter magnitude M_S , although it was found that a relationship of the type ($m_b = M_S + \text{constant}$) fit the data as well as any (VESIAC Magnitude Conference, April, 1963). Most of the m_b magnitudes were based on teleseismic recordings. This 1963 seismicity study also shows such a relationship is valid for teleseismic recordings. However, at closer distances the two scales do not appear to relate in this manner. Consequently, it is recommended that continued study of the relationship between m_b and M_S be made, emphasizing the dependence, if any, upon distance. Study of amplitude variations as a function of distance should be an integral part of such studies.

VELA UNIFORM is particularly interested in the seismicity of USSR and China, and more specifically, in determining the expected annual numbers of earthquakes in these areas which might be confused with nuclear explosions. In addition, the precise determination of the locations where this activity may be expected to occur is of considerable importance. In order to satisfy these needs more adequately than is currently possible, two recommendations are offered:

- (1) The establishment of more high-quality seismograph stations, with the capability of monitoring seismic activity down to magnitude 4.0 in USSR and China, distributed so as to improve the azimuthal coverage of these areas, and
- (2) Continued improvement in techniques for determining earthquake hypocenters, employing maximum use of computer technology and including recent developments in the understanding of the earth's crust and upper mantle variations. Along with this, confidence limits should be established on the hypocenters to provide estimates of the precision of locations.

SECTION II

PRESENTATION OF DATA

A. WORLDWIDE RESULTS

The 1963 seismicity was, as is usual, concentrated in the circum-Pacific belt. Of those earthquakes for which $M \geq 5.0$, 76 per cent of the shallow, 85 per cent of the intermediate and 93 per cent of the deep focus shocks were located in the circum-Pacific seismic belt. Other seismic activity occurred in the Alpide zone (principally in the Eastern Mediterranean, Hindu Kush to the western Himalayas, southern Sumatra and eastern Java, and the eastern extremity of the Sunda arc), in the Caribbean loop and along most of the oceanic ridges and rises.

Figures 1 through 5 illustrate the geographical distribution of seismic activity in 1963. Figures 1 and 2 show plots of epicenters for which $M_S \geq 4.0$. Epicenters in Figure 1 are only for shallow and normal focus shocks ($h \leq 70$ km) while epicenters in Figure 2 are for both intermediate ($70 \text{ km} < h \leq 300$ km) and deep-focus ($h > 300$ km) earthquakes. Figures 3 and 4 parallel Figures 1 and 2 in content, except that in these figures, epicenters are shown for which $m_b \geq 4.0$. Figure 5 is a seismicity map which shows annual numbers of earthquakes per unit area in the magnitude range $5.0 \leq M < 6.0$. The unit area chosen is approximately the size of a 5-degree grid, or 3×10^5 square kilometers.

Several features of 1963 seismicity, as illustrated in Figures 1 through 5, are of particular interest. These are:

- (1) The earthquake swarm in the Kurile Islands which began 12 October. Several minor swarms occurred earlier in the year, such as in June and July, and may have been heralding the onset of the major activity.
- (2) The clear delineation of oceanic ridges and rises by seismic activity. The mid-Atlantic ridge is well outlined by earthquake epicenters, as are the ridge systems in the Indian Ocean and the Southeastern Pacific.
- (3) The return of activity in southern Chile to near that level existing before the great earthquake swarm of 1960.
- (4) Somewhat increased activity along the southern USSR border in the vicinity of the Caucasus Mountains and in the Kopet-Dag region.

- (5) Greatly increased intermediate depth activity in the Banda Sea-Molucca Passage area. The only "class a" ($M > 7\frac{3}{4}$) earthquake recorded in 1963 (magnitude 8.2), coordinates 6.8 S; 129.6 E; depth, 80 km; date, 4 November; 01:17:09 GCT was located in this area.

A more detailed analysis of the geographical distribution of seismic activity as pictured in the first five figures, plus consultation of similar data for 1960 seismic activity, reveals a clear pattern of stable areas surrounded by zones of varying seismicity levels. By tracing these seismic zones and extrapolating some of their trends, the major tectonic features of the earth or global zones of maximum stress may be defined. Beginning at a point just off the east coast of Kamchatka at about 65 degrees north, a fault system may be traced through the Komandorskie Islands along the Aleutian Island arc extending up the Alaska peninsula and the Aleutian range to about the Arctic Circle north of Fairbanks (this may extend on to the northern coast of Alaska) where a sharp turn to the southeast may be traced. From this point, the tectonic system trends along the coast and then just off the Alexander archipelago to the Queen Charlotte Islands, where a lesser zone branches off to Vancouver Island (and possibly connects to the activity in Montana-Wyoming-Utah area across Idaho), while the main branch parallels the Washington and Oregon coasts, some 400 or 500 kilometers off shore, to about 45 degrees latitude north, where it curves back to the California coast at about the point where the San Andreas fault disappears into the ocean. After reaching the coast, the fault system follows along the coast ranges into southern California where an intersection is made with a fault system trending along the strike of the Sierra Nevadas (this may be connected with the branch through Vancouver Island, thus forming a loop about a small stable area in western Oregon) and continuing down to and through the Gulf of California, then south along the 110th west meridian to the Revilla Gigedo Islands, where another turn (approximately 90 degrees) in the trace leads to an intersection with the Jalisco, Mexico coast.

Just off the coast at this point another branch occurs. The main branch continues along the coasts of Mexico and Central America while the other branch trends generally south to about the equator and then curves to the southwest toward Easter Island. The main branch continues along the Central America coast to the Peninsula de Azuero, where it leaves the Panama coast and continues in a southerly direction to about 5 degrees north latitude and turns sharply to the east. From this point, yet another branch extends westward to the Galapagos Islands (this branch may connect with the Easter Island-to-Revilla Gigedo Islands branch).

 $(5.0 \leq M < 6.0)$

Figure 5. Worldwide Seismicity for 1963, Based on Annual Numbers of Earthquakes $(5.0 \leq M < 6.0)$ Per Unit Area 23/24

Upon reaching the Colombia coast, the main branch divides into two parts: one continues along the coast of South America; the other crosses northern Colombia to the Venezuela coast east of Lake Maracaibo, and continues along that coast to Trinidad, where it follows the trend of the Lesser Antilles and then back to the west along the Greater Antilles to Jamaica and across to Honduras, forming the Caribbean loop.

The southern branch continues along the Colombia and Ecuador coast to northern Peru, where another division is made; the major fault system continues along the coast, while a lesser system follows along the eastern side of the Andes to about the eastern Bolivia-Argentina border where it curves more to the west to rejoin the coastal branch at about 30 degrees south latitude. These recombined branches continue southward along the coast to about 45 degrees south latitude. At this point, these branches intersect with a branch from the Easter Island vicinity, which completes a loop in the southeast Pacific.

A lack of epicenters south of Easter Island to about 50 degrees south latitude renders a connection between the Easter Island tectonic system and that in the south Pacific between 50 and 60 degrees south latitude and 110 and 140 degrees west longitude, somewhat hypothetical. The same may be said for a connection between this last mentioned zone and that in the Macquarie Islands area. However, a system of rises exists here which is considered the boundary of the Pacific basin. The remoteness of this area from land masses, and thus from seismograph stations, makes location of shocks of magnitude less than 5.0 difficult. Hence, the existence of fracture zones along these ridge systems is not improbable, although such zones are certainly less active than in the better known portions of the circum-Pacific belt.

From the Macquarie Islands two zones may be traced. One follows northward in a long arc through New Zealand, Kermadec Islands and Tonga Islands to the Samoa-Fiji Islands area. Here it follows a shorter arc through the Fijis to the New Hebrides, where it bends northward along the New Hebrides arc to the Solomon Islands, through the Solomons to New Britain and along the northern coast of New Guinea to the Molucca passage where an intersection is made with the Alpide zone at the eastern end of the Sunda arc.

At this point, the trace turns northward along the eastern side of the Philippine Islands to Formosa and up the Ryukyu Islands to Japan. Branching southward from southeastern Honshu, another fault zone passes through the Volcano Islands, the Mariana Islands and into the Caroline Islands where it terminates. Apparently, there is no connection between this point and the Bismarck archipelago. Thus, this branch does not completely enclose the Philippine Sea.

The zone in Japan continues along eastern Honshu to Hokkaido and up the Kurile Islands arc and eastern Kamchatka, the starting point of our trace. Thus, it is seen that a continuous trace of fault zones of varying activity may be traced completely about the Pacific Ocean.

Earlier it was mentioned that two zones may be traced from the Macquarie Islands. The second follows along the Indian-Antarctic swell south of Australia trending toward Madagascar. At about 30 degrees south latitude, 70 degrees east longitude, an intersection is made with a zone extending southward from the Persian Gulf. From this intersection a line may be inferred curving south and west to an intersection with the southern extremity of the mid-Atlantic ridge in the Bouvet Islands area, and continuing westward to the Sandwich Islands and South Shetland Islands, through Drake Passage and then curving upward along the extreme south Chilean coast to meet the more active zone in southern Chile at about 45 degrees south latitude. By returning to Southern Chile, a continuous zone of relatively low activity has been traced around the stable Antarctic continent.

From the Bouvet Islands, the mid-Atlantic ridge zone follows a nearly northerly direction to about the equator where it turns sharply west to about 30 degrees west longitude and then curves north and east to the Azores, where a northerly direction is resumed. The shocks which have occurred off the coast of Portugal (not in 1963) may imply a connection between the Alpide zone and the mid-Atlantic zone westward from the Azores to Morocco.

The Alpide zone extends from Morocco along the Algerian coast up to southeastern France, then across northern Italy, the Yugoslav coast, Greece, Cyprus, Turkey, the Caucasus Mountains, northern Iran, Afghanistan, the Himalayas and northern Burma, where the zone turns sharply south down to the Andaman and Nicobar Islands and then follows the Sunda arc to the intersection with the circum-Pacific zone.

Several branches of the Alpide zone may be observed. Beginning at the western end of the Alpide zone, the first branch appears as a southern extension of Caucasus Mountains portion of the Alpide zone and follows that trend along the Iran-Iraq border and the eastern shore of the Persian Gulf. The branch then enters the Arabian Sea following the coastline of the Arabian peninsula to about 55 degrees east longitude where an intersection is made with a previously mentioned branch which continues southward into the Indian Ocean. Also from 55 degrees east longitude, a zone continues west through the Gulf of Aden and joins the African rift zone. The possibility also exists that the African rift is connected with the Indian Ocean zone eastward from Southern Rhodesia across Madagascar.

Traces now have been completed which surround the stable portions of Africa, continuing our pattern of stable areas separated by fault zones.

Another branch from the Alpidic zone occurs at the Hindu Kush. This zone extends along the Pamirs, into Sinkiang, China, Mongolia, and northward to Lake Baikal in the USSR. Also, several small loops may be observed in western China which follow along mountain systems and separate stable plateaus.

The zone extending to Lake Baikal may be connected with the Arctic zone across eastern Siberia but seismic evidence for such a link is lacking. Available data tends to show, rather, that a loop is formed by a zone extending south across Mongolia and central China.

The northern end of the mid-Atlantic zone joins the Arctic zone north of Iceland. The Arctic zone then turns eastward toward Norway and north to Spitzbergen and Svalbard and continues on, remaining south of the North Pole, to the Laptev Sea and across Eastern Siberia to Sakhalin Island, intersecting the circum-Pacific zone at Hokkaido.

Thus, the picture of worldwide tectonic features is complete. The stable masses of the Americas, Eurasia, Africa, Antarctica and Pacific basin are seen to be surrounded by large scale fracture zones. Some exceptions to the pattern also appear. Among these are: absence of a connection between the Leeward Islands and the mid-Atlantic ridge; no apparent zone through the Red Sea to isolate the Arabian peninsula from Africa; no apparent zones to separate the Indian shield, the eastern Indian Ocean and Australia; and the gap between the Caroline Islands and the Bismarck archipelago.

A statistical view of seismicity is presented in Tables III and IV which present statistics in terms of M_S and m_b , respectively. Data are shown for all recorded shocks above magnitude 3.0 in each case, although worldwide coverage is considered complete only above magnitude 5.0 (M_S and m_b). S, I and D refer to shallow ($h \leq 70$ km), intermediate ($70 \text{ km} < h \leq 300 \text{ km}$) and deep ($h \geq 300 \text{ km}$) focus earthquakes, respectively. Regions are as given by Gutenberg and Richter (1954). The column on the right show the percentage of worldwide activity ($M \geq 5.0$ or $m_b \geq 5.0$) which occurred in 1963 in each region.

For comparison purposes, Table V shows similar data obtained in the 1960 study. On the basis of earthquakes for which $M_S \geq 5.0$, 1963 seismicity was at a lower level, worldwide, than in 1960. In 1963, a total of 1,540 shocks at all depths ($M_S \geq 5.0$) were recorded as compared to

REGIONAL MAGNITUDE STATISTICS 1960 (M_S)30

1,693 in 1960. However, the number of intermediate and deep-focus earthquakes in 1963 exceeded the totals in 1960; 267 and 107 compared to 227 and 81 in 1960. A contributing factor in this apparent increase in deeper-than-normal depth activity is probably the improved depth determination in 1963 resulting from use of electronic computers and the availability of more data from an increased number of high-quality seismograph stations.

The decrease in shallow and normal focus activity may be attributed in part to the marked decrease in seismic activity in Southern Chile, compared to the extremely high level existing in 1960. As mentioned, the depth determination improvement probably resulted in fewer shocks being considered shallow when the depth actually exceeded 70 km.

Another comparison of 1963 seismicity can be made with the results of Gutenberg and Richter (1954). Their statistics show mean annual numbers of shallow earthquakes as: $M \geq 7\frac{3}{4}$ -2; $7.0 \leq M < 7\frac{3}{4}$ -12; $6.0 \leq M < 7.0$ -108; and $5.0 \leq M < 6.0$ -800. Similar figures for 1963 are 0, 8, 158, and 1000. The numbers of earthquakes $\pm 1/4$ magnitude unit above magnitude 5.0 were determined for the 1963 data and a linear least-squares solution of the form $\log N = a - b M_S$ was determined for all three depth classes. Figure 6 shows the points plotted and the least-squares solutions. The values found were:

shallow	$a = 8.00 \pm 0.09, b = 0.96 \pm 0.04,$
intermediate	$a = 8.14 \pm 0.10, b = 1.11 \pm 0.02,$
deep	$a = 6.70 \pm 0.05, b = 0.92 \pm 0.01.$

Modifying the results of Gutenberg and Richter (1954) to the same format as above yields:

shallow	$a = 7.42 \pm 0.02, b = 0.90 \pm 0.02,$
intermediate	$a = 9.1 \pm 0.02, b = 1.2 \pm 0.2,$
deep	$a = 8.4 \pm 0.02, b = 1.2 \pm 0.2.$

The 1960 data were sorted only into numbers per unit of magnitude. However, an estimate of values of "a" and "b" for 1960 are:

shallow	$a = 6.99,$	$b = 0.83,$
intermediate	$a = 6.21,$	$b = 0.83,$
deep	$a = 7.66,$	$b = 1.21.$

Considerable variation is apparent in these determinations. It appears that the average of 1963 and 1960 shallow activity would result in a relationship closer to that found by Gutenberg and Richter, although the

Figure 6. Worldwide Earthquake Recurrence Curves Based on 1963 Data

number of shocks less than magnitude 6.0 still would be larger than the estimate of Gutenberg and Richter (1954). Intermediate and deep-focus data may be too small a sample to yield valid results for mean annual activity as more variation is apparent in the recurrence relationships for these depths.

Statistics were also accumulated based upon the USC&GS unified magnitude, m_b , and are presented in Table IV. Many more earthquakes are listed for $m_b \geq 3.0$ than for $M_S \geq 5.0$. However, inspection of the data shows fewer events for $m_b \geq 5.0$ than $M_S \geq 5.0$. In comparing results of individual event magnitude calculation, it appeared that for the very small shocks, m_b was larger than M_S ; while for the bigger shocks, m_b was usually less than or equal to M_S . Most of the smaller shocks were recorded by stations near the epicenter while the larger events were recorded at teleseismic distances; therefore, an investigation of the differences in the two magnitude scales as a function of distance was warranted. Figures 7 and 8 illustrate the results of this investigation.

Figure 7a is a plot of the differences ($M - m_b$) as a function of distance. Here, M is called M_{TOT} , which means it is the average of both body and surface wave magnitudes (when both are recorded). Considerable scatter is apparent; however, a dependence on distance seems to exist up to about 15 to 20 degrees. Beyond this point a horizontal line at $(M_{TOT} - m_b) = 0.8$ seems to fit the data rather well. Figure 7b is a similar comparison except m_b is subtracted from surface wave magnitudes only. No dependence upon distance is readily discernible and the same horizontal line, as in the previous figure, fits the data.

Figure 8 represents a further investigation of the relationship between m_b and M_S . Figures 8a—8d plot m_b as a function M_{TOT} in various distance ranges; 8a — $\Delta \leq 6$ degrees, 8b — $6 \text{ degrees} < \Delta \leq 16$ degrees, 8c — $16 \text{ degrees} < \Delta \leq 30$ degrees and 8d — $\Delta > 30$ degrees. In Figures 8a and 8b, the slope of the linear best-fits appears to be different from 45 degrees. In 8c and 8d, lines with slopes of 45 degrees and intercepts of 0.6 to 0.8 seem to give good fits.

Figure 8e plots m_b as a function of M_{RL} , the surface wave magnitude determined in this study. The reduction in the magnitude range available for plotting plus somewhat increased scatter in the points makes a linear fit to the points difficult. However, the lines determined for 8c and 8d would fit the data in 8e, also.

Figure 7a. $M_{TOT} - m_b$ as a Function of Epicentral Distance

Figure 7b. $M_{RL} - m_b$ as a Function of Epicentral Distance

Figure 8. Unified Magnitude m_b Versus (a) M_{TOT} , $0^\circ < \Delta < 6^\circ$; (b) M_{TOT} , $6^\circ < \Delta < 16^\circ$; (c) M_{TOT} , $16^\circ < \Delta < 30^\circ$; (d) M_{TOT} , $\Delta > 30^\circ$; (e) M_{RL} , $\Delta > 30^\circ$.

This brief investigation of the $m_b - M_S$ relationship shows further work is needed to yield valid results in comparing seismicity data based upon the two scales. Comparison of Tables III and IV shows wide variation from region to region in the relationship of the two scales. In general, regions where stations are located yield different results than where recordings are made from only distant seismograph stations. For these reasons, a detailed comparison of seismicity based upon the two magnitude scales is deemed unfeasible at this time.

B. REGIONAL DISCUSSIONS

Regional trends of seismic activity have been indirectly covered in the worldwide discussion. The following will be an elaboration in more detail of regional seismicity. Figure 9 shows the regional boundaries, adopted from Gutenberg and Richter (1954), and the geographical distribution of the seismograph stations from which data were used in this study. The stations and their coordinates are listed in Table VI.

1. Circum-Pacific Belt

Activity in the Aleutian arc followed the classic Pacific type. In general, shallow and normal focus earthquakes were located along the arc away from the Pacific. This is shown graphically in Figures 10 and 11. Epicenters of the intermediate depth shocks are, however, not significantly displaced from the shallow depth epicenters. If, as has been postulated, hypocenters fall along a plane dipping into the earth, this plane dips very steeply, approaching the normal, in the Aleutian arc. No deep-focus activity is found in this region.

Seismic activity in 1963 increased over 1960 for both shallow and intermediate depths as is shown by comparing data for Region 1 in Tables III and V. However, one shock of $M > 7.0$ was recorded in 1960 and none in 1963. Percentage of worldwide activity increased from 4.5 and 4.8 to 6.6 and 5.6 for shallow and intermediate shocks, respectively.

Region 2 extends from southeastern Alaska to Puget Sound. Only shallow activity is found in this region and that accounted for only 0.1 percent of worldwide totals in 1963 and 0.2 in 1960. The most seismic area of the region occurs from Queen Charlotte Islands to Vancouver Island.

California and the adjacent areas comprise Region 3. Here, also, only shallow earthquakes occur (in southern California, particularly, they are quite shallow) and in 1963 accounted for only 0.2 per cent of the worldwide totals. Seismicity in 1963 decreased sharply from 1960 and in both years appears less than the mean annual values of Gutenberg and Richter (1954).

* Not plotted on Station Location Map.

Figure 9. Seismic Regions* and Location of Seismograph Stations Used in 1963
 *(Adapted from Gutenberg and Richter, 1954)

Similar observations as the preceding hold true for Region 4. Only shallow earthquakes are observed, with most of those observed in 1963 occurring at the northern end of the Gulf of California and on the adjacent mainland. Shallow shocks in this region were about 0.2 percent of the worldwide totals ($M \geq 5.0$). Activity in 1960 was somewhat greater (0.3 percent) and for both years, less than Gutenberg and Richter's mean annual numbers.

Regions 5 and 6 include Southern Mexico and Central America. Seismic activity follows along the coast lines of this area in typical arcuate structure of Pacific activity. Intermediate depth earthquakes occur in the southern part of this arc and epicenters exhibit little or no lateral separation from the shallow epicenters. Thus, the plane defined by the hypocenters is nearly vertical in this region. Figures 12 and 13 show epicenters in these regions.

Activity in the range $M \geq 5.0$ is less than half that of 1960 for both shallow and intermediate depth. Percentages in 1963 were 2.1 and 3.5 and in 1960, 4.3 and 8.8 for shallow and intermediate activity ($M \geq 5.0$). Thus, in 1963, intermediate activity was about that shown by Gutenberg and Richter while shallow activity was considerably less. In 1960, shallow activity was still less than that given by Gutenberg and Richter and intermediate, considerably more.

Region 7 is the Caribbean loop. In 1963, activity in this region occurred principally in Colombia. Some intermediate shocks were located in Colombia and in the Windward Islands. About 0.1 percent of shallow and 2.2 percent of shallow and intermediate earthquakes ($M \geq 5.0$) were located in this region. In 1960 the percentages were 1.5 and 0.9, respectively.

The Andean zone stretches from Colombia to southern Chile and includes Regions 8 and 9. Figures 14 and 15 show epicenters in Regions 8 and Figures 16 and 17 show epicenters in Region 9, for 1963. Deep-focus shocks as well as shallow and intermediate were located in Region 8 (to 37 degrees south latitude); while in 1963, only shallow earthquakes occurred. A progressive landward displacement may be observed in the epicenters except in Argentina, where both intermediate and shallow epicenters are found in the same areas. The assumption to be made here is that generally, the plane defined by hypocenters does not dip as sharply as observed in the Aleutians and Central America.

In 1960 the activity in Region 9 was the primary feature of the seismicity map. However, in 1963 comparatively little activity is noted in this area. A dramatic comparison can be made in the numbers of shallow shocks ($M \geq 5.0$) recorded in each year — 230 in 1960 and only 10 in 1963. The Andean zone as a whole in 1963 made up 4.9 percent of the shallow activity, 9.7 percent of the intermediate and 2.8 percent of the deep. In 1960 the comparable figures were 19.8, 15.0 and 0.0 percent. Shallow activity exceeded Gutenberg and Richter's mean annual values in both years, although not greatly so in 1963. Shocks deeper than normal were less compared to Gutenberg and Richter's data in both years.

Region 10 is included in the circum-Pacific as a loop similar to the Caribbean loop by Gutenberg and Richter (1954), although it would appear more closely connected with the mid-Atlantic ridge based on 1963 data. Activity is centered in the Sandwich Islands, where three intermediate shocks were located in 1963. Shallow shocks in the southern Antilles were 2.1 percent of the worldwide totals ($M \geq 5.0$) and intermediate 1.1 percent.

The eastern and southern Pacific activity (Regions 43 and 44) was restricted to the oceanic ridges and rises, as discussed in the worldwide results. Only shallow shocks ($M \geq 5.0$) were located in these regions in 1963 and these were 2.7 percent of such worldwide activity. This represents an increase over 1960 and about the same as that found by Gutenberg and Richter.

Region 11 includes the area from the Macquarie Islands to New Zealand. The only intermediate depth activity occurs in New Zealand. In 1963, more activity was found in the Macquarie Islands area. New Zealand experienced little seismic activity in 1963. Percentages for the region were 0.4 and 1.1 for shallow and intermediate depths, respectively.

Regions 12 and 13 include two arcs at about right angles. The larger and most active trends northward from New Zealand through the Kermadec and Tonga Islands to the Samoa Islands. The other trends westward from the Samoa Islands through the Fijis to the New Hebrides. Epicenter plots for these regions are shown in Figures 18 and 19. Intermediate and deep-focus shocks occur mainly in the north-south arc. Here again, we see the feature of lateral separation of shallow, intermediate and deep focus epicenters. The separation appears intermediate between that in South America and in the Aleutians and the deeper focus shocks occur away from the Pacific side of the arc.

Shallow activity is somewhat decreased from the level of 1960 while intermediate and deep-focus activity is increased. Percentages for 1963 are 16.4, 13.5 and 73.8 for shallow, intermediate and deep-focus activity.

In 1960 similar figures were 16.7, 10.6 and 69.1. Both years' data indicate considerably higher activity than the data of Gutenberg and Richter (1954).

The New Hebrides to Loyalty Islands arc is included in Region 14. This arc is concave toward the Pacific and trends generally north-south. Here, shallow activity appears greatest on the west side of the arc, intermediate-focus epicenters lie along about the same portion of the arc and, in 1963, deep-focus shocks were located to the east, or Pacific side of the arc, reversing the usual situation in Pacific structures. Epicenters in this region are shown in Figures 20 and 21.

Percentages of worldwide activity ($M \geq 5.0$) in Region 14 during 1963 were 3.1, 10.9 and 0.9 for shallow, intermediate and deep focus, respectively. This compares with 4.3, 6.6 and 0.0 in 1960. Shallow and intermediate activity appears less than Gutenberg and Richter's mean values and deep-focus activity about the same.

From the Solomon Islands through New Guinea (Regions 15 and 16) three separate arcs of activity were observed. All trend more or less east-west. Shallow activity was greatest in the easternmost arc while that deeper-than-normal was observed mostly in the center arc, the New Britain area. This intermediate and deep-focus activity is again located on the side of the arc away from the Pacific with little lateral separation in epicenters from shallow through deep-focus earthquakes. Thus in this area, the plane defined by hypocenters is dipping quite sharply. Epicenters in these regions are shown in Figures 22 and 23.

Percentages of worldwide activity in 1963 ($M \geq 5.0$) were 6.5, 13.0 and 2.8 for shallow, intermediate and deep focus, respectively. In 1960 the percentages were 5.9, 11.5 and 4.9. In comparison to Gutenberg and Richter's mean annual numbers, shallow activity was less in both years, intermediate considerably higher and deep about the same.

Region 23 is an area of considerable complexity. It includes the Celebes, Moluccas and Ceram. Epicenters for the region and some adjacent areas are shown in Figures 24 and 25. Seismic activity occurred along a series of intersecting arcs: one stretches from Mindanao through Halmahera, the Molucca Passage and Ceram, connecting with the New Guinea activity; an arc along northern Celebes intersects the first arc at Halmahera; and also the eastern end of the Sunda arc intersects the first arc in the southeastern Banda Sea. Shallow activity was greatest in the Halmahera-Molucca Passage area in 1963. Intermediate activity was greatest in the southern Banda Sea where some deep-focus earthquakes were located. Considerable intermediate depth shocks were located north of Halmahera, also.

Percentages in 1963 ($M \geq 5.0$) were 4.4, 11.2 and 1.9 for shallow, intermediate and deep, respectively. In 1960 these percentages were 5.6, 2.2 and 1.2. Comparing with Gutenberg and Richter's mean annual values, it is seen that 1963 and 1960 shallow activity was somewhat higher, 1963 intermediate activity considerably higher and in 1960 about equal to the average, while deep-focus activity was also higher in both years.

In the Philippines (Region 22) two arcs were observed: one convex toward the Pacific along eastern Mindanao and Samar; and another concave along western Luzon, extending up to Formosa. Both shallow and intermediate activity were concentrated in the southern end of the first arc and the northern end of the second arc. Some deep-focus shocks were located in south Mindanao. Figures 26 and 27 show the epicenters in the Philippines during 1963.

Percentages of worldwide activity ($M \geq 5.0$) in 1963 were 2.1, 3.4 and 0.9 for shallow, intermediate and deep, respectively. In 1960 these percentages were nearly the same, namely 2.4, 3.1 and 1.2. In comparison to Gutenberg and Richter's values, these represent low shallow activity, normal for intermediate and high activity for deep focus.

Region 21 includes Formosa where the concave arc from Luzon terminates and a convex (toward the Pacific) arc begins, extending up the Ryukyus. Activity is centered off the east coast of Formosa and is mostly shallow focus. In 1963 about 1.2 percent of the shallow and 0.4 percent of the intermediate shocks ($M \geq 5.0$) were located in Region 21.

The Ryukyu arc extends northward along the east coast of Kyushu and shallow earthquakes generally occur along the east side of the arc, although a few are located a considerable distance to the west in the East China Sea. Intermediate depth epicenters are generally to the west of the shallow, as usual in Pacific structures. Percentages in 1963 were 1.0, 1.1 and 0.9 for shallow, intermediate and deep, respectively. In 1960 these percentages were 0.9, 2.6 and 0.0. These data reflect lower-level seismicity than that given by Gutenberg and Richter. Figures 28 and 29 show epicenters in the region during 1963.

From southern Honshu southward, an arc concave to the Pacific extends down to the Marianas and a second arc, convex to the Pacific, continues down through the Caroline Islands. Regions 17 and 18 include these arcs. The Mariana Islands constitute the most active part of these regions. Shocks of all depth classifications occur throughout the arcs. The usual Pacific feature of lateral separation of the deeper earthquake epicenters away from the Pacific may be observed. In 1963 the two regions had 2.1, 3.7 and 5.6 percent of the shallow, intermediate and deep-focus activity ($M \geq 5.0$). In 1960 these percentages were 2.0, 4.0 and 7.4, representing

little difference in the two years' data. Gutenberg and Richter's data indicates somewhat higher shallow and intermediate activity than in 1960 and 1963 but about the same level for deep. Figures 30 and 31 picture epicenter locations in Regions 17 and 18.

Region 19 includes Japan (except Kyushu), the Kuriles and Kamchatka. Epicenters in Japan are shown in Figures 32 and 33. The greater activity is from central Honshu to southern Hokkaido along an arc convex to the Pacific. Shallow shocks cluster along the eastern side of the arc and intermediate depth epicenters are located west of the shallow. Deep shocks are located in the Sea of Japan and eastern Manchuria (Region 46) and are usually considered as structurally related to the shallow and intermediate earthquakes even though they appear isolated from the latter on epicenter maps.

Another convex arc begins east of Hokkaido and extends through the Kuriles and eastern Kamchatka. Epicenters along this arc are shown in Figures 34 and 35. In 1963 this arc was considerably more active than Japan. A large earthquake swarm occurred in the Kuriles in 1963 from about 44 to 47 degrees north latitude and 148 to 155 degrees east longitude, and was the most seismic area in that year. Other activity in the region occurred east of central Kamchatka along the Komandorskie Islands trending toward the Aleutians. The typical Pacific feature of intermediate and deep shocks located away from the Pacific was also noted here in 1963.

Percentages of worldwide activity in Region 19 (and 46) as a whole were 24.8, 9.0 and 3.7 for shallow, intermediate and deep, respectively. In 1960 these percentages were 8.0, 9.7 and 4.9. Compared to Gutenberg and Richter's data, 1963 activity was quite high for shallow, low for intermediate and quite low for deep. The 1960 shallow activity was somewhat low and other activity about the same as 1963.

2. Alpide Belt

The Sunda arc is included with the circum-Pacific by Gutenberg and Richter, although it does not front on the Pacific; probably because it is a Pacific-type structure. It extends from the Lesser Sunda Islands through Java and Sumatra to the Nicobar and Andaman Islands. Epicenters in 1963 show a wide gap between the Andaman Islands and Burma which was not so great in 1960. For this reason, it appears in this study that it is just likely to be included in the Alpide belt as the circum-Pacific.

In 1963, southern Sumatra and western Java were the most active areas in this region (Region 24). Considerable deep-focus activity was located north of Java while intermediate activity was along the arc and

south of Java. Percentages of worldwide activity ($M \geq 5.0$) in 1963 were 3.4, 9.0 and 4.7 for shallow, intermediate and deep, respectively. In 1960, these were 2.7, 4.0 and 3.7. Shallow activity was low both in 1963 and 1960, intermediate was normal in 1963, low in 1960 and deep was normal for both years, as compared to Gutenberg and Richter's data.

Excluding the Sunda arc, the Alpidic belt begins in northern Burma and trends along the Himalayas to the Hindu Kush. Regions 25 and 26 include these areas. Some intermediate activity occurred in northern Burma in 1963 although most activity was shallow. The shallow activity was greatest in northern Burma and the India-Tibet-Kashmir areas. Percentages of worldwide activity ($M \geq 5.0$) were 0.8 and 0. in 1963 and 1.5 and 2.2 in 1960 for shallow and intermediate, respectively.

Region 48 includes the Hindu Kush and the eastern part of Central Asian USSR. Figures 36 and 37 show epicenters in the region in 1963. The Hindu Kush occurs at the intersection of the Himalayan and Baluchistan arcs. Northeast of the Hindu Kush is the Pamir-Baikol block faulting zone. Shallow epicenters to the north in Figure 36 are associated with the latter zone and are the principal source of shallow activity in the USSR within Region 48, which is the most seismic area of mainland USSR (i. e., excluding Kamchatka and the Kuriles). Percentages of worldwide activity in 1963 were 0.4 and 3.4 for shallow and intermediate, respectively. In 1960 these percentages were 0.9 and 5.7. Intermediate activity was low in 1963 and about normal in 1960, compared to Gutenberg and Richter's data. Shallow activity was about normal in each year.

Region 29 includes Iran and the immediate vicinity, including the Kopet-Dag area of the USSR. A gap is shown in the Alpidic belt between the Hindu Kush and eastern Iran-USSR border region. In the latter area, a small amount of activity is shown in Figure 38 during 1963 while in 1960 no epicenters for shocks $M \geq 4.0$ were located here. Principal activity in Region 29 was along the north shore of the Persian Gulf. Activity observed east of this in 1960 was not observed in 1963. One intermediate shock of $M \geq 5.0$ was located in the region in 1963. Percentages of worldwide activity were 1.0 and 0.4 in 1963 and 2.4 and 0.4 in 1960 for shallow and intermediate, respectively. Compared to Gutenberg and Richter's data, 1963 activity was low and 1960 normal.

The eastern Mediterranean and Turkey are included in Region 30. Epicenters in the region are plotted in Figures 39 and 40. Principal activity, both shallow and intermediate, occurred along the coasts of Yugoslavia, Albania and Greece as well as in Cyprus. Some intermediate activity also occurred at the southwest coast of Turkey. Little activity in this region in 1963 was within the territory of the USSR. Percentages of

worldwide shallow activity ($M < 5.0$) were 1.0 in 1963 and 2.2 in 1960. Low for 1963 and normal for 1960 compared to Gutenberg and Richter's data.

The western end of the Alpidic belt includes activity in northern Italy and the North African coast. This is included in Region 31. Percentages of activity were 0.4 and 0.0 in 1963 and 0.6 and 0.4 in 1960 for shallow and intermediate, respectively, somewhat high in both years compared to Gutenberg and Richter's data.

3. Oceanic Ridges

As has been discussed, the mid-Atlantic ridge was well defined by seismic activity in 1963 and fairly well distributed throughout its length. In 1963 the percentage of shallow activity was 3.0 and in 1960 was 2.2. Both years represent low activity compared to Gutenberg and Richter's data.

Indian Ocean ridges and rises were also rather well defined by shallow seismic activity in 1963. Distribution of the shocks was covered in the worldwide discussion. In 1963 the percent of worldwide activity was 1.6 and in 1960 it was 1.2. Compared to Gutenberg and Richter's data, both years represent low activity for the region.

The Arctic belt (Region 40) was well defined from Iceland to about 80 degrees north latitude. Little activity was observed from that point into Siberia. In 1963, about 1.1 percent of shallow activity occurred in this belt and only 0.4 percent in 1960. The 1960 level is about normal in comparison with the Gutenberg and Richter data.

4. Non-Alpidic Asia

The Pamir-Baikal zone was active up to about the Mongolia-China border in 1963 and some activity was located around Lake Baikal and northern Mongolia. Some activity was also located along the mountain ranges in western China. Percentages of worldwide shallow activity were 1.2 and 0.7 in 1963 and 1960, respectively. Both years appear to have been low compared to the Gutenberg and Richter data.

5. Others

The remainder of the active seismic areas of the world are located in or near stable areas and shocks are generally small. These areas include North America, except the west coast, western South America, central Europe, the bulk of the USSR, Africa, the Arabian Peninsula and Australia.

SECTION III

CRITIQUE

A. GENERAL OBJECT

The study of worldwide seismic activity in 1963 was accomplished on a quantitative basis from data reduced from seismograms. Seismic activity above $M_S \geq 5.0$ was documented and described both worldwide and by regions, and comparisons made with the 1960 study and with activity in other years as represented by the data of Gutenberg and Richter (1954).

Magnitudes on the unified scale, m_b , were calculated and statistics accumulated. Inconsistencies in these data, however, precluded any meaningful comparison of seismic activity on the two scales.

B. APPLICABILITY OF METHODS

The computational methods employed in magnitude determination are in agreement with the originators of the magnitude scales involved. Unified magnitudes were studiously separated from other magnitude determinations from the beginning of data reduction through the computer output. The methods of magnitude averaging used were adapted from Båth (1954), who has tested the method for several years in determination of average magnitudes from recordings of Swedish seismograph stations.

Seismicity was presented as numbers-per-unit-area in the lowest magnitude unit for which data were complete, $5.0 \leq M \leq 6.0$. This method permits comparisons to be made of seismicity in various regions whether larger shocks occur in the regions or many smaller shocks are recorded. If larger shocks occur they distort, for comparison purposes, the picture of seismicity calculated by the summed energy method. Presence of numerous small shock recordings, such as in the United States, can give a false picture of the relative seismicity of a region, when seismicity is defined as the total number of shocks.

The divisions into shallow, intermediate and deep earthquakes were taken from Gutenberg and Richter (1954), as were the regional boundaries. Use of these allows direct comparisons to be made with the data published in "Seismicity of the Earth," the acknowledged source book for worldwide seismicity data.

C. ADEQUACY OF DATA

The stations from which data were received gave about as good azimuthal and areal coverage of the world as any combination of stations. Most of the stations possessing superior capabilities to those included in this study are located in the United States. Addition of these stations would add little to the azimuthal distribution of seismograph stations about seismic areas and their areal coverage would not extend far into the southern hemisphere where coverage is poorest.

Figures 41 and 42 show the combined theoretical perceptibilities of the stations used in the study. No figures are shown for $m_b = 5.0$, as earthquakes of this magnitude and greater should be recorded by at least five stations, no matter where the earthquakes are located. Figures 41a and 41b show those areas in the northern and southern hemispheres, respectively, covered by the network of stations used in this study. Only the South Atlantic, Antarctic, Indian Ocean and Southwestern Pacific earthquakes of $m_b = 4.5$ in are not recorded by five or more stations, although one to four stations should record down to $m_b = 4.5$ in practically all the above-mentioned areas. Coverage down to $m_b = 4.0$ is sharply reduced from that at $m_b = 4.5$, as is shown in Figures 42a and 42b. Only in North America is coverage by five or more stations relatively complete. However, one to four stations should record $m_b = 4.0$ earthquakes throughout the northern hemisphere. In the southern hemisphere, coverage is very poor.

Theoretical perceptibility is calculated by transposing the magnitude equation to read:

$$A_2 = m_b - \log \frac{A}{T} \quad (4)$$

where A_2 is the depth-distance factor used in calculating m_b and $\frac{A}{T}$ is the average maximum short-period noise amplitude divided by the period at each station in microns-per-second. Thus, the figures shown are an average situation which varies with the noise background.

Also, data were not available from all stations for every month of 1963. For example, some of the better standard stations were not installed until after the first of the year, others sent in records too late for copies to be obtained, and some records for certain days (especially in October during the Kurile earthquake swarm) were not sent in at all. Records from the Canadian stations for the last six months of the year were not analyzed, as they were received too late for analysis to be completed on schedule. For these reasons,

the coverage shown in Figures 41 and 42 is somewhat optimistic, although coverage above $m_b = 5.0$ is probably accomplished throughout the year.

D. QUALITY OF DATA

The Worldwide Standard Station Network represents the best seismic instrumentation ever installed on such a wide scale. Since the instrumentation is standard, comparisons of data made from different stations are more valid than ever before. However, it is apparent from inspection of the seismograms that there is considerable variation in operational quality of stations. Poor optical adjustment is a commonly encountered problem which negates the advantage of the superior equipment installed. When this problem is coupled with a high-noise background, records are rendered practically useless. Overall, the quality of data furnished for this study was superior to any available in the past on a worldwide basis.

E. VALIDITY OF CONCLUSIONS

Results of the 1963 study show variations from that of 1960 as well as from Gutenberg and Richter's (1954) data. Such variations from year to year have been observed and are expected. No study has been made to statistically determine the size of seismicity data samples necessary to give "true" average values, either worldwide or regionally. The periodic occurrence of earthquake swarms in the circum-Pacific belt, such as that in Chile (1960), the Kuriles (1963) and Alaska (1964), result in somewhat different pictures of worldwide seismicity than is obtained by the averaging of data collected over several years.

Conclusions concerning the distribution of seismic activity and supposed connections between seismically active areas are dependent upon the quality of hypocenter determinations. Such determinations were beyond the scope of this study and the hypocenters listed in the Appendix were, for the most part, determined by the USC&GS. The quality of these determinations would be sufficient for all but detailed studies, such as precise correlation with tectonic features smaller than regional.

Although the problem of relating the m_b and M_S magnitude scales has not been resolved by this study, the tentative conclusions concerning the distance dependence of the relationship are clearly indicated by the data. Results based upon teleseismic recordings are compatible with other studies. Therefore, work in this area should be considered as only pointing the direction for more detailed study in the future.

Key: Recorded by 5 or more stations.
 Recorded by at least one but less than 5 stations.
 Not Recorded.

Figure 41a. Areal Coverage by Stations Used in 1963 Seismicity Study,
 $m_b = 4.5$ (Northern Hemisphere)

Key:

	Recorded by 5 or more stations.
	Recorded by at least one but less than 5 stations.
	Not Recorded.

Figure 41b. Areal Coverage by Stations Used in 1963 Seismicity Study,
 $m_b = 4.5$ (Southern Hemisphere)

Key:

	Recorded by 5 or more stations.
	Recorded by at least one but less than 5 stations.
	Not Recorded.

Figure 42a. Areal Coverage by Stations Used in 1963 Seismicity Study for Normal Focus Earthquakes, $m_b = 4.0$ (Northern Hemisphere)

Key:

	Recorded by 5 or more stations.
	Recorded by at least one but less than 5 stations.
	Not Recorded.

Figure 42b. Areal Coverage by Stations Used in 1963 Seismicity Study for Normal Focus Earthquakes, $m_b = 4.0$ (Southern Hemisphere)

APPENDIX A

EVENTS LIST

The event list represents only information concerning those primary events ($M \geq 3$) which were recorded, located and/or assigned a magnitude during 1963. In addition to the 4797 events listed, other events were evaluated, including 6066 locals ($M < 3.0$) that were recorded and 746 teleseisms for which epicenters could not be obtained.

Epicenters located by individual stations and not reported by USC&GS were added to give a more complete list of events. Many station bulletins were scanned and a significant number of events was added after checking bulletins from Trieste, Italy, Strasbourg, France, Uppsala, Sweden, and Trinidad, B. W. I.

SYMBOLS AND ABBREVIATIONS

MAG	Average of published M_S values
MCGS	m_b reported by USC&GS on PDE cards
MTOT	Value of M_S computed in study
MB	Value of m_b computed in study
Local PMG 4.8°	Small event recorded at a certain station within a certain Δ° .

APPENDIX B

REVIEW OF PREVIOUS REPORTS

Contributions this program has made toward improving knowledge of seismicity and related studies during the past three years are provided for quick referral by the following summaries of reports submitted and published.

A. SEMIANNUAL TECHNICAL AND FINAL REPORTS

1. No. I, 20 November 1961

The first semiannual technical report pointed out many large gaps in the coverage of earthquakes in the magnitude range four to five. The reasons for these gaps were the limited capabilities of some established stations and insufficient areal coverage, even if all had been first order. In many regions of the earth, it is doubtful if earthquakes of magnitude five were recorded by a sufficient number of stations to permit evaluation, while shocks of magnitude four went undetected.

The report also discussed data collection, data interpretation problems and magnitude determination.

a. Data Collection

The study required a large number of records from many regions of the earth. Several methods of collection were tried and microfilming was found best.

Original seismograms were copied at seismograph stations with a Recordak portable microfilmer using 16-mm microfilm. This permitted a great amount of data to be amassed in a relatively short time.

Based on evaluation of several film viewers, Texas Instruments chose the Recordak MPC-1 for use with both 16-mm and 35-mm film. The principal advantage of the viewer is image adjustment which allows precise enlargement of the record.

b. Data Interpretation

Non-uniformity in time marks, time calibration, drum rate and instrument calibration was resolved by use of a standardized data collection

form and establishment of a portfolio of pertinent facts for each station visited. The analysis form and procedure included entries for the determination of magnitude, P/S ratios and amplitude of ground motion.

c. Magnitude Determination

Seismicity calculation depends upon accurate determination of earthquake magnitudes; therefore, considerable effort was made to investigate and refine determination methods.

Most events were recorded only by high-gain, short-period instruments. This limited the choice of magnitude methods to two: the original Richter near-event method and the body-wave method for P. Most of the high-gain, short-period instruments available were vertical component, thus the original Richter method could be used in only a very limited number of situations. This required that the attenuation curves for P used with the body-wave method be extrapolated to distances less than 5 degrees. An extrapolation was made and tested by comparing results with the original Richter method for stations where short-period horizontal instruments were available also. Both horizontal and vertical surface wave methods and others were used for teleseisms.

d. Determination of Radii of Perceptibility

When constructing maps of seismicity, it is desirable to know the limits of a station's capability to record an event of given magnitude. For very near shocks recorded on short-period instruments, the original magnitude formula may be extended to the instrument in use and $\log A$ determined for a given magnitude. A chart of $\log A_0$ versus Δ is given by Richter (1958), and an approximate range of perceptibility may be obtained if a certain amplitude signal is assumed to be necessary for magnitude determination.

Radii of station perceptibility can be estimated crudely at best, but these estimates show in general the amount of coverage to be expected with existing instrumentation.

2. No. II, 1 May 1962

This report contained discussions of magnitude determination, perceptibility calculations, seismicity evaluation and a method for obtaining relative noise power density spectra from polarity information.

a. Magnitude Determination

Station correction factors for magnitude determination were calculated routinely. The magnitudes obtained from short-period instruments for teleseisms were frequently one unit or more lower than those of the BCIS or the USC&GS, thus requiring some very large station corrections. These corrections, however, did not seem applicable to shocks at less than shadow-zone distances, which suggested that short-period seismic P-waves were attenuated at a higher rate than long-period P-waves for the paths affected by the shadow-zone mechanism. Longer period instruments indicated station corrections of less than half a magnitude unit. These instruments were similar to the ones used by Gutenberg and Richter in deriving the attenuation curves of P-waves. Additional study was suggested to determine the spectral content of P-waves and the manner in which the various components were attenuated as a function of distance.

b. Evaluation of Discrimination Criteria

A study of magnitudes showed that a considerable variation in the attenuation of P and S phases may be expected for different paths, particularly in the 6- to 20-degree range, and for short-period P-waves at teleseismic distances. Evaluation of radiation patterns expressed as P/S ratios or Rayleigh wave amplitudes must be assessed with knowledge of path attenuation variability which may be as great as the variation caused by source type. Thus, studies were initiated to determine attenuation functions of common earthquake phases as an aid to improving discrimination criteria as well as magnitude determination.

c. Radii of Perceptibility

Several calculated radii of perceptibility were verified by studies of magnitudes as a function of distance for shocks recorded by particular stations. The problem was shown to be a three-dimensional one where, in general, deeper focus shocks are perceptible over larger areas than are shallow-focus ones. The radii of perceptibility for shocks of magnitude five and larger often terminated in the shadow-zone region where the station correction was shown to change drastically. Much additional research would be needed to delineate this problem.

d. Noise Studies

A research program to determine practical methods of obtaining noise spectra from visual records was completed. A method utilizing only the polarity of the recorded trace was found to be a promising one for finding relative power density spectra.

3. No. III, 31 October 1962

a. Earthquake Recurrence Curves

Richter (1958) stated that the logarithm of the number of earthquakes of a given magnitude is a straight line function of the magnitude. That is: $\log N = a - bM$. For most areas of the world the only data available to assess the constants in this relation were from earthquakes of magnitudes greater than six. Because large earthquakes do not occur frequently, many years of data had to be analyzed before these constants were obtained and little was known concerning the accuracy of the formula when applied to smaller magnitude events. Initial studies under this program showed that the recurrence curve for small earthquakes varied in slope and intercept from region to region.

b. Noise Spectra

The theoretical details of a method to obtain relative power density spectra of noise from polarity data only were presented. Assumptions were justified and examples given.

c. Microseisms

Maps of ground motion during January, May and September, 1960, were constructed for the 6-second period microseism range. These contoured world maps showed a consistent pattern of high activity over oceans and lower activity over continents. Anomalous areas suggested that further research might be profitable. The study indicated that the noise seen on seismographs, although fundamentally ground motion due to external causes such as weather and surf conditions, is dependent to a great extent on instrument response characteristics. To study the true ground motion, records from similar, recently calibrated instruments must be used.

4. No. IV, 30 April 1963

Research efforts in several areas peripheral to the main seismicity theme were presented. These included fault motion studies, fault-plane mapping, channel phases and the azimuthal variation of Rayleigh waves.

a. Fault Motion Studies

Methods were developed for obtaining fault-plane solutions from P and S measurements made at a given instant in time. These methods did not require a great number of stations nor did they always require stations well distributed radially and azimuthally about the epicenter as does Byerly's (1955)

method. The equations were derived from those of Nakano (1923) which expressed the displacement of P, SH and SV at large distances from a Type 1 source (single couple with moment). Because of uncertainties in the amplitudes of SV and SH at distances shorter than 40 degrees, the method as developed at this time could be used only with very large teleseisms.

b. Fault Mapping

Fault-motion maps were presented to improve understanding of major fault motions in seismic areas. It was not anticipated that these maps would be of immediate aid in detecting nuclear explosions; however, the study has long-range application. That is, after obtaining a better and more accurate picture of the fault motions around the world, it may be much easier to identify atypical events.

Generally, there is a close relationship between faulting and major tectonic features. Original fault patterns are easily recognized in many areas. Fault-plane solutions from first motion are limited to shocks of magnitude greater than six. However, if fault patterns and constancy for small shocks in a given area are similar to those of large shocks, first-motion polarity, S-polarization and amplitude patterns should be consistent and would constitute diagnostic means for separation of atypical events in a given area.

c. Channel Waves

An investigation was made of parameters affecting propagation of some channel phases. A few records of the Russian test series of 1961 and GNOME were scanned for indications of select phases such as Pa and Sa, which were discovered by Caloi (1953). No conclusive picks could be made.

This failure is probably due to instrument limitations and lower energy release rather than the mechanism involved.

According to Bath (1962), continental channel waves are propagated from blasts as well as earthquakes; hence, their presence or absence from recordings is not indicative of either type of mechanism. Channel waves are not recommended as criteria for discrimination between earthquakes and underground nuclear explosions.

d. Surface Wave Radiation Patterns

Radiation patterns about earthquake epicenters were obtained by:

- (1) Plotting residuals of published magnitudes subtracted from calculated magnitudes,

- (2) Plotting maximum trace amplitude, corrected for epicentral distance at all stations recording surface waves, and
- (3) Determining and comparing the same seismic peak at various stations.

All methods showed some promise of yielding information on patterns of surface-wave radiation about a source. However, there are several variables and potential errors such as path dependence and magnification errors which must be considered.

Considering these factors, the radiation pattern method of identification is recommended only as minor supporting criteria. The worldwide standardized stations should improve the capability to evaluate radiation patterns because of matched instrumentation and better known instrument response curves. However, path dependence, station distribution and human error in identification will still present problems.

Determining amplitude variations with azimuth by Brune's (1961) method requires records from similar long-period instruments recently calibrated. It is necessary to know the approximate phase velocity or the crustal thickness between the epicenter and station or between adjacent stations. Most earthquake records do not satisfy the criteria necessary for this method.

e. Appendices

Several very useful appendices were included. They presented the theory of the newly developed fault-plane solution method, a study of the large Chilean earthquake sequence of 21 May to 1 June 1960 using these methods, a summary of 300 events for which fault-plane solutions were obtained from the literature, and travel time curves for several channel waves.

5. No. V, 31 October 1963

This Semiannual Technical Report was presented in the following three volumes:

a. Volume I — Review of the Program

A general discussion of the 1960 and 1963 studies and a review of procedures, methods and problems encountered in the previously mentioned reports.

b. Volume II — Station Assessment

Capabilities of seismograph stations in existence in 1960 are discussed in this volume. An integral factor in accurate epicenter determination is a capable network of stations. For that reason, the task of assessing or evaluating seismograph stations was undertaken. Based upon this study, which included perceptibility, instrumentation, noise level and personnel, twenty-three stations were selected for best recording capabilities in 1960.

c. Volume III — Noise Spectra

Methods for obtaining absolute noise spectra and ground motion from relative spectra are described in this volume. It was concluded that the combined accuracy limitations of the average noise power estimates and instrument calibrations limit absolute power density estimates for 1960 data to about an order of magnitude. Relative power densities not less than about two and one-half orders of magnitude below the peak power density of a particular spectrogram are accurate.

6. No. VI, Earthquake Studies, 17 June 1964

This report contained discussions of polarity studies, fault-plane studies and attenuation studies.

a. Polarity Studies

The polarity method of fault-plane solutions requires the observation of polarity at a number of stations. Data from Sprengnether instruments of the Worldwide Standard Seismograph network showed waveforms of P and S could be traced across areas of continental dimensions and larger. Ability to follow the waveform has allowed polarity determinations which were highly consistent with the general polarity pattern.

b. Fault-Plane Solutions

Fault-plane solutions were attempted for several earthquakes using the P-polarity method. Although these events show few P-polarities which are inconsistent, little confidence can be placed in any tentative solution. Since all solutions contain some nodal figures which were arbitrarily drawn, the data will allow other configurations. Use of S-data has permitted the exclusion of some possibilities in fault-plane orientation as well as exclusion of certain mechanism types.

c. Attenuation Studies

Attenuation patterns in the vicinity of nodal lines were evaluated. In one instance, the attenuation pattern was not clear; in another it was found that the calculated magnitude in the vicinity of the nodal surface was on the order of one unit lower than the calculated magnitude far removed from the nodal surface.

Two distinctly different polarity and attenuation patterns were found in a suite of Kurile Islands earthquakes; similar polarity patterns, however, yielded similar attenuation patterns. Evidence is presented which suggests that it may be practical to identify the polarity patterns from attenuation data recorded at a limited number of stations.

7. "Worldwide Collection and Evaluation of Earthquake Data," 15 January 1960, Final Report on 1960 Seismicity Evaluation

A quantitative view of seismicity results from this study, since data are presented which allow direct comparison of earthquake activity from region to region. Magnitude data are much more complete than previously available from any other source.

To provide a comprehensive view of seismic activity, several presentation methods are used; among them are seismicity and epicentral maps which permit both a region-to-region comparison of activity and a comparison of the 1960 activity with the average annual seismicity.

Emphasis in this study was placed upon earthquakes in the magnitude range 5.0 to 6.0 (Richter scale) because capabilities of the seismograph stations furnishing data were sufficient for recording all shocks of magnitude 5.0 or greater. Many shocks of magnitude 3.0 to 5.0 were also recorded and results are given for these events.

Magnitude calculations, which accounted for a large portion of work in this study, are given for as many events as possible. These calculations permit energy classification of nearly all earthquakes listed in bulletins of the Bureau Central International de Seismologie (BCIS) for 1960. Publication of these magnitude data allow better assessment of the earth's seismicity and also enables seismologists to evaluate, quantitatively, capabilities of the seismograph stations which recorded the listed earthquakes.

B. SPECIAL REPORTS

In addition to the Semiannual Reports, ten special reports have been submitted:

1. "Seismogram Atlas of Nuclear Explosions," 6 April 1962, Report (Unnumbered)

This includes seismograms collected from worldwide stations for the USSR nuclear test series of October, 1961, and recordings of the GNOME shot by eight U. S. and foreign stations. The atlas presents a sampling of records from 978 to 8044 kilometers epicentral distance.

For the atmospheric explosions, surface waves from similar sources at the same station seemed to duplicate themselves. No Love waves were observed from atmospheric explosions at teleseismic distances.

2. "Provisional Appraisal of First-Motion Data," 22 January 1963, Special Report No. 1

The percentages of undefined polarity and the predominance of a single polarity on records from one station indicate that first motion may be unreliable criteria for identifying seismic events.

3. "Russian Seismicity Methods and the Seismicity of the USSR and China," 20 February 1963, Special Report No. 2

Russian literature concerning seismicity methods and seismicity of the USSR and China was reviewed. It was shown that much of the Sino-Russian border and the whole northwestern quarter of China is relatively seismic for small events. These regions or the highly seismic Kamchatka Peninsula would be ideal sites for concealed underground tests. A controversy in the Russian literature concerning whether earthquake recurrence is or is not a linear relation was reviewed. Work under the seismicity project shows that each region has its own recurrence characteristics.

Seismic areas in the USSR probably do not exceed ten percent of the country's total area, but about half of continental China is subject to earthquake activity. A map was prepared showing areas of perceptibility for magnitude-four events for most high-gain modern stations near, but outside, the USSR and China. Seismically active zones which are not covered adequately by existing instrumentation, particularly those with surficial material which would highly attenuate signals from buried explosions, were shown.

4. "Worldwide Microseismic Activity," 21 February 1963, Special Report No. 3

This is an extension of previously reported work. Microseismic noise was plotted for each month. In general, amplitudes were low over continents and high over oceans; seasonal variations were found. Some persistent

anomalies such as a Pacific low and an Antarctic high were also found. These noise background maps should be helpful for locating new stations, developing new instruments, determining the type of instrument best suited for a station and studying possibilities of detecting low-yield underground nuclear explosions.

5. "Application of Source Mechanism Studies to Identification of Nuclear Explosions," 21 February 1963, Special Report No. 4

This is an extension of the fault-plane plotting previously reported.

6. "Evaluation of Records from Normandy Array ALPENS," 22 March 1963, Special Report No. 5

The capabilities of the ALPENS station were assessed to prove or disprove that the network could record low-magnitude events better than other stations and particularly to emphasize the capability for recording low-magnitude events in the USSR. Several shocks from various azimuths recorded at a number of stations were compared. Signal-to-noise ratios from the ALPENS records appeared better than those at the other stations. Theoretical limits of perceptibility for ALPENS for $m_b = 5.0$ includes all of the USSR except a shadow zone in eastern Siberia. For shocks of $m_b = 4.0$, theoretical perceptibility is very small with none of the USSR included. The ALPENS network appears to be more capable than most seismograph stations in its ability to record teleseismic events.

7. "An Assessment of the Present Capability to Monitor Seismic Activity in the USSR and China," 27 May 1963, Special Report No. 6

Seismograph stations outside Communist areas in 1960 did not possess the capability to detect all seismic events of $m_b = 4.0$ within the USSR and China.

Good estimations of the annual number of earthquakes comparable in size to underground nuclear explosions depend upon knowledge of foreshock-aftershock sequences and recurrence relationships between shocks. For much of the area of interest, the smallest shocks for which data may be accumulated have $m_b = 4.5$. Underground nuclear blasts in many parts of China and the USSR with equivalent seismic magnitudes of $m_b \leq 4.0$ would not be detected.

The report recommended that the capability to record seismic events in Asia be improved by:

- (1) Increasing the number of standard stations, particularly in the Middle East, India, Pakistan, and Southeast Asia;
- (2) Moving some of the present installations to sites having lower microseismic background levels, or apply filtering techniques to remove objectionable noise; and
- (3) Constructing highly capable array stations south and west of the USSR and China.

8. "Surface Wave Attenuation," 27 June 1963, Special Report No. 7

Objectives of the study were to use the data available in the program to determine azimuthal and path dependence of surface-wave amplitudes for possible application to the problem of distinguishing earthquakes from explosions.

Although data from nuclear explosions were meager, the study showed that surface waves from blasts, like those from earthquakes, do not form circular radiation patterns about their points of origin. Change in relative surface-wave amplitude is expected as a function of azimuth from earthquakes, but the reason is less clear why very much deviation from the circular pattern should be evident for nuclear blasts, as was the case with the limited data studied. The anomalous amplitudes appear to be related to surface-wave travel paths and local geology.

Path dependency of surface wave attenuation was indicated from the study. Since there is no theoretical cause for azimuthal dependence inherent in elastic wave radiation from an explosion, any variation noted at distance must be primarily a function of the travel path.

9. "Comparison of Earthquake Magnitude Determination Methods," 28 July 1963, Special Report No. 8

Magnitude determination from P-waves recorded by short-period instrumentation is shown to require an inordinately high positive station correction for teleseismic distances. The correction needed for longer period instrumentation is less.

The relationship between m_b and the original Richter magnitude M , or its equivalent, is explained. The relationship is not simple and includes effects caused by the use of short-period instruments and different rules for measuring P amplitudes.

10. "Preliminary Report on Earthquake Studies," 20 March 1964, Special Report No. 9

Objectives of the study were to determine the feasibility of obtaining polarity data from secondary phases and to gain a better insight into the control that the focal mechanism exerts on the seismic record. Specifically, an attempt was made to determine:

- (1) If polarity of secondary phases can be determined from Standard recordings,
- (2) The actual effect of the focal mechanism on the attenuation patterns of P and S, and
- (3) The significance of observed radiation patterns of secondary phases.

This report discusses the methods, procedures and problems encountered in earthquake studies.

C. PAPERS PUBLISHED

1. Hofmann, R. B. and Wylie, R. W., "Computer Programs for Magnitude Determination and Seismic Data Handling," Earthquake Notes, (Seismological Society of America, 1963), V. 34, No. 3—4

A computer program to calculate magnitudes by most of the well known methods is described. One, two and three dimensional attenuation curves and seventeen formulas are stored in the program. Station corrections and deviations are automatically computed.

The feasibility is discussed of combining this program with others developed by Texas Instruments Incorporated under VELA UNIFORM contracts to obtain a seismic data handling system compatible with the current state of knowledge.

2. Guidroz, R. R., "International Cooperation to Improve Seismological Research," Paper presented to the 44th Annual Meeting of the American Geophysical Union and Subsequently Published under the Title "Standards for Seismograms," Geotimes, (1963), V. 8, No. 3

Seismograms from stations all over the world are being collected and compared in the course of studies of seismicity and other subjects. Unfortunately, these records are not uniformly marked for data such as component orientation and identification and they often lack the basic information which would permit them to be used effectively. Recommendations are presented that a set of minimum international standard requirements for seismogram marking be adopted.

3. "Fisher, R. L., "Worldwide Seismicity," Paper Presented to the 60th Annual Meeting of the Geological Society of America, (Seattle, March, 1964)

Seismicity in 1960 is defined in terms of every release and annual numbers of earthquakes for the range $5.0 \leq M_S < 6.0$. Maps are presented that show the worldwide seismicity evaluation and also epicenters of shocks ($M_S \geq 4.0$) that were studied. Regional distribution of earthquakes with respect to magnitude and depth are also shown.

More than 4100 events with magnitudes of at least $M_S = 3.0$ were studied from the data of 61 seismograph stations. Distribution and capabilities of these stations are such that results should be complete for shocks greater than or equal to magnitude five.

The year was highly seismic compared to the average year pictured by Gutenberg and Richter (1954). According to their figures, mean annual numbers for shallow shocks are: Class a ($M_S \geq 7-3/4$) — 2.2, Class b ($7.0 \leq M_S < 7-3/4$) — 11.9, and Class c ($6.0 \leq M_S < 7.0$) — 108. Also, an estimate of 800 per year was given for the range $5.0 \leq M_S < 6.0$. The corresponding figures for 1960 are 4, 14, 199, and 1188.

4. McGarr Arthur Hofmann, Renner B. and Hair, George D. "A Moving-Time-Window Signal-Spector Process," Geophysics (1964), V. 24, No. 2, pp. 212—220.

Spectra of signals of short time duration may be obtained from either long or short samples.

Long samples result in more accurate power-density spectra, but most of the spectrum power will be contributed by noise. Spectra from short samples are significantly altered by truncation effects. A process is described which makes use of the advantages of both methods. Truncation effects are reduced by "hanning" in the frequency domain. The average spectrum of noise immediately preceding the signal is subtracted from all spectra. A moving-window process allows investigation of signal spectra as a function of time. Examples of the same earthquake signal recorded on several types of instruments illustrate the broad, total spectra content of P-waves.

5. O'Brien, D. P. and Harley, T. W., "An Amplitude-Ratio Fault-Plane Solution Method, With Application to the May, 1960 Chilean Series," Paper Presented to the 45th Annual Meeting of the American Geophysical Union, (Washington, April, 1964)

A fault-plane solution technique, which uses ratios of Nakano's theoretical expressions for P, SV and SH displacements at large distances from a Type-I source, is presented. SV/SH ratios are used to determine fault-motion direction and P-ratio data are used to determine fault-plane orientation. The method requires a relatively small amount of data, so that it may be applied to Type-I earthquakes with poorly distributed or sparse data, which cannot be solved using Byerly's extended distance technique. Three earthquakes of the May, 1960 Chilean aftershock series are solved using the amplitude ratio technique. The solutions indicate that the abrupt increase in the slope of the Chilean series strain-release curve, which occurs one day after the main shock, corresponds to a change from transcurrent to dip-slip faulting; the subsequent decrease in slope about 2.5 days after the main shock corresponds to a return to transcurrent faulting.

6. Guidroz, R. R., "A Summary of Primary Findings—Worldwide Collection and Evaluation of Earthquake Data," Paper Presented to the 45th Annual Meeting of the American Geophysical Union (Washington, April 1964)

The study of 1960 data from worldwide stations was grouped in three categories: seismicity, noise and earthquake studies. The seismicity evaluation included special studies of magnitude determination, station assessments and recurrence curves. Areal coverage by established stations during 1960 was insufficient to record all earthquakes of magnitude four to five. In several regions of the earth it is doubtful that earthquakes of magnitude five were recorded by a sufficient number of stations to permit evaluation while shocks of magnitude four probably went undetected. This study, which included investigation of over 4100 events, indicated that each seismic region has its own recurrence characteristics. The noise studies included comparison of digital and visual determination of noise background. Visual noise measurements yield an indication of the average peak amplitudes but cannot be directly related to the amplitude or power density spectra of the noise record. Storm-generated microseisms with 2- to 10-second periods were more prevalent in winter months and were strongly attenuated at continental margins. This study substantiated findings by other investigators that there is considerable variation in attenuation of short-period P-waves at teleseismic distances and of P and S phases for different paths, particularly in the 6- to 20-degree range.

7. Hofmann, R. B., "Magnitude Determination Problems for the World-wide Collection and Analysis Program," Proceedings of the VESIAC Conference on Seismic Event Magnitude Determination, Acoustics and Seismics Laboratory, Institute of Science and Technology, University of Michigan, May 1964, pp. 51-57.

Until recently, most of the world's seismograph stations were not equipped with short-period horizontal instruments. Thus, the near-event method cannot be used with 1960 data from most stations to determine magnitudes at short distances. The body wave methods remain the only alternative, but, at short epicentral distances, S is difficult to distinguish from surface modes and PP is not frequently observed. The remaining P method has been the principal method for determining magnitudes of small events ($M < 5$) for this project.

8. Hofmann, R. B., "Limitation of Correction Factor Application to Magnitude Formulas," Proceedings of the VESIAC Conference on Seismic Event Magnitude Determination, Acoustics and Seismics Laboratory, Institute of Science and Technology, University of Michigan (May 1964) pp. 59-61.

Within the normal errors inherent in a single magnitude determination at conventional observatories, a station magnitude correction is shown to provide reasonable magnitudes for teleseisms regardless of the cause of anomaly. The reason for station magnitude corrections has usually been cited as the effect of local geology or pier mounting at the station, although it is general knowledge that calibration errors are also influencing factors. If station corrections of short-period seismographs are assumed applicable for events at all distances, instrument magnifications are suspect. A downward revision of as much as one hundred times would eliminate the necessity for large correction. The much smaller correction at short distances detracts from this or allied possibilities.

If, from a different point of view, the relationship between unified magnitudes, m , and the Richter magnitude M is desired, then M determined by established stations can be plotted against m determined by the station to be calibrated. The best line through the points will then establish the conversion formula.

9. Fisher, R. L., "A Study of Magnitude Determinations From World-wide Data," Proceedings of the VESIAC Conference on Seismic Event Magnitude Determination, Acoustics and Seismics Laboratory, Institute of Science and Technology, University of Michigan (May 1964), pp. 63-73.

One of the principal objectives of Texas Instruments contract for Worldwide Collection and Evaluation of Earthquake Data for 1960 is a study of the recent seismicity of the earth, based upon smaller-magnitude shocks. Magnitude data for most areas are quite incomplete except above $M = 6.0$; consequently, calculation of magnitudes was a necessity.

It was found in collecting data from a total of 150 stations that the instrumentation varied widely in type and quality. There were 16 types of instruments at stations which had records of sufficient quality for study, with generally large variation in instrument constants within each type. Most of these instruments were types which record body waves best; as a result, more magnitudes were determined from body waves than from surface waves. Magnitudes, however, were calculated by as many methods as possible, to accumulate such data from more stations and for more events than any single method would allow.

10. Hofmann, R. B. and Wylie, R. W., "Magnitude Calculation for the Worldwide Collection and Analysis Program," Proceedings of the VESIAC Conference on Seismic Event Magnitude Determination, Acoustics and Seismics Laboratory, Institute of Science and Technology, University of Michigan, (May 1964) pp. 75-81.

Several methods of magnitude determination are in common use; each has advantages and limitations. The methods and conditions under which each may be used are presented.

11. Hofmann, R. B. and Wylie, R. W., "A Magnitude Calculation and Data Handling System," Earthquake Notes, Seismological Society of America, (1964) V. 35, No. 1-2, pp. 14-27.

A computer system has calculated magnitudes for earthquakes recorded at 100 different stations and for 63,000 station events. Sixty-six different formulas are utilized to calculate magnitudes, depending upon the input data available. Measurements of P, S, PP, L, and R, recorded on up to three different types of three-component or single seismometers at a station, may be converted to magnitudes. Hypocenters from different distances and depths are utilized.

The system provides averaged magnitude for each event from many stations with a wide variety of instruments. Statistics lists, including the station correction and its standard deviation for each magnitude type at each station, are automatically provided.

Combination of this system with the Automated Bulletin System, which identifies phases from arrival times and hypocenter data, could provide advanced seismic data processing and retrieval needed to compliment the improved instrumentation now available.

13. ABSTRACT		
Seismic activity in 1963 is documented and compared to 1960 and other years. Other studies undertaken over the past three years are reviewed and summarized. ~~TOP~~ The worldwide level of seismicity in 1963 is shown to have been considerably lower than in 1960. Comparison with Gutenberg and Richter's (1954) data shows 1963 seismic activity about average with respect to total shocks $M_s \geq 6.0$. However, more shocks in the range $5.0 \leq M_s < 6.0$ were recorded in 1963 than predicted by Gutenberg and Richter (1954). ~~TOP~~ Epicenter maps showing events for which $M_s \geq 4.0$ and $m_b \geq 4.0$ for shallow and normal focus and also for intermediate and deep focus events are included. A seismicity map based on annual numbers of shocks ($5.0 \leq M_s < 6.0$) per unit area is also shown. Some 4800 events are listed, representing all known epicenter locations plus local earthquakes ($\Delta \geq 1000$ km) $M_s \geq 3.0$, which were recorded. Computed and published magnitude data are included in the lists. ~~TOP~~ delta

INSTRUCTIONS

1. ORIGINATING ACTIVITY: Enter the name and address of the contractor, subcontractor, grantee, Department of Defense activity or other organization (*corporate author*) issuing the report.

2a. REPORT SECURITY CLASSIFICATION: Enter the overall security classification of the report. Indicate whether "Restricted Data" is included. Marking is to be in accordance with appropriate security regulations.

2b. GROUP: Automatic downgrading is specified in DoD Directive 5200.10 and Armed Forces Industrial Manual. Enter the group number. Also, when applicable, show that optional markings have been used for Group 3 and Group 4 as authorized.

3. REPORT TITLE: Enter the complete report title in all capital letters. Titles in all cases should be unclassified. If a meaningful title cannot be selected without classification, show title classification in all capitals in parenthesis immediately following the title.

4. DESCRIPTIVE NOTES: If appropriate, enter the type of report, e.g., interim, progress, summary, annual, or final. Give the inclusive dates when a specific reporting period is covered.

5. AUTHOR(S): Enter the name(s) of author(s) as shown on or in the report. Enter last name, first name, middle initial. If military, show rank and branch of service. The name of the principal author is an absolute minimum requirement.

6. REPORT DATE: Enter the date of the report as day, month, year, or month, year. If more than one date appears on the report, use date of publication.

7a. TOTAL NUMBER OF PAGES: The total page count should follow normal pagination procedures, i.e., enter the number of pages containing information.

7b. NUMBER OF REFERENCES: Enter the total number of references cited in the report.

8a. CONTRACT OR GRANT NUMBER: If appropriate, enter the applicable number of the contract or grant under which the report was written.

8b, 8c, & 8d. PROJECT NUMBER: Enter the appropriate military department identification, such as project number, subproject number, system numbers, task number, etc.

9a. ORIGINATOR'S REPORT NUMBER(S): Enter the official report number by which the document will be identified and controlled by the originating activity. This number must be unique to this report.

9b. OTHER REPORT NUMBER(S): If the report has been assigned any other report numbers (*either by the originator or by the sponsor*), also enter this number(s).

10. AVAILABILITY/LIMITATION NOTICES: Enter any limitations on further dissemination of the report, other than those imposed by security classification, using standard statements such as:

(1) "Qualified requesters may obtain copies of this report from DDC."

(2) "Foreign announcement and dissemination of this report by DDC is not authorized."

(3) "U. S. Government agencies may obtain copies of this report directly from DDC. Other qualified DDC users shall request through _____."

(4) "U. S. military agencies may obtain copies of this report directly from DDC. Other qualified users shall request through _____."

(5) "All distribution of this report is controlled. Qualified DDC users shall request through _____."

If the report has been furnished to the Office of Technical Services, Department of Commerce, for sale to the public, indicate this fact and enter the price, if known.

11. SUPPLEMENTARY NOTES: Use for additional explanatory notes.

12. SPONSORING MILITARY ACTIVITY: Enter the name of the departmental project office or laboratory sponsoring (*paying for*) the research and development. Include address.

13. ABSTRACT: Enter an abstract giving a brief and factual summary of the document indicative of the report, even though it may also appear elsewhere in the body of the technical report. If additional space is required, a continuation sheet shall be attached.

It is highly desirable that the abstract of classified reports be unclassified. Each paragraph of the abstract shall end with an indication of the military security classification of the information in the paragraph, represented as (TS), (S), (C), or (U).

There is no limitation on the length of the abstract. However, the suggested length is from 150 to 225 words.

14. KEY WORDS: Key words are technically meaningful terms or short phrases that characterize a report and may be used as index entries for cataloging the report. Key words must be selected so that no security classification is required. Identifiers, such as equipment model designation, trade name, military project code name, geographic location, may be used as key words but will be followed by an indication of technical context. The assignment of links, rules, and weights is optional.
