FOREWORD

(U) This Interim Technical Status Report (Contractors Reference No. PWA 3717) was prepared by Pratt & Whitney Aircraft, Division of United Aircraft Corporation, East Hartford, Connecticut, as the third Semiannual Report under United States Air Force Contract F33615-68-C-1208, Project No. 3066, Task No. 306606. This report was submitted by the Contractor on 30 June 1969, and covers the report period from 1 January 1969 to 30 June 1969.

(U) The findings and conclusions of this report are not deemed as final by the Contractor. They are subject to verification or revision in the Final Report to be published upon the completion of this Contract.

(U) The Air Force Program Monitor is Mr. Wayne Tall, APTC, Air Force Aero Propulsion Laboratory, Wright-Patterson Air Force Base, Ohio, 45433.

(U) This report contains no Classified information extracted from other Classified documents.

(U) Publication of this report does not constitute Air Force approval of the report's findings or conclusions. It is published only for the exchange and stimulation of ideas.

Wayne Tall
Project Engineer
Air Force Aero Propulsion Laboratory

UNCLASSIFIED

UNCLASSIFIED ABSTRACT

(U) An extensive, four-phase, three-year program is in progress to investigate methods of improving the performance of fan-drive turbines. The goals of this program are to develop turbine design procedures and aerodynamic techniques for high work, efficient, low-pressure turbines. The first phase effort defining the preliminary turbine design has been completed, and the results were reported. The second phase consists of an experimental evaluation which includes establishment of both two-dimensional loss levels and three-dimensional flow behavior for the baseline airfoils and for airfoils utilizing boundary layer control devices. The design of the cascade hardware and baseline airfoils was previously reported. The test results of baseline airfoil performance in the annular cascade and the status of the other tasks are presented in this report.

Distribution of this abstract is unlimited.

SECTION I

INTRODUCTION

(U) The bypass turbofan engine has seen increased use in recent military aircraft applications, and future mission studies indicate continued interest in this type of jet engine. A characteristic of the bypass turbofan is that the fuel economy increases with the bypass ratio. However, increased bypass ratios require increased fan power which must be supplied by the fan-drive or low-pressure turbine. It is imperative that the turbine meet these increased turbine loading requirements without a turbine efficiency penalty.

(U) The efficiency of a turbine is the result of optimization studies based on trade-offs between turbine diameter, rotational speed, number of stages and airfoil loading. The fan-drive turbine design is constrained by further requirements. The rotational speed of the turbine must be limited in order that the fan tip Mach number does not exceed the limit for reasonable losses. At high bypass ratios, where larger fan diameters are required, this problem is further aggravated. Applying conventional aerodynamics, at fixed rotational speed, increased work can only be realized by a further increase in the number of stages and/or the turbine diameter. Reduction of the turbine diameter or airfoil solidity results in a lighter turbine, but with a sacrifice in efficiency due to losses associated with increased airfoil loading. If the turbine diameter and solidity can be reduced without a penalty in turbine efficiency, considerable gains can be realized by the engine. Therefore, present turbine technology must be improved in order to provide the desired level of performance for future turbofan engines.

(U) The objective of the work done under this contract is to analyze and test concepts which will increase the low pressure turbine loading and maintain or increase current turbine efficiency levels. The goals of this program are to develop design procedures and turbine aerodynamic techniques for efficient high-work, low-pressure turbines by means of analytical studies and cascade testing, and to demonstrate the effectiveness of the techniques by designing and testing a two-stage turbine that meets or exceeds the contract stage work and efficiency goals.

(U) The complete program is being conducted in four phases over a three year period which began on 1 January 1968. Phase I defined the basic turbine design and an analysis of promising increased loading concepts was completed. The results of the Phase I study are reported in Reference 1. Phases II and III consist of experimental testing to verify and extend the turbine aerodynamic techniques and design procedures for high loading levels. As part of the Phase II effort, the design details of the baseline cascade test airfoils for both the annular and plane cascade rig were reported in Reference 2. Phase IV will subject the aerodynamic techniques and design procedure to a two-stage rotating rig test.

(U) Work on this contract during the report period proceeded on Phase II, with a design effort initiated on Phase III. The annular cascade testing of the four baseline airfoils was completed and the results are described in this report. The status of the other Phase II tasks is also presented.

SECTION II

BACKGROUND

(U) The Phase I analysis of this program has been completed and the results are described in Reference 1. The objective of the Phase I study was to select a preliminary turbine design that is capable of meeting the performance requirements of this Contract (see Table I).

TABLE I

TURBINE DESIGN PARAMETERS

Number of Stages	2
Average Load Coefficient, C_2^*	2.2
First Blade Tip Wheel Speed	1000 fps
First Blade Inlet Hub-Tip Diameter Ratio	≤ 0.8
Exit Swirl Angle - Without Exit Guide Vane	20°
With Exit Guide Vane	0°
Turbine Inlet Temperature	1450°F
Airflow	≥ 50 lb/sec
Average Stage Efficiency	91%
Life	10,000 hr.

CONFIDENTIAL

The final choice of the preliminary turbine configuration was based on analyses formed during Phase I. These analyses included consideration of the flowpath, reaction level, load coefficient level, and variations in work distribution for which velocity triangles were generated. Furthermore, as part of Phase I, preliminary airfoil contours were defined for the same velocity triangles for three levels of reaction and three levels of solidity for equal work-split stages.

(U) The selected airfoils for Phases II and III baseline evaluation were the medium-reaction normal solidity airfoils. After the airfoil sections were subjected to additional refinement, the selection was based on the resulting two-dimensional suction surface pressure coefficients and diffusion parameters, and on two-dimensional boundary layer calculations. These baseline airfoil contours, for the first and second vane and the first and second blade, were described in Reference 2. All of the baseline airfoils were fabricated for evaluation in the annular segment cascade and plane cascade rigs.

SECTION III

TWO-DIMENSIONAL DESIGN VERIFICATION (Task IIa)

1. RFP OBJECTIVE

- (U) Provide an experimental verification of the two-dimensional design characteristics.

2. TASK OBJECTIVE

- (U) The purpose of this Task is to conduct plane cascade tests in order to verify the aerodynamic concepts applied to the turbine design during the Phase I program, and to establish the two-dimensional loss levels for the chosen turbine airfoil profiles at design conditions.
- (U) The plane cascade tests will serve two, equally important, purposes. First the measured profile losses will be compared with those contained in the computer programs to verify the existing design procedures. Second, the total pressure and flow angle profiles at the exit plane will indicate whether or not the surface boundary layer has separated. Each airfoil has been designed so that such two-dimensional separation should not occur, and these tests will constitute a verification of the entire airfoil section design procedure.

3. AIRFOIL SECTION AND FACILITY DESIGN

- (U) Under this task, the six medium reaction normal-solidity airfoil sections are to be tested. These are the mean sections of each airfoil row as well as the second vane and blade root sections. These sections will be manufactured as plane cascade packs consisting of constant sections. The design details of the airfoil sections, including the airfoil coordinates and the fabrication details of the cascade test packs, were presented in Reference 2.
- (U) The design of the plane cascade rig was also presented in Reference 2, where all important features of the rig were described and illustrated.

4. STATUS

- (U) The fabrication of the plane cascade test packs has been completed. The surface static pressure taps were installed in one airfoil of each pack as indicated in Reference 2. One of the completed packs, the first vane mean cascade pack, is shown in Figures 1 and 2.
- (U) The rig was also fabricated and has been installed in the Aerodynamic Cascade Facility. The first test pack has been placed into the rig, and check-out runs were being made at the time of this report.

SECTION IV

BASELINE AIRFOIL EVALUATION (Task IIb)

1. RFP OBJECTIVE

- (U) Determine the design point performance of the baseline turbine airfoils and the need for corner boundary layer control.

2. TASK OBJECTIVE

- (U) Each of the baseline airfoil designs, as determined by the Phase I portion of this Contract, will be evaluated in an annular segment cascade. Turning vanes will be located ahead of the test airfoil cascade to provide the correct incidence angle over the airfoil span. The central test airfoil in each of the four cascade packs will be instrumented with a row of surface pressure taps at the root, mean and tip portions to obtain the surface pressure profiles. Each airfoil design will be separately tested at the design incidence angle and Reynolds number, and three Mach numbers near the design point. Exit surveys will be made over the entire central passage containing the test airfoil to obtain local and circumferentially mass averaged profile loss coefficients and exit angle deviations. The exit plane data will indicate the high and low loss regions of the passage and, specifically, will indicate boundary layer separation if it occurs. The mass-averaged flow characteristics will indicate the cumulative effect of the local losses over the passage width. The airfoil surface pressure measurements will be compared with predicted pressure profiles and will also provide an indication of flow separation. During these tests simple flow visualization techniques will be employed to determine the approximate chordwise location of any separated regions, if they occur. If the results of these tests indicate that corner separation does not occur, or is not pending, the baseline airfoil designs will not require boundary layer control. On the other hand, if corner separation occurs, as is often the case for highly loaded airfoils, the results of these tests will serve as a guide for the application of boundary layer control methods. At this point, the vane and blade showing the highest tendency for corner separation will be selected for testing the most promising boundary layer control methods (Task IIc).

- (U) These task objectives were met by the following steps:

- Measurement of all important aerodynamic properties at the cascade inlet and exit planes
- Reconstruction of the entire exit plane loss distribution
- Reconstruction of the entire exit plane flow pattern
- Flow visualization of the airfoil and end-wall flow patterns
- Measurement of the airfoil surface static pressure distributions at three radial locations

UNCLASSIFIED

- Careful analysis of all data and visual clues
- Selection of appropriate end-wall boundary layer control techniques.

3. BASELINE AIRFOIL AND TEST PACK DESIGN

- (U) The design of the baseline airfoil, medium-reaction normal-solidity cascade packs was described in Reference 2; sketches of the cascade flowpaths for each of the four baseline airfoils were also shown. The inlet to each cascade consists of a bellmouth transition section followed by turning vanes which provide the proper radial flow distributions. The test airfoils are placed behind the turning vanes and these are followed by exit wall extensions.
- (U) The required exit angles, vane elevations, coordinates and all design details of the inlet turning vanes were shown in Reference 2. As previously indicated, two long chord turning vanes-per-pack were used.
- (U) The design details of the first and second stage vane and blade airfoils were also presented in Reference 2. These details include the airfoil elevations, profiles and their coordinates, design values of the airfoil angles, gaging distances, axial chords, gaps and uncovered turnings.
- (U) Airfoil surface static pressure taps were distributed around each cascade test airfoil at root, mean and tip sections. Location of these taps for the first vane were shown in Reference 2. A close-up view of a pressure tap installation is shown in Figure 3. Static pressure taps were drilled into small bore tubing installed in spanwise grooves machined into the airfoil surfaces. A finished airfoil surface with taps installed is shown in Figure 4. A view of a completed cascade test pack indicating the method of bringing out the airfoil surface static pressure tap connections is shown in Figure 5. These taps can also be seen on the airfoil surfaces in the flow visualization photographs which will be discussed later in this report.
- (U) A single cone probe was designed for measuring exit plane total and static pressures simultaneously, and exit gas flow angles. A sketch of the probe design was shown in Reference 2. The probe was calibrated to determine total and static pressure errors due to the pitch angle over the test Mach number range. Based on the calibration, corrections for the theoretical pitch angle were added to the data reduction program.
- (U) A total pressure traverse probe was also installed just upstream of the test airfoils in order to measure the losses due to the turning vanes. The total pressure loss measured for the inlet turning vane was used to determine the local inlet total pressure profile upstream of the test airfoils. Turning vane losses are accounted for in the data reduction program used to calculate the test airfoil performance.

4. DISCUSSION

(U) The four baseline airfoils, namely the medium-reaction, normal-solidity first vane, first blade, second vane and second blade were tested in the annular segment cascade. The entire collection of data points that were taken during these tests is tabulated in Table II. The design values indicated in this table are placed next to the nearest experimental data point. The most useful data (at the nearest to design test value) is presented herein, including photographs of the flow visualization tests. Analysis of this data and the visual information indicated that the four baseline airfoils behaved similarly in all important respects. Therefore, the results of all four airfoils will be discussed in each aerodynamic performance category. The behavior of these airfoils will be discussed, in the following paragraphs, in the order of the listing of steps taken to meet Task Objectives (See paragraph 2 of this section).

- (U) The inlet guide vane total pressure loss for each cascade was determined by traversing the inlet to the test airfoils. The measured spanwise total pressure distributions are shown in Figures 6 through 11. For both the first and second vanes, two sets of data are shown: with and without turbulence screen. In order to determine if the loss levels could be significantly affected by an increase in cascade turbulence levels, a screen with a 0.009 inch diameter wire (with a 0.063 inch center-to-center spacing) was mounted at the cascade inlet flange approximately one inch upstream of the leading edge. The screen was designed in order to produce 6% turbulence intensity, which is representative of turbine levels. Photographs of the screen are shown in Figures 12 and 13.

- (U) The inlet flow angle approaching the test foils was also measured for each cascade. The design of the inlet guide vanes was acceptable, since the flow angles were within approximately 4 degrees of the design value. A typical trace of the inlet flow angle variation is shown in Figures 14 through 16 for the first stage vane cascade.

Figure 16 First Stage Turning Vane Exit Angle Measurement

- (U) The plots of the important aerodynamic quantities based on the inlet and exit plane measurements for the four baseline airfoils are shown in Figures 17 through 52 at exit flow Mach numbers nearest to the design value. These plots include the total pressure loss and exit gas flow angle contours over three passages. Further, the average spanwise distribution of the total pressure loss, loss coefficient, exit flow angle and exit Mach number are presented.
- (U) The contour plots for both the total pressure loss and exit gas flow angle for each airfoil show wakes from the inlet guide vanes which are readily distinguishable from the loss patterns of the test foils themselves. The diagonal orientation of these wakes with respect to the cascade passages requires loss calculations in different passages over the span in order to avoid wake losses which should not be charged to the test airfoils. Therefore, the data reduction program was modified to calculate the average spanwise distribution of any flow parameter over selected passage intervals. It is felt that this yields the fairest measure of the test foil performance. Future tests (Task IIc) will avoid this problem since the inlet guide vanes for the second vane cascade were restacked with the trailing edges approximately parallel to the leading edges of the test airfoils. This change is indicated in Figure 53. A baseline second vane retest will be made when fabrication of the new hardware is completed and those results will be compared with the results presented here, based on the selected passage interval data reduction procedure.

Figure 53 New Inlet Guide Vane Design, Second Stage Vane Cascade Plane at Leading Edges of Test Airfoil Looking Downstream

- (U) The performance of a turbine depends directly on the sum of the total pressure losses through the machine. The measure of the total pressure drop through each turbine airfoil row is, therefore, the most useful indication of a successful turbine design. The loss coefficient ($1-\phi^2$), which is a monotonically increasing function of the total pressure loss, is also presented since it is widely used in industry as a measure of turbine efficiency.
- (U) Contours of the total pressure loss for all of the tested airfoils indicate similar results. Low loss pockets are evident over the midspan areas with high loss regions in the suction surface corners. These losses probably originate at the end-wall but migrate from the pressure surface to the suction surface and

UNCLASSIFIED

UNCLASSIFIED

accumulate in the corners. Such a collection of end-wall losses in the channel passages at the inside and outside diameters is reflected in the plots of the average spanwise variations of the total pressure loss and loss coefficients. This is indicated by peak loss values in the 5-10% and 95-99% radial span regions, which obviously is a separate phenomena at both the root and tip. The minimum losses occur at the midspan, which represent essentially the two dimensional airfoil profile drag only. There is no evidence of large boundary layer thicknesses at the cascade walls, since the accumulated waste at the end walls was swept into the cascade corners. There is also no evidence of flow separation in the pressure loss and loss coefficient data.

- (U) A summary plot of the average spanwise loss variation for the four baseline airfoils is presented in Figure 54. This plot indicates very small differences in the behavior of these airfoils. The turbulence screen that was installed ahead of the first and second vane cascade does not appear to have significantly affected cascade losses. Figures 55 and 56 compare the change in spanwise distribution of the loss coefficient for both airfoils. Although there is some difference in Mach numbers at which the data were taken, there is very little difference in loss profiles. This difference in Mach number is not significant since, as shown in Figure 57, there was a very small effect of Mach number variation on loss for these airfoils. Any small variation may be attributed to the fact that, during the tests, the Reynolds number increased slightly with Mach number. Since airfoil losses decrease with increasing Reynolds number, some decrease in losses may be charged to this effect. It can also be concluded that none of the airfoils exhibited a transonic drag rise over the Mach number range tested.

- (U) A comparison of the predicted and measured loss coefficients is shown in Table III. Two prediction methods were used to determine midspan or profile losses. One method used the Ainley and Mathieson correlation based on global airfoil design parameters, as the amount of turning, gap-to-chord ratio, airfoil thickness, convergence ratio, etc. The other method was based on boundary layer parameters computed by the Airfoil Boundary Layer Deck. The airfoil surface static pressure and velocity distributions were calculated from predicted values. The overall predicted value was based on the global profile loss correlation with a correlated end loss value added. For all four airfoils, the midspan measured profile losses are well below the predicted values, indicating that the normal solidity airfoil profiles were well designed. The measured overall losses were also below predicted overall values, leading to the conclusion that the baseline design can meet the turbine design requirements.

*With inlet turbulence screen

- (U) The exit plane flow patterns were reconstructed and these results are presented as the exit gas flow angle contours over three flow passages, average spanwise exit gas flow angle and Mach number distributions at the nearest-to-design test conditions. The exit gas angle contours indicate close to design angles for the midspan portion of each airfoil, with some overturning at the roots and underturning at the tips. This is more clearly shown on the exit angle spanwise plots on which the design exit angles are also plotted. There was no evidence of flow separation. The turbulence screen that was installed ahead of the first and second vane cascades does not appear to have significantly affected the gas exit flow angles. A comparison of these angles, with and without screens, is shown in Figure 58.
- (U) To provide additional clues as to the behavior of the flow in these cascades, a mixture of oil and graphite was painted on two airfoils (one on either side of the test airfoil) for each airfoil cascade test pack. Movies and still photographs were taken of the flow patterns at various test conditions. Selected photographs for each test pack are shown in Figures 59 through 70. The location of the surface static pressure taps are also shown on these photographs.

- (U) The patterns indicate that the corner flow remains attached, although the end-wall losses are high. Studies of the movies indicate that separation and reattachment of the airfoil suction surface boundary layer frequently occurs to some extent in all of the cascades, caused by shocks on portions of the airfoil surface where local supersonic flow exists. It is slight on the first vane but indicates a significant separated strip on the first blade over approximately 70% of the span. The losses for these airfoils, even with local separation and reattachment, were low, as previously indicated. Strong cross-flow patterns can be observed from these photographs at the walls but no separation on these walls in the vicinity of the airfoils was detected. The first vane and first blade inside diameter wall extensions have a slight axisymmetric separation. (The cause of this effect will be explained later.) This resulted in the elimination of these cascades from being chosen for the Task IIc effort. It can also be noted on these figures that the airfoil surface static taps are well within the corner vortex. Furthermore, comparisons of the photographs taken with and without the turbulence screens for the two vane packs indicated only slight differences in local airfoil surface separation patterns.
- (U) Since the annular segment cascade does not perfectly reproduce the exit conditions that the airfoils would have in the complete turbine, we cannot expect that the resulting flow patterns will exactly duplicate what would be found in the rotating machine. Nonetheless, the important systematic differences in the flow patterns caused by slight experimental imperfections can be readily understood and identified. Correct interpretation of the data becomes possible when the systematic differences are anticipated and are not attributed to the cascade airfoils. It should be noted in advance that it is possible to conclude that the annular segment cascade actually provided a very realistic environment for the aerodynamic tests, and that the experimental data is very consistent and reliable.
- (U) Figure 71 is a sketch which indicates the important features of the Task IIb cascade. The fundamental difference between the annular segment cascade and rotating rig is that finite extension of the inside and outside diameter walls tends to make the exit plane static pressure uniform and atmospheric, rather than reproducing the radially increasing static pressure of the axisymmetric rotating flow. The allowable extension of the inside and outside diameter walls is determined by the length of a practical cantilevered measuring probe. Since the cascade flow field is almost entirely subsonic, the effect of the altered exit plane static pressure distribution can be far-reaching, even though it is not especially strong. The following discussion focuses on the two dimensional effects of these changes.

UNCLASSIFIED

UNCLASSIFIED

Figure 71 Annular Segment Cascade - Flowpath Cross-Section

- (U) The altered, more uniform exit-plane static pressure distribution is clearly seen in Figure 72, which contains theoretical and measured spanwise distributions of circumferentially area-averaged static pressures. The same trend is also evident in a similar exit-plane Mach number distribution, shown in Figure 73. The gentle droop of the measured Mach number near the inside and outside diameter walls is due to the lower total pressures there, which are caused by end losses. The turbine design procedure distributes end losses uniformly across the airfoil span and does not, therefore, exhibit such inside and outside diameter droops.
- (U) There are two direct and observable consequences of the exit-plane effect. First, the airfoil roots are slightly less loaded and the airfoil tips are slightly more loaded than the complete turbine required. However, the differences between the desired loading and the measured loading never exceed a few percent at any spanwise location. Furthermore, the measured loading in the midspan region was almost identical to the desired value for all airfoil cascades. Consequently, the experiments provided a suitable test for each section of each airfoil. Second, the inside diameter wall boundary layer must overcome a static pressure increase in order to reach atmospheric pressure and can, therefore, possibly separate. Such separation can be clearly seen in Figures 60 and 64. Since the cascades were designed with this possibility in mind, the separation always occurred downstream of the measuring probe. The outside diameter boundary is subject to a favorable pressure gradient and always remained attached. Once again, it is unlikely that this effect had an important influence on aerodynamic performance.

- (U) The previously discussed inability of the annular segment cascade to exactly reproduce the desired exit-plane condition for the airfoils must also be reflected in the airfoil pressure distributions. The pressure distributions are shown for the four airfoils in Figures 74 through 91. This is so because the area enclosed by the pressure-axial distance curve equals the airfoil section loading, which has already been shown to be affected by altering the static pressure spanwise distribution.
- (U) Since the midspan loading was found to be almost identical to the design value, it is not surprising to find that the static pressure distribution at all midspan sections was almost identical to the prediction. The previous discussion indicated that the root loading would tend to be reduced, and the tip loading increased in the annular segment cascade. No separation is evident from the airfoil surface pressure distributions and this verifies the pressure distribution design technique.

- (U) However, in addition to these effects, it is evident that the loading at the root and tip will both be reduced because they are required to turn the low total pressure end-wall fluid through essentially the same turning angle as the remainder of the airfoil. As a result, the root loading is reduced by both effects, while the tip loading has an indeterminate outcome. There is no doubt that these qualitative observations explain the differences between experimental and theoretical pressure distributions.

5. CONCLUSIONS

- The results of the baseline tests entirely verified the soundness of the two-dimensional airfoil design procedures and the ability of the annular segment cascade to simulate turbine conditions realistically. The data taken in these tests was sufficiently comprehensive and detailed that a clear, thorough understanding of the aerodynamic behavior was obtained.
- The performance of each of the four medium-reaction, normal-solidity baseline airfoils was very similar and no distinguishing characteristics for any particular airfoil warrants selection over another for applying boundary layer control techniques.

UNCLASSIFIED

UNCLASSIFIED

- The normal solidity second vane was chosen for further study by the process of elimination. The first stage vane and blade inside diameter end-wall extensions indicated some separation beyond the test cascade, which could influence probe readings near this wall in future tests if it became more severe. The short second stage blade chord makes the fabrication of end-wall boundary layer control techniques difficult.
- The results of the baseline data analysis indicate that reduction of secondary flow, rather than corner separation, is required. The applicable boundary layer control techniques that were chosen are local contouring, local recambering, end wall contouring, addition of flow fences and increased surface roughness. These will be applied to the second vane under the Task IIc effort.
- Since four boundary layer control techniques will now be applied to one airfoil under Task IIc, rather than two techniques to two different airfoils as initially planned, the need for Task IIId was eliminated. It was recommended, therefore, that the Task IIb tests should be repeated by a test of a lower solidity design as a substitute for the original Task IIId. Analysis of the data for the normal-solidity airfoils shows that the limit of airfoil loading has not been reached, and further gains may be achieved by increasing the airfoil load coefficient.

6. TEST PROCEDURE

- (U) The test procedure which was followed during the Task IIb annular segment cascade evaluation of the baseline airfoils is outlined below.
- The cascade test pack was installed on the stand and all of the instrumentation was connected
 - The exit plane traversing probe was installed and the circumferential tracking along the outside diameter shroud was checked and adjusted as necessary by lateral positioning of traverse probe mount assembly
 - The exit traversing probe was positioned at midspan and set at the airfoil exit metal angle. This was done by sighting along the probe head and shank
 - Then, the radial tracking was checked by traversing the probe from the inside to outside diameter. Shims were placed under the actuator to achieve constant distance from trailing edge to the probe tip
 - The probe distance aft of the trailing edges along the projection of the airfoil exit metal angle was set at 0.50 inches with a scale. Adjustment screws were incorporated into the traverse actuator assembly for this purpose

UNCLASSIFIED

UNCLASSIFIED

- The inside and outside diameter limits were set with the probe at the minimum angle. The minimum angle of 15° was set with a sheet metal template placed between the test airfoil trailing edges and the probe shank.
- The exit probe calibration was made through the data recording system, with the calibrated lowest angle of 15° and the maximum angle of 62° . The actuator was preset in the laboratory for a 47° total travel
- The data recording system calibration was made for radial travel of both the exit and inlet traverse probes
- Secondary calibrations were completed for all transducers
- The J-75 slave engine was started and air was bypassed around the rig in order to remove moisture that may have been present during the initial start-up. Air was bled through the bypass until operating temperature was reached and the moisture cloud had disappeared
- The bypass was then closed and air was directed through the rig. A pressure check was then made with a soap solution. No leaks were permitted on instrumentation lines. Small, fuzzy leaks around rig flanges were allowed
- The inlet pressure and temperature were set to achieve the desired Mach number and Reynolds number
- The inlet traverse probe was traversed from the inside to the outside diameter
- The exit traverse probe was traversed from left to right (looking upstream) and from the inside to the outside diameter
- The inlet traverse was repeated
- The static pressures were recorded manually from U-tubes
- The next test point was set and the last four steps were repeated.

SECTION V

BOUNDARY LAYER CONTROL EVALUATION (Task IIc)

1. RFP OBJECTIVE

- (U) Determine the effects of the most promising boundary layer control techniques on corner flow separation.

2. TASK OBJECTIVE

- (U) Initially, two methods of boundary layer control indicating the best potential for reducing end-wall losses were to be applied to two airfoils selected in Task IIb. For the reasons given in Section IV, four boundary layer control methods were selected and these are only to be applied to one airfoil, for which the second vane was chosen.
- (U) The RFP Objective indicates that methods to eliminate flow separation will be considered. Since the baseline tests indicated that the end-wall problem for these airfoils was that of high loss without corner boundary layer separation, the apparent source of the high end-region loss is secondary flow of the end wall boundary layer across the channel. This is reflected in the baseline tests as high loss regions in suction surface corners. These regions probably originate at the end wall but migrate from pressure surface to suction surface and accumulate in the corners. Therefore, the boundary layer control methods that are applicable to the baseline airfoils involve those that have a tendency to reduce the secondary flow at the end-walls.
- (U) The selected techniques that will be experimentally evaluated are (1) local recontouring (2) local recambering (3) end wall contouring and (4) use of flow fences and application of increased surface roughening.

3. DESCRIPTION OF BOUNDARY LAYER CONTROL METHODS

(a) Locally Recontoured Second Vane

- (U) The local recontourings of the second vane root and tip sections are shown in Figures 92 and 93. The airfoil surface static pressure gradient at the leading portion was reduced in order to decrease the loading toward the airfoil leading edge, while keeping the overall loading constant. This change is intended to delay the onset of strong secondary flow in the upstream portion of the channel and to reduce the total accumulation of losses near the airfoil suction surface corners. These recontoured sections were faired into the existing midspan contour at approximately the 25% and 75%-span locations.

Figure 93 Second Vane Baseline Airfoil Recontouring, Tip Section Static Pressure Redistribution

UNCLASSIFIED

UNCLASSIFIED

(b) Locally Recambered Second Vane

(U) The application of the local recambering to reduce secondary flow at the root and tip sections of the second vane required streamline analysis of the entire study turbine. Inlet angles were held constant to allow the use of the same inlet bellmouth and inlet guide vane rig sections. The tip exit angle was reduced (or closed) by 5 degrees, while the root exit angle was increased (or opened) by 5 degrees. These camber changes were then curved-line faired into the original camber at the 25% - and 75% - span sections as shown in Figure 94. The streamline analysis indicated that, in order to maintain the same turbine stage work and reaction level, the second stage blade had to be opened by increasing the exit angle by 0.5 degrees.

Figure 94 Second Vane Recambering, Exit Angle Distribution

UNCLASSIFIED

UNCLASSIFIED

- (U) Figures 95 and 96 show the recambered second vane root and tip sections. These changes will have the tendency to reduce the root overturning and the tip underturning as was observed in the baseline tests. The tip airfoil surface static pressure distribution indicates that with the high turning, the overall loading is increased, but the increase in passage convergence shifts the loading toward the trailing edge. This reduces the pressure difference between the suction and pressure sides of the channel at the forward end and will tend to delay the onset of strong secondary flow. The reduction in camber at the root will result in a lower overall airfoil loading. This reduction should occur more or less uniformly over the chord length. The effects of the airfoil recambering are summarized in Table IV.

TABLE IV
SUMMARY OF LOCAL RECAMBERING EFFECTS

Parameter	Tip	Root
Exit Angle	Closed	Opened
Tangential Force	Increased	Decreased
Zweifel Load Coefficient	Decreased (0.85 to 0.65)	Increased (1.1 to 1.3)
Channel Convergence	Increased	Decreased
Suction Pressure Distribution	Descending	Flat
Crossflow Potential	Increased but shifted toward trailing edge	Decreased overall

UNCLASSIFIED

(c) End Wall Contouring

- (U) Another boundary layer control method is the application of end wall contouring. This method holds the promise of reducing the local airfoil loading, and consequently the secondary flow losses, without causing any appreciable disturbance to the flow at other sections of the airfoil or downstream of the airfoil row. Secondary flows occur when the momentum of the fluid near an end-wall has been reduced to a point where it can no longer withstand the circumferential pressure gradient impressed by the potential flow. One way to achieve a reduction in strength of the secondary flow field is to reduce the tangential pressure difference near the end-wall.

- (U) Two computer programs were used to design the final wall contours. The first calculated the pressure distribution around an airfoil of the desired profile on a cylindrical surface. This program allows streamtube height variations but can not account for radial pressure gradients. The second deck performs axisymmetric intrablade calculations. The basic requirements that were set for a good wall contouring design are:
- The contour must decrease the local airfoil loading
 - The contour must not cause flow separation on the end wall
 - The increase in positive incidence caused by the contour must be less than 5°
 - The contour must not increase the adverse pressure gradient on the uncovered portion of the suction surface.
- (U) Contours were designed for both the inner and outer walls of the airfoil. Airfoil pressure distribution studies established that end-wall contouring using depths large enough to produce a significant reduction in the tangential pressure difference should not be accomplished by contours completely within the airfoil row. More acceptable was a contour designed to relieve the airfoil blockage effects by increasing the annulus area in the leading edge region.
- (U) After a study was made of many wall contours, the final contour which was judged to be the best design was one with sinusoidal inlet and exit sections, having the leading and trailing edges intersecting at the inflection points. The final design is shown in Figure 97. The inlet and exit sections were connected by a constant area section starting at approximately 24% of axial chord and ending at approximately 76% of axial chord. The static-to-total pressure distribution computed along the mean streamline at the airfoil root section is shown in Figure 98. This design met all the conditions which were established as requirements for wall contouring.
- (d) Flow Fences and Surface Roughness
- (U) Exploratory methods of boundary layer control which were deemed useful of some consideration were the use of flow fences and increased surface roughness. The flow fences are intended to block or impede channel cross flows at the passage walls, while increased surface roughness would force the boundary layer to an early transition from laminar to turbulent flow. Much promise was not held for the effectiveness of these two methods. They were simple to test, since as add-ons to the existing rig they could be run while hardware was manufactured for the more promising methods.

UNCLASSIFIED

- (U) The design of the flow fences is shown in Figure 99. These are to be applied to the second vane outside diameter wall and their height was obtained from the suction surface secondary flow patterns that were observed in the baseline tests described in Section IV. The flow lines, indicating a radially inward boundary layer movement, at the airfoil trailing edge, extended to approximately 0.5 inch from the wall surface. Allowing for the growth in corner vortex size from inside the passage to the exit plane, the fence height required to significantly reduce the end wall crossflow was estimated to be one-half the trailing edge size indication, or 6.3% of the span height. The fences were mounted in four passages midway between airfoil surfaces and extended the full passage length from leading edge to trailing edge.

Figure 99 Second Vane OD Shroud Fence Installation

- (U) Roughening of the inside diameter end wall was accomplished by attaching emery cloth to the end wall region in four passages. Calculations of the wall boundary layer indicated that the boundary layer would be transitional in the region between the inlet guide vanes and the test airfoils. Since this calculation involved approximations to the pressure gradient through the rig, it was decided to try the increased surface roughening in case the boundary layer had not actually transitioned. The calculated boundary layer thickness prior to transition was 0.020 inch. The coarsest emery cloth available was No. 50 grit which has an average roughness height of 0.013 inch. This value is above the computed critical value for boundary layer transition. This was cemented to the inside diameter end-wall and to the leading edges of the airfoils adjacent to the inside diameter wall.

UNCLASSIFIED

UNCLASSIFIED

4. STATUS

- (U) The locally recontoured airfoil design and fabrication was completed and the airfoils were inspected. Fabrication of the annular cascade pack is in process.
- (U) The locally recambered airfoil design was completed and the airfoils were fabricated. The airfoils will be installed into the annular cascade pack after inspection.
- (U) Extended airfoils for the wall contoured second vane tests were designed and fabrication of the airfoils was completed. The contoured walls are being fabricated.
- (U) Tests of the flow fences and increased surface roughness were completed. These tests were run simultaneously with the flow fences mounted on the outside wall and the roughness additions to the inside wall. The data from these tests is being analyzed.

UNCLASSIFIED

SECTION VI

MEDIUM SOLIDITY AIRFOIL EVALUATION (Task IIc)

1. OBJECTIVE

- (U) The initial objective of Task IIc was to investigate two additional boundary layer control methods, other than the two methods that were investigated under Task IIb, on two different airfoils. Since the performance of the four baseline airfoils (Section IV) were very similar, Task IIc was modified so that four boundary layer control methods were applied to only one airfoil, eliminating the need for Task IIc as originally conceived. By mutual agreement with the Air Force, the work substituted for the original Task IIc will now include the evaluation of the performance of higher load coefficient airfoils designed for the same velocity triangles as the baseline airfoils of Task IIb. The performance of these lower solidity airfoils will be compared to the performance of the nominal solidity airfoils reported in Section IV.

2. TASK OBJECTIVE

- (U) Each of the four medium solidity airfoils will be evaluated in an annular segment cascade. The entire testing program run previously for Task IIb will be reproduced for these airfoils.

3. AIRFOIL SECTION AND FACILITY DESIGN

- (U) The medium-reaction, medium-solidity airfoils were designed to the same turbine velocity diagrams as the normal solidity airfoils. A summary of the pertinent design values is presented in Table V. The elevations, gaging distribution, airfoil section, predicted surface pressure distribution, and airfoil radius of curvature distribution for each of the four airfoils is presented at five spanwise locations in Appendix I. The four airfoils are the first and second vanes and first and second blades. The fabrication coordinates of each of the airfoils are tabulated in Tables VI through XXXVI of Appendix II. The airfoil angles, airfoil areas, axial chords and uncovered turnings are also tabulated.
- (U) The test section design for each of the four medium-solidity airfoils is the same as those for the normal solidity airfoils. The inlet guide vane designs will be identical to those for the already completed normal solidity evaluation. The designs of the normal solidity cascades and inlet guide vanes were presented in Reference 2.

- (U) The instrumentation that will be installed for these tests will be essentially identical to that used for the normal solidity tests. The method of installation of surface static pressure taps, as shown for the normal solidity airfoils in Reference 2, was varied in that all the grooves for laying in the airfoil surface static pressure tubes were made on the pressure side, and holes were drilled through from the suction surface for those taps required on the suction surface. This method improved the suction surface finish since back filling of the grooves on the suction surface was not required. A radial traversing probe which can be positioned at different circumferential stations will be used to measure exit plane conditions.
- (U) A sketch of the test stand is shown in Figure 100. This stand is located in the Willgoos Laboratory, East Hartford.

4. STATUS

- (U) The design and fabrication of the test stand has been completed. Reoperation of the test stand has been completed. The cascade packs are being fabricated and the first vane cascade pack, shown in Figures 101, 102 and 103, has been completed. This pack has been installed into the rig and testing has been initiated.

SECTION VII

PRELIMINARY DESIGN MANUAL PREPARATION (TASK IIe)

1. RFP OBJECTIVE

(U) Prepare the preliminary draft of the Turbine Design Procedure Manual.

2. TASK OBJECTIVE

(U) The purpose of this task is to prepare and deliver a complete Turbine Design Procedures Manual. This manual will contain the following information for each computer program used to design the contract turbine: a flow diagram; a listing for all input and output items and their definitions; a list of definitions for each term used in the computer code; a write-up of the pertinent engineering equations; a listing of the computer code in Fortran IV; a copy of the computer program decks in Fortran IV; any necessary test cases for deck check-out.

3. STATUS

(U) Work is in process on the following computer programs:

- Turbine Meanline Design Program
- Turbine Stage-Off Design Program
- Turbine Streamline Analysis Program
- Airfoil Pressure Distribution Program
- Airfoil Boundary Layer Program
- Turbine Airfoil Design and Section Properties Program
- Airfoil Curved Line Fairing Program
- Airfoil Straight Line Fairing Program

(U) All of the decks have been converted to Fortran IV, and these were checked out on an IBM 7094. Flow diagrams for all decks have been completed. Listings have been made for all variables and for the input and output items of these decks. Engineering writeup of these decks has been initiated.

13. ABSTRACT (U) An extensive, four-phase, three-year program is in progress to investigate methods of improving the performance of fan-drive turbines. The goals of this program are to develop turbine design procedures and aerodynamic techniques for high work, efficient, low-pressure turbines. The first phase effort defining the preliminary turbine design has been completed, and the results were reported. The second phase consists of an experimental evaluation which includes establishment of both two-dimensional loss levels and three-dimensional flow behavior for the baseline airfoils and for airfoils utilizing boundary layer control devices. The design of the cascade hardware and baseline airfoils was previously reported. The test results of baseline airfoil performance in the annular cascade and the status of the other tasks are presented in this report. Distribution of this abstract is unlimited.
