Contract Number 7560: NABUSTDS 65 Ser. 300.

Library of Congress Catalog Card Number: Map 66-74

Preface

This atlas has been prepared for the radio engineer who wants an estimate of the behavior of the radio refractive index at any point on the earth. It has many limitations, which the authors have tried to point out in the text, but should provide useful information for engineering design and predictions of tropospheric radio circuits.

The work upon which this atlas is based has been in progress for several years in the Radio Meteorology Section of the Central Radio Propagation Laboratory, National Bureau of Standards, Boulder, Colo.* Many people have contributed to this research effort through the years, and it is not feasible to acknowledge them all individually. Those most directly involved with the preparation of material for this atlas include W. B. Sweezy and W. A. Williams, who were responsible for most of the computer programming; Mrs. B. J. Weddle, who assisted in processing and cataloging of the data; T. D. Stevens, who did most of the compiling, checking, and plotting of the maps, graphs, and tables; and L. P. Riggs, J. D. Horn, and Mrs. G. E. Richmond (deceased), who contributed to the atlas project in its early stages.

The National Weather Records Center of the U. S. Weather Bureau in Asheville, N. C., supplied the meteorological data upon which this atlas is based, and also performed the preliminary conversions of these data to refractivity parameters.

Finally, we thank the personnel of the U. S. Navy Weather Research Facility at Norfolk, Va., who foresaw a need for such an atlas and have arranged for support of the project over a period of years.

*Now the Institute for Telecommunication Sciences and Aeronomy (ITSA), Environmental Science Services Administration.

Abstract

This atlas presents world maps and graphs of upper-air radio refractivity, $N(z)$ (where z is the altitude), mean monthly ΔN (the difference between the refractivity at the surface and at 1 km above the surface), extreme values of gradients of refractivity observed in the lowest layer of the atmosphere (including maps of minimum trapped frequency ducting gradients), and monthly mean tropopause heights. All refractivity values were derived from radiosonde data. The $N(z)$ maps are presented in terms of a three-part exponential model, with separate exponentials for the water vapor and air density terms of $N(z)$, with the latter separated into tropospheric and stratospheric terms. The ΔN data were derived by interpolation from fixed pressure-level data.

1. Introduction

There has been a need in radio engineering for a method whereby the radio refractivity, N , at some height, z , or the gradient of N with respect to height, dN/dz , could be accurately estimated for any world location during any season of the year. Previous studies have attempted to solve this problem by determination of the value of surface refractivity, N_s , and the use of an exponential decay with height [Bean et al., 1960a]¹, or by presenting seasonal means and distributions of N at fixed pressure levels in the atmosphere for various radiosonde stations [U. S. Navy, 1955-59; Michaelis and Gossard, 1958]. However, these results did not provide any means whereby $N(z)$ could be obtained at any arbitrary location, i.e., places for which meteorological measurements were not available. In addition, specific information on the gradient of the refractive index has not been available previously on a worldwide basis, especially for the very important layers of the atmosphere at or near the surface where the presence of superrefractive or ducting gradients can produce anomalous propagation of microwaves.

This atlas presents maps, charts, and discus-

sions of the worldwide variations in the radio refractive index. With the aid of this atlas, estimates of the following parameters may be readily determined for any part of the world: the refractivity at any height, $N(z)$; the average gradient of N over the first kilometer above the surface, ΔN ; and the gradient of N in the lowest layer of the atmosphere (with emphasis on subrefractive, superrefractive, and ducting layers and the probability of trapping of radio waves by ducting layers). The world distribution of $N(z)$ is presented in the form of a three-part exponential model, with separate exponential terms for the water-vapor term, the density term in the troposphere, and the density term in the stratosphere; the parameters used to represent this $N(z)$ model are the reduced-to-sea-level values of surface water vapor and density terms, the scale heights of the three exponential terms, and the transition height between the tropospheric and stratospheric density exponentials. Seasonal maps of mean tropopause heights, which were obtained in the course of the data reduction required for the three-part exponential model, are also presented.

¹ Literature references on page 26.

2. Discussion of Basic Data

The radio refractive index of the atmosphere, n , exceeds unity by at most 450 parts per million; it is therefore customary to utilize the radio refractivity, N , given by ²

$$N = (n-1) \times 10^6. \quad (1)$$

The radio refractivity of air for frequencies up to 30,000 Mc/s is given by Smith and Weintraub [1953]:

$$N = 77.6 \frac{P}{T} + 3.73 \times 10^5 \frac{e}{T^2}, \quad (2)$$

where P is the total atmospheric pressure in millibars (mb), T is the absolute temperature in degrees Kelvin (K), and e is the partial pressure of water vapor in millibars. [For the development of this equation from theory, c.f. Bean, 1962]. The P/T term in (2) is frequently referred to as the "dry term" (even though there is a small water vapor component in the total pressure) and the e/T^2 term, as the "wet term."

The radiosonde is in general use throughout the world to measure the pressure, temperature, and relative humidity of the upper air. These data can be used to obtain the corresponding vertical profile of radio refractivity. However, there are a number of disadvantages in the use of radiosonde data for the purpose of obtaining N -profiles; perhaps the most important of these is the relatively slow response (large lag constants) of the radiosonde temperature and humidity sensors [Bunker, 1953; Wagner, 1960, 1961; Bean and Dutton, 1961]. Also of some importance is the method of selecting levels for which data are reported. The procedure followed by most meteorological services consists of reporting temperature, humidity, and height at certain fixed pressure levels, called "mandatory levels" (e.g., 850 mb), plus a sufficient number of additional "significant" levels to provide a profile of temperature and relative humidity such that linear segments between levels will not depart from the original data at any point by more than 1°C or 10 percent relative humidity. Such tolerances, although acceptable for most meteorological purposes, may result in errors of as much as 30 N -units (under

extreme conditions) in a linear-segment N -profile constructed from radiosonde data. Some punched-card refractivity data are available which were calculated from significant levels chosen with an even wider tolerance, 2°C and 30 percent relative humidity [Bean and Cahoon, 1961a]. In spite of these deficiencies, this atlas is based entirely upon radiosonde data, since no other worldwide, long-term upper-air data are available. (More detailed measurements, obtained primarily from wiresonde and aircraft refractometer flights, are available only for a very few locations and for very limited periods of time.)

The first step toward obtaining a broad sample of upper-air refractivity data was the selection (by geographic-climatic considerations and period of record available) of 112 radiosonde stations from the worldwide network.³ Wherever possible, a total of 5 years of data was obtained for each of the 4 representative "seasonal" months of February, May, August, and November.

Five-year means were selected for use in the preparation of this atlas for two reasons: (a) a large number of stations, including all of those in the U.S.S.R., have available records dating back only to the International Geophysical Year (IGY), 1958; (b) 5 years seemed to represent the best compromise between the number of stations and the length of record, since the total amount of data which could be processed was naturally limited. A large number of stations is desirable for mapping purposes (better coverage), while longer periods of record yield more stable (accurate) estimates of long-term means (of climatic variables). For each radiosonde ascent, the reported values of pressure, temperature, and humidity at each mandatory or significant level were converted by means of (2) to radio refractivity values (by the National Weather Records Center, Asheville, N. C.). These data, when received at ITSA, were used to obtain four monthly *mean N-profiles* for the available period of record for each of the 112 stations. The procedure followed was to obtain for each profile the values of N at a number of standard height levels by assuming separate exponentials for the dry and wet terms between each reported level. The mean N -profile for the

² Throughout this atlas, the term atmosphere should be understood to mean the nonionized atmosphere, i.e., excluding the ionosphere.

³ A list of these stations is included in appendix A.

standard height levels was then computed as the arithmetic mean of the individually interpolated values of N at each standard height for all of the profiles in the sample. In this way, 5-year mean values of refractivity were obtained for a large number of levels, ranging from the surface to 30 km (or more) above the surface, for a worldwide sample of stations. Over 18,000 individual values of mean N were determined in this way.

In addition to these calculations, the approximate height of the tropopause was determined for each profile; this was the height of the bottom of the lowest atmospheric layer which met the following criteria:

- (a) the layer thickness was ≥ 2 km,
- (b) the temperature gradient $\geq -2^\circ\text{C}/\text{km}$.

The 2-km thickness could be made up of two or more consecutive layers from the radiosonde data. Mean monthly values of tropopause heights were obtained for the period of record for each station by averaging the individual profile tropopause heights; maps of these tropopause heights are shown in appendix D.

The monthly mean value of the average N -gradient between the surface and 1 km above the surface has been recognized as a radio-meteorological parameter of some importance

⁴ Data from these two publications (published by the National Weather Records Center, Asheville, N.C., under the sponsorship of the World Meteorological Organization [WMO] and the U.S. Weather Bureau) will hereafter be referred to as "weather summary data."

[Saxton, 1951; Bean and Meaney, 1955; CCIR, 1965]. Therefore, maps are included of the mean value of this parameter for all 12 months, with a more comprehensive network of stations than was available from the complete radiosonde data sample discussed above. For this purpose a sample of 268 stations was chosen from those available in the Monthly Climatic Data for the World and the National Summary of Climatological Data (U.S.A.).⁴ These publications list monthly mean values of pressure, temperature, and relative humidity or dew point for the surface and some of the mandatory pressure levels from radiosonde data. For stations near sea level, the 900-mb level is very close to 1 km above the surface, but for most stations outside of the U.S.A. the 850-mb level was the lowest reported; the altitude of this pressure level varies between roughly 1.3 and 1.5 km above sea level. However, it was felt that interpolation from the 850-mb data, using separate exponentials for the wet and dry terms, would yield fairly accurate values of monthly mean N at the required 1-km height.

The radiosonde-derived data described in the preceding paragraphs constitute the basic data from which this atlas has been prepared. In the following sections the methods of reduction and presentation of these data are discussed, as well as the consistency and reliability of the results so obtained.

3. World Maps of $N(z)$

3.1. Development

In order to prepare worldwide maps of upper atmospheric N from the 5-year mean N -profiles described previously, it was decided to reduce the quantity of necessary $N(z)$ maps by abstracting each mean profile in terms of a model atmosphere which would use three negative exponential functions of altitude. The three functions which are used to represent each mean profile are a single exponential for the wet term, W , and two exponentials for the dry term, D . Two exponential functions are necessary for the dry term because of the change in the lapse rate of the temperature from the normal $6.5^\circ\text{C}/\text{km}$ in the troposphere to the nearly isothermal stratosphere where the temperature may increase with height. Least-squares fits were obtained for $\log \bar{W}$ versus height over the interval 0 to 3 km above the surface. The ranges to be covered by the two fits for the dry term were determined from the mean tropopause heights and their standard deviations which had been obtained during the analysis of the N -profiles in each sample. The tropospheric dry term, D_1 , was fit over the interval 0 to the tropopause height minus one standard deviation, and the stratospheric dry term, D_2 , was fit from the tropopause height plus one standard deviation to the upper limit of data for that profile. In both cases, $\log \bar{D}$ was fit to height using least squares. The resulting model atmosphere is given by

$$\bar{N}(z) = \bar{D}_0 \exp\left(-\frac{z}{H_1}\right) + \bar{W}_0 \exp\left(-\frac{z}{H_w}\right), \quad (3)$$

$$z \leq z_t,$$

$$\bar{N}(z) = \bar{D}_0 \exp\left(-\frac{z_t}{H_1} - \frac{(z - z_t)}{H_2}\right) + \bar{W}_0 \exp\left(-\frac{z}{H_w}\right), \quad (4)$$

$$z > z_t;$$

$\bar{D}_0$ and $\bar{W}_0$ are the mean sea-level values of the dry and wet terms (reduced from the surface values using the free-atmosphere scale heights), H_w is the wet-term scale height, H_1 is the tropospheric dry-term scale height, H_2 is the stratospheric dry-term scale height, and z_t is the altitude above mean sea level of the point of transition between the tropospheric and stratospheric dry-term exponentials. The altitude, z_t ,

may thus be thought of as an effective density tropopause.

Examples of the application of this model to actual mean refractivity profiles are given in figures 1 and 2: a very good fit (Koror) and one of the worst fits encountered (Dakar). The good fit obtained in figure 1 is especially significant since Koror represents a climatic type (equatorial station with a very high mean surface refractivity, 387.6) for which exponential models of N were previously thought to be unsatisfactory [Misme et al., 1960]. Dakar (fig. 2) is an example of the climatic type (characterized by a persistent low-level temperature inversion with dry subsiding air above) where this model (or any other simple model) of N versus z is inadequate to explain the N -structure at low latitudes. It was found that the behavior of the wet term (measured on figs. 1 and 2 by S_w , the rms error over the first 3 km) was a good indicator of whether or not the data would provide a good fit to the profile. However, it can be noted in figure 2 that, even though the rms wet-term error below 3 km is 14.6 N -units, the profile at Dakar above an altitude of 6 km is well represented by the three-part exponential.

Maps were prepared for each of the 4 "seasonal" months of the parameters necessary to utilize the three-part exponential in estimating upper-air refractivity. These are the reduced-to-sea-level values, $\bar{D}_0$ and $\bar{W}_0$; the three scale heights, H_w , H_1 , and H_2 ; and the transition altitude, z_t . The surface values of $\bar{N}$ can be recovered by substituting the elevation of the surface above sea level at the desired location in (3), which amounts to inverting the process used to reduce the surface values of $\bar{N}$ to sea level. The series of maps given in appendix A can be used to estimate the mean value of N at any desired altitude for each of the seasonal months at any world location except those areas outlined in figure A-30 (which summarizes the wet-term rms error values found in figures A-26 through A-29).

3.2. Discussion of $N(z)$ Map Contours

The world maps of $N(z)$ parameters reveal a number of interesting trends. Some of these are:

(1) The D_1 scale height, H_1 :

(a) is smaller than average over the arctic seas in winter because of dense stratified air;

(b) remains higher than average over land areas during their warm seasons due to a steep temperature lapse rate with height.

(2) The D_2 scale height, H_2 :

shows a minimum in the equatorial region because of the colder temperatures found above the tropical tropopause.

(3) The wet scale height, H_w :

(a) is larger than average in the general area of the equatorial heat belt during all seasons. This indicates a steep temperature gradient with a very small lapse of *absolute* humidity with height in the turbulently mixed deep layer of warm air. However, in some tropical areas

FIGURE 1. Three-part exponential fit to mean N -profile: Koror.

definite changes may occur in H_w because of seasonal shifting of small, but persistent, anti-cyclonic circulations which modify to a considerable vertical extent the normal zonal transport of water vapor in those latitudes. The seasonal differences of H_w in the Coral Sea area seem to confirm the existence of such a cellular structure northeast of Australia [Hutchings, 1961].

(b) is larger than average over two types of convectively heated continental interiors:

(1) high-latitude land masses where the sea-level wet term is less than 20 N -units;

(2) temperate desert steppe regions where the sea-level wet term is between 20 and 60 N -units.

(c) is lower than average in areas where subsidence or tradewind ducting persistently occurs below 3 km.

(4) The dependence of the dry sea-level values, D_0 , upon temperature (because $D_0 = 77.6 P/T$) is revealed in such features as the 332 high in Siberia during February and the 260 low in the Sahara Desert during May and August.

(5) The wet sea-level values, W_0 , are also

very dependent upon temperatures because of the larger water content possible at high temperatures. There are two exceptions:

(a) Large interior deserts, where mountains block the normal moisture flow, tend to have low wet-term values relative to their temperatures.

(b) In August, when the monsoonal moisture is trapped south of the Himalayas, India shows unusually high wet-term values.

(6) The intersection height, z_t , is closely related to the height of the tropopause, but in areas where an isothermal layer precedes the stratospheric increase of temperature, the D_2

FIGURE 2. Three-part exponential fit to mean N-profile: Dakar.

curve may intersect the D_1 curve as much as 2 km below the tropopause heights given in figures D-1 through D-4 (see appendix D).

3.3. Reliability of Contours of $N(z)$ Maps

Although radiosonde stations are the only worldwide source of upper-air meteorological data, many areas of the world had few, if any, radiosonde reporting stations before 1957. As a result of the IGY, many new stations were established, especially in the lower latitudes; however, radiosonde data are still not available

for a number of large areas, such as Brazil, China, and the Indian Ocean. High latitudes also show a noticeable sparsity of upper-air data; fortunately, there is a fairly small and uniform transition in most parameters at these far-south and far-north latitudes. Even in the U.S.A., where the first radiosonde network was established in 1938, radiosonde stations are still several hundred miles apart.

The maps were hand-contoured by interpolation between the widely-spaced plotted data points, using a technique similar to that used in the analysis of synoptic weather maps. Each

map was then carefully checked by another analyst to make certain all data points had been properly considered. The contours were modified in some areas on the basis of other information or considerations not accounted for in the machine-analyzed radiosonde data. For instance, supplementary surface data [Knoll, 1941; Serra, 1955; Bean and Cahoon, 1957; UNESCO, 1958; Bean et al., 1960b; Air Ministry, 1961; Dodd, 1965] were considered in the contouring of those parameters (D_0 and W_0) dependent upon surface observations. Also, if spurious "high" centers of the wet term (such as the isolated values found at Tananarive, Malagasy Republic) were produced at high elevation stations by reduction-to-sea-level procedures, these values were smoothed to some extent. It was also found that the wet scale heights derived from mean N -profile data for stations at altitudes greater than 1 km tend to give more unrealistic sea-level wet terms than the average wet-term scale height of 3.0 km suggested by Hann [List, 1958]. When this "standard atmosphere" scale height was substituted for H_w , the maximum error of $N(z)$ values calculated from (3) or (4) for all stations above 1 km which are listed in table A-1 was 6.2 percent of the true 5-year mean value at Tananarive in August; the second largest error was 5.5 percent at Nairobi in February.

Another contouring check was made of all modified contours; a third analyst reviewed the smoothing to be sure it was consistent with the original plotted data as well as with the supplementary information.

To further check the contouring, calculated $N(z)$ values (using (3) and (4) with values read from figs. A-1 through A-25) were compared with actual observed values at 32 representative stations. The results of this check (reported in detail in table 2 of sec. 7) emphasize that, although some error undoubtedly results in $N(z)$ values below 1 km due to contouring, it is not a problem for $N(z)$ values at 3 km or above.

3.4. Problem Areas of $N(z)$ Maps

The use of wet and dry scale heights in a bi-exponential radio refractive index model has proved to be a good indicator of climatic differences [Bean, 1961; Misme, 1964]. The dry term, or atmospheric density component of refractivity, decreases with height in a uniform manner throughout the troposphere so that its scale height is an accurate indicator of the degree of density stratification, but the water-vapor component (the wet term) is not so well-behaved. Because the saturation vapor pressure, e_s , is itself an exponential function of temperature (which generally decreases linearly

with height), one of the best wet-term models is probably an exponential curve [Reitan, 1963; Dutton and Bean, 1965]. However, an exponential model of the wet term must be used with discretion because humidity is extremely variable, both vertically and horizontally (because of its high dependence upon the temperatures within the different air masses, as well as various terrain and land-water effects).

To show actual physical changes in H_w , the wet scale height, it would be desirable to present contoured values based not only on a large number of stations, but also on data representative of various times of day. Figures A-6, A-12, A-18, and A-24 present the seasonal values of H_w , but worldwide maps of the diurnal variability of the wet scale heights are not yet available.

There are three specific areas of the world where the assumption of an exponential distribution of the wet term is largely invalid and can be used only with reservations. Two of the areas have one thing in common—a low sea-level wet term. At continental stations in high latitudes where strong temperature inversions persist during winter months, the wet term at 3 km may be as large as, or even larger than, that at the surface (because of the increase of water vapor "capacity" with temperature), and the result is a negative or a very large positive value of the wet scale height, neither of which is physically realistic. At any tropical desert station where the sea level wet term is < 30 N -units, deceptively high wet scale heights also may result. Fortunately, because of the small contribution of the wet term in these cases, the total N -error remains small. The wet-term profiles at nine stations with low values of W_0 were examined, and the largest error at any height was 3.7 percent of the true 5-year $N(z)$ value at Niamey (a desert station) in February (fig. 3). In the arctic areas (represented by Barrow, Alaska, in this same figure) the maximum error never exceeded 1.5 percent of the total $N(z)$ value.

The third area presents a more serious problem because it exists in a subtropical climate (15° – 35° north and south of the equator) where the wet term contributes from $1/4$ to $1/3$ of the total N . The sharp decrease of humidity and increase of temperature which is found in atmospheric layers between the surface and 3 km in the subsidence regions of semipermanent subtropical highs destroys the exponential distribution of the wet term. In fact, in regions such as this, the exponential fit may be valid only at two or three points. This can be noted in figure 4, where the mean wet term for May is graphed, and the H_w value from the least-squares fit from 0–3 km of $\log \bar{W}$ versus height is indicated, for

four dissimilar stations: Dakar (low-level subsidence), Antofagasta (intermediate subsidence-trade wind ducting), Hilo (trade wind inversion), and Balboa (steep exponential gradient). A check of figure A-30 reveals that the

first three of these stations are located in areas where, because the rms of the wet-term error exceeds 5 N -units for at least 1 month, the three-part exponential model is not recommended.

FIGURE 3. *Five-year mean wet refractivity term: February.*

FIGURE 4. Five-year mean wet refractivity term: May.

4. World Maps of $\overline{\Delta N}$

4.1. Development

Twelve maps of monthly mean ΔN were prepared from the 5-year mean values obtained by interpolation of mandatory pressure level radiosonde data for the 268 stations listed in table B-1 and located in figure B-1 in appendix B. These maps, contoured in the same manner as the $N(z)$ maps (sec. 3.3), are figures B-2 through B-13.

Previous work has shown that a good correlation may exist between ΔN and surface N on a monthly mean basis [Bean and Thayer, 1959; Bean and Cahoon, 1961b; CCIR, 1965]. In fact, in many areas of the world this seasonal correlation is very high, and in such areas a regression line might provide better estimates of monthly mean ΔN than the maps in appendix B (if the mean value of surface N were available for that particular month of that year for the desired location). This regression line could also be used with the N_s distribution data from table A-1 to provide estimates of the ΔN distribution. Correlations were therefore calculated for the 12 monthly mean values of ΔN and surface N for each of the stations in the sample. The equations resulting from these calculations were put into the form of deviations from the annual means:

$$\overline{\Delta N} = b(\overline{N}_s - \overline{N}_s) + \overline{\Delta N} \pm \text{S.E.}, \quad (5)$$

where N_s is the surface value of N , the single bar represents a monthly mean value, the double bar represents the annual mean, b is the slope of the regression line, and S.E. is the standard error of estimate. The equations were put in this form because the intercept of the equations in the ordinary form is equal to $\overline{\Delta N} - b\overline{N}_s$, which is too unwieldy for contouring on maps. Maps, which appear in appendix B, were prepared of the slope (b), the annual means ($\overline{\Delta N}$ and $\overline{N}_s$), and the standard error of prediction and correlation coefficient of the regression lines.⁵

4.2. Discussion of Contours and Reliability of $\overline{\Delta N}$ Maps

The world $\overline{\Delta N}$ maps of this atlas do not show as much detail as may be found in other publications which consider only specific areas [Bean

et al., 1960b; du Castel, 1961; Rydgren, 1963; CCIR, 1963]. It was necessary in this study to omit some of the available radiosonde data in areas with relatively dense weather networks (e.g., the U.S.A. and Europe) in order to obtain a more nearly uniform worldwide coverage. Even with this coverage, the map scale size precluded the contouring detail which would be necessary if localized terrain effects were to be included; for example, mountainous locations (higher than 1 km) probably have lower values of ΔN than those indicated in figures B-2 through B-13. Some dissimilarity in the contour patterns between the maps in appendix B and other $\overline{\Delta N}$ maps may also be found because of the differences in the time period used in the samples; such disagreements emphasize the fact that 5 years of data are not adequate for reliable means in many areas.

The map contours of worldwide $\overline{\Delta N}$ indicate that:

- (1) Low values of ΔN are characteristic of:
 - (a) large desert and steppe regions such as the Sahara, the Australian interior, the southwestern U.S.A., and the Asian region southeast of the Caspian Sea all year;
 - (b) high plateau areas during all seasons except winter.

- (2) High values of ΔN are found in:

- (a) all areas where large masses of subsiding air prevent the normal diffusion of water vapor, creating an unusually large N -gradient between the moist surface air and the very dry air at 1 km. Specific examples are:

- (1) continental west coasts at latitudes $20^\circ - 35^\circ$ in the summer hemisphere and $10^\circ - 25^\circ$ in the winter. In fact, the true $\overline{\Delta N}$ may be higher than indicated on the maps at locations such as Dakar, Senegal, where a very thick (~ 250 m) surface or near-surface ducting layer occurs much of the time;

- (2) tropical ocean areas where a trade-wind inversion leads to a persistent elevated ducting layer below 1 km. [Note: In a few cases where the entire thickness of an elevated layer lies between 1 km and the height of the 850-mb level, the interpolation method gives a map value which may be 5 to 10 N -units too high.]

- (b) southeast Arabia and the Gulf of Persia during July and August, when orographic subsidence traps moisture from the southwest monsoon in the gulf and lowlands between the mountains.

⁵ N_0 is an approximate sea-level value of N_s , defined by the equation $N_0 = N_s e^{0.12z}$, where z is the elevation above sea level in km.

(c) Siberia and the Canadian interior in winter because of the intense surface temperature inversion.

(d) the Mediterranean and Black Seas during summer when convective mixing greatly increases the near-surface humidity.

(e) India in the spring, when increased heating over land produces a low-pressure region which leads to onshore winds and humid

weather conditions until the onset of the monsoon.

In winter a combination of high and low $\overline{\Delta N}$ values appear near the tip of southwest Africa as the subsidence from the South Atlantic High causes a large moisture gradient to appear off the coast, whereas a small humidity gradient is characteristic of the dry plateau region inland.

5. World Maps of Extreme N -Gradients

5.1. Development

The gradient of N near the surface of the earth is of particular importance in many applications of telecommunications; e.g., extreme values of these initial gradients are responsible for much of the unusual behavior of radio systems. Superrefractive gradients (defined here as values between -100.0 N/km and -156.9 N/km) are responsible for greatly extended service horizons, and may cause interference between widely separated radio circuits operating on the same frequency. Ground-based radio ducts (layers having a negative gradient larger in absolute value than 156.9 N/km) can cause prolonged spacewave fadeouts within the normal radio horizon [Bean, 1954] and allow radar to track objects many hundreds of kilometers beyond the normal radio horizon. On the other hand, subrefractive gradients (zero or positive gradients) produce greatly reduced radio horizons, and may result in diffraction fading on normally line-of-sight microwave paths.

In the process of obtaining the mean N -profile for each station and month, cumulative distributions were prepared of the gradients occurring between the surface and the 50-m and 100-m levels. Each gradient was calculated as the simple difference between the surface N and the value at 50 or 100 m above the surface, divided by the height interval. For 99 out of the 112 stations in the mean N sample, cumulative distributions were also prepared of the gradients and thicknesses of all observed ground-based superrefractive or ducting layers, regardless of the thickness of the layer (except that no layer less than 20 m thick was included, because the gradients obtained in such cases are not considered to be reliable). In addition, cumulative distributions were prepared of the minimum trapped frequency for each of the observed ducts in the sample. (This sample size averaged 208 pieces of data for each month; for all months the smallest sample was 30 and the largest, 620). The minimum trapped frequency refers to the approximate lower limit of frequencies that will be propagated in a duct in a waveguide-like mode, and is given by [Kerr, 1951]

$$f_{\min} = \frac{1.2 \times 10^5 \text{ (c/s)}}{(t)^{3/2} \left[-\frac{dn}{dz} - \frac{1}{r} \right]^{1/2}}, \quad (6)$$

where $f_{\min}$ is the minimum trapped frequency in

c/s, t is the total thickness of the duct in km, dn/dz is the average gradient over the duct (n/km), and r is the radius of the earth in km. Equation (6) is derived under the assumption of a constant gradient throughout the duct, but moderate departures from this assumption do not seem to affect the results greatly. The $f_{\min}$ corresponds to an absolute attenuation of the guided energy of about 3 dB/km (5 dB/mile) [Kerr, 1951].

The maps in appendix C were prepared from the cumulative distributions discussed above. The distributions of gradients for the 0 to 100-m layer were used to obtain maps of the positive (subrefractive) gradient exceeded for 10 and 2 percent of the observations at any location, and the percent of observations with 0 or positive N -gradients. Maps were also prepared of the extreme values of negative gradients observed; these are referred to as "lapse rates" of N (i.e., decrease with height, a term normally used in referring to atmospheric temperature gradients; it is used here to avoid the awkwardness of referring to a very strong negative gradient as being "less than" a given negative value). Included in appendix C are maps of the lapse rate of N exceeded for 25, 10, 5, and 2 percent of the observations for the 100-m layer. Cumulative probability distribution charts of the gradients at 22 representative world locations are also presented.

Other maps in appendix C were prepared from the distributions of superrefractive and ducting layer gradients, thicknesses, and $f_{\min}$ values for ducts. These include the percent of time that the lapse rate of N in the ground-based layer is equal to or larger than 100 N/km and equal to or larger than 157 N/km (ducting gradient), the percent of superrefractive layers that were more than 100 m thick, and the percent of ducting layers that were more than 100 m thick (the last two refer to the percent of thick layers out of the number of observed layers of that type). The distributions of $f_{\min}$ values were used to prepare maps of the percent of all observations which showed ground-based ducts having an $f_{\min}$ value of less than 3000 Mc/s, 1000 Mc/s, and 300 Mc/s.

5.2. Discussion of Gradient Map Contours (Subrefraction)

Ground-based subrefractive layers may be

found in the same tropical and subtropical locations as superrefractive layers, because a small change in relative humidity at high temperatures produces a very noticeable change in absolute humidity, and the N -change (either positive or negative) with height is highly dependent upon the variation of absolute humidity. For instance, subrefractive gradients occur quite often during the afternoon at stations which experience superrefraction or ducting during the night and early morning. Other stations may have nocturnal subrefraction during winter and superrefraction during the same hours in summer. However, subrefraction, unlike superrefraction, rarely occurs at surface temperatures below 10°C (the only exception would be locations greater than 1 km above sea level).

The surface conditions conducive to subrefractive gradients are of two rather opposite types:

(a) temperature $> 30^{\circ}\text{C}$; relative humidity < 40 percent;

(b) temperature 10° to 30°C ; relative humidity > 60 percent.

Type (a) is usually found during the daylight hours of months when intense solar heating occurs at warm, dry continental locations and forms a very nearly homogeneous surface layer (no decrease of density with height) which may be several hundred meters thick. Since a moist parcel of air is less dense than a dry parcel at the same temperature and pressure, the intense convection which occurs within such a layer of absolutely unstable air tends to concentrate the available water vapor near the top of the layer, because a moist adiabatic upper boundary is formed where the superadiabatic lapse rate changes abruptly to a subadiabatic or very stable lapse rate. The result is an increase (sometimes as large as 50 percent of the surface value) with height of the wet term through the ground-based layer. This increase, coupled with no change in the dry term, leads to a subrefractive (or positive) gradient.

This layer may retain its subrefractive nature throughout the early evening hours at stations where conditions are favorable for the development of a temperature inversion. As the ground cools rapidly, the air very near the ground cools and becomes more dense, but the water vapor which is trapped between the two stable layers causes the positive wet-term gradient from surface to the top of the original layer to remain large enough to overbalance the slightly decreasing gradient of the dry term. This evening subrefraction is an outgrowth of type (a); however, it may resemble type (b) at the surface because it can be found with a temperature as low as 20°C and a relative humidity as high as 60 percent.

Type (b) occurs most often during night and early morning hours, and is characteristic of coastal trade-wind and sea-breeze areas where differential heating of land and sea results in the advection of air which is warmer and more humid than the normal surface layer. In this type, both dry and wet terms may increase with height, creating a surface layer of subrefraction which is generally more intense in gradient than type (a) but not so thick. This form of subrefraction might also be found for short periods in *any* location where frontal passages or other synoptic changes create the necessary conditions.

Type (a) subrefraction is hard to evaluate from figures C-1 through C-4 because its percentage occurrence at any specific location is so dependent upon the time of day represented by the radiosonde data at that location. For instance, because the local radiosonde observation times in the southwestern U.S.A. were 0800 and 2000 for the data period used in this atlas, only the subtype (a) of evening subrefraction is recorded. Because conditions are more suitable for inversions in February and May, these months appear to have surface-based subrefractive layers more often than August. However, a detailed check of midafternoon observations near White Sands, N. Mex., reveals that midday subrefractive conditions are quite prevalent during much of August and September. The same diurnal problem is found in northern Africa and the desert region south and east of the Caspian Sea, where many of the stations take observations between 0300 and 0600 LST. Furthermore, even at those stations which do have midday data, the "motorboating" problem (i.e., humidities too low to be measured by the radiosonde — see sec. 5.5) during the warmest seasons at very dry locations probably masks out a large percentage of subrefractive occurrences; e.g., the occurrence of subrefraction recorded in November and February for the interior of Australia (where afternoon observations are included) is probably too low.

Figures C-1 through C-4 reveal that type (b) subrefraction can be expected 10 to 20 percent of the time in the western Mediterranean Sea and the Red Sea area, and also in the Indonesian-Southwest Pacific Ocean region. These locations seem to indicate a slight seasonal trend, with a higher probability of occurrence during winter months. Another region with a 10 to 20 percent level of subrefractive gradient occurrence is the Ivory Coast and Ghana lowlands of Africa where onshore winds prevail all year.

Occurrences of type (b) subrefraction exceed 5 percent at these locations and times of year:

(1) Southeast coast of U.S.A. all months;

- (2) Hawaiian Islands all months except May;
- (3) South Africa all months except November;
- (4) Southeast coast of South America in November and February;
- (5) Southern California in November;
- (6) North Indian Ocean in May;
- (7) Isthmus of Panama in November.

5.3. Discussion of Gradient Map Contours (Superrefraction and Ducting)

Superrefractive and ducting gradients in ground-based layers are most often associated with temperature inversions (temperature increasing with height within the layer), not only because a positive temperature height-gradient causes a negative N -gradient, but also because the low eddy diffusion qualities associated with a temperature inversion often lead to a steep negative gradient of humidity through the inversion. However, previous investigations [Bean, 1959] have shown that there are at least two other typical situations encountered in the formation of strong ground-based gradients: The first of these is the arctic situation, where, with surface temperatures below about -20°C , a strong temperature inversion (typical of continental arctic air masses) produces a superrefractive or ducting layer, while the vapor pressure may actually increase with height. More often, in this case, the wet term is negligible throughout the layer. The second case is typical of very humid tropical areas when the surface temperature is 30°C or greater. In these locations (which are usually coastal) a common occurrence is a slight decrease of temperature with height, accompanied by a very strong lapse of *absolute* humidity. Such profiles may show only a slight decrease of *relative* humidity with height, but, because the saturation vapor pressure is nearly an exponential function of temperature, the resulting vapor pressure gradient may be very large, thus causing a steep N -gradient.

Figures C-41, C-45, C-49, and C-53 show that persistent ducting (D) or superrefractive (SR) initial gradients can be found more than 25 percent of the time for at least two seasons in seven general areas of the world:

- (1) Dakar - Fort Lamy transitional strip in Africa (D: all seasons),
- (2) northern Arabian Sea including coastal areas of the Gulf of Aden and the Persian Gulf (D: all seasons),
- (3) India, Bay of Bengal, southeast Asia, Indonesia, and north tip of Australia (SR: all seasons),
- (4) southwest coast of North America, including portions of the North Pacific (SR: Feb-

ruary, May, November),

- (5) Gulf of Mexico and Caribbean region (SR: May, August, November),
- (6) northwest coast of Africa and western Mediterranean (SR: May, August),
- (7) Antarctica (D: May, August).

Area (1): Tropical west coast locations in the vicinity of 15° – 22°N or S are affected annually by three or four latitudinal weather zones [Trewartha, 1961]. In winter the Dakar-Fort Lamy region is under the influence of dry anticyclonic Saharan air, but even at the time of low sun, the prevailing surface air movement is onshore from the southwest. The vertical depth of this maritime current is more shallow than in summer, but during the early morning hours, the surface relative humidity is 80 to 90 percent compared with 40 to 60 percent in the dry subsiding air above. Even with radiational cooling, the night temperatures throughout the marine layer (from 50 to 600 m thick) still remain over 20°C . This combination of temperature and humidity creates trapping conditions for frequencies below 300 Mc/s about 30 percent of the time in February (fig. C-31).

The weather zones advance rapidly northward [Thompson, 1965], so that by July the Dakar-Fort Lamy strip is in the wet tropical regime associated with the fluctuating, unstable Intertropical Convergence Zone (ITC). The marine current of the westerlies becomes much deeper, but the ducting layers are shallower and can exist only intermittently between the turbulent, showery periods common to the region. Figures C-22, C-24, C-26, and C-28 indicate that more than 30 percent of the ducting layers are over 100 m thick for all seasons except summer.

Area (2): The coastal areas of Arabia experience high surface humidities all year from monsoonal and sea-breeze effects, but during May and August these values are reinforced by temperatures above 25°C in a marine layer which may extend up to a height of 800 to 900 m before it meets the overrunning dry northeasterlies [Tunnell, 1964]. The percentage occurrence of ducts at Bahrain seems much higher than at Aden because all observations at Bahrain were taken at 0300 LST (when the surface humidity is at its maximum of 75 to 90 percent), whereas the Aden observations, taken twice a day, include as many observations at 1500 LST (when the relative humidity value is much less) as at 0300 LST. For instance, 50 of the 66 ducts recorded in August at Aden were from early morning observations. However, the fact that ducting gradients at Bahrain trap frequencies below 300 Mc/s over 75 percent of the time as compared to 5 percent at Aden (fig. C-37) is due to another factor: the thickness of the moist marine layer, when ducting is present

at Bahrain, is greater than 300 m over half the time.

Area (3): A moist surface layer is also found in the monsoonal areas. Its temperature is 25 to 30°C and, during occurrences of ducting, the surface relative humidity ranges from 85 to 100 percent, but the trapping incidence is much less than in either area (1) or (2). The surface layer is shallower and its gradient is less intense because the humidity decrease between it and the air mass directly above it is only 10 to 20 percent. Because brief periods of stable weather occur even between surges of the summer monsoon, the ducting incidence remains over 10 percent for all of area (3).

Area (4): Along the western coast of North America, from Southern California to Central Mexico, the most important month for unusual radio propagation due to surface conditions is February, when frequencies below 300 Mc/s are trapped 10 percent of the time. During the period studied, 30 percent of the superrefractive gradients were at least 300 m thick in all 4 months. Closer examination of the ducting structure in Mazatlan reveals that if near-surface layers (bases of 100–300 m) were included, the percentage of occurrence would be increased by 20 to 40 percent for all months except August. During February, May, and November the surface temperature of 20 to 30°C remains nearly constant through the ducting layer, but the relative humidity decreases from a surface value of 70 to 80 percent to values ranging from 20 to 40 percent. The dry air in the upper layer results from subsidence in the eastern margin of the Pacific high pressure cell, which shifts northwestward in August, thus decreasing the ducting incidence in Mazatlan but increasing it in lower California and the Hawaiian Islands (figs. C-21, C-23, C-25, C-27).

Area (5): The center of most intense ducting in the Caribbean Sea and Gulf of Mexico changes with the seasons (figs. C-41 through C-56). The smallest percentage of superrefractive ground-based gradients is found in February, with the stronger gradients concentrated near the east coast of Central America. By May the superrefractive area has shifted eastward into the Caribbean and northward into Florida. In August it includes parts of the eastern U.S. but is still most intense in the Swan Island area, and in November the area encompasses all of the Caribbean. The ground-based superrefractive layers are thicker than 100 m approximately 70 percent of the year, but the ducting layers are never intense enough to exceed the 1-percent trapping level for 300 Mc/s.

Area (6): The cause of superrefraction in the western Mediterranean and northwest Africa is very similar to that in area (4). During the summer season, subsidence along the eastern

edge of the Atlantic high-pressure cell superimposes a dry layer over the marine surface layer; during the winter season, the major subsidence area shifts southward, the temperatures throughout the surface layer are 5 to 10°C lower, and the percentage of superrefraction and trapping incidence decreases.

Area (7): During the long Antarctic night, intense radiation from the snow-covered ground keeps the surface temperature much lower than that in the air several hundred meters above. This temperature inversion of 10 to 25°C is the cause of all the ducting gradients in May and August, which trap frequencies <1000 Mc/s at least 40 percent of the time (see appendix E).

5.4. Discussion of Cumulative Distributions of Ground-Based Gradients

Data from 22 representative stations were selected as a sample of the kinds of ground-based gradient distributions from the surface to 100 m which occur in various climates and locations throughout the world.

Interesting similarities which exist among the gradient distributions imply that the refractivity climate of any station may be related more to the season or month of the year than to any particular latitudinal location. For instance, consider the interesting relationships between Bangui (a tropical station), Bordeaux (temperate), and Amundsen-Scott (arctic). The gradient distribution at Amundsen-Scott in February resembles that of Bordeaux in February, but its August distribution slope resembles that of Bangui in May. However, Bangui's distribution slope and range in August resembles Bordeaux in May. Amundsen-Scott forms another interesting climatic triad with Saigon and Long Beach. In August the distribution slope and range of Amundsen-Scott is very similar to that of Saigon (a tropical station), but the negative gradient intensity is about 100 *N*-units greater at all percentage levels. However, Saigon in May, before the monsoon, resembles Long Beach in February.

It was expected that a pronounced diurnal effect would exist in the gradient structure near the surface, so two stations, Aden, Arabia, and Nicosia, Cyprus, where data were available at two thermally opposite times of day—2 and 3 a.m. and 2 and 3 p.m. (0000 and 1200 GMT⁶)—were studied. Figures C-57 and C-71 in appendix C show the diurnal differences in the cumulative distribution of initial gradients from 0 to 100 m for these two stations for the 4 months studied.

Superrefractive conditions normally accompany nocturnal inversions. At Nicosia this

⁶ GMT (Greenwich Mean Time) is the same as UT (Universal Time).

proves to be the case for all seasons, with a very definite maximum in August, when anticyclonic upper air circulation intensifies the humidity decrease aloft and radiational cooling lowers the surface temperature 15°C below that found during the day.

Aden, a coastal station with less change in its diurnal temperature cycle than Nicosia (an interior valley station on a fairly large island), exhibits superrefraction day and night for all

seasons. During August and November initial gradients have a wide range of values, with the largest variation occurring at 0000 GMT, but in February and May the nocturnal stability apparently is seldom destroyed by convective mixing, and the 1200 GMT (1500 LST) initial refractivity gradient may exceed the 0000 GMT (0300 LST) gradient. However, the early morning inversion is usually more significant from a radio-meteorological viewpoint because

FIGURE 5. Five-year mean vertical refractive gradient profile: Aden.

the refractivity gradient is much more intense from 250 m to 750 m, thus affecting more radio frequencies. This can be noted in figure 5, representing a 5-year mean of the vertical gradient observed from 0 to 4.5 km during May.

Figure 6 presents the same data for Nicosia during a 5-year August period. Because scale heights are also a measure of stability and stratification, figures 5 and 6 not only give the differences in the mean total N -gradient values in the lower atmosphere, but also the wet (H_w) and dry (H_1) scale heights. Five-year mean values of N_s at Aden in May were found to be 382

(surface wet term of 123) at 0000 GMT and 374 (surface wet term of 119) at 1200 GMT. The corresponding values at Nicosia in August were 341 (wet term of 83) and 310 (wet term of 62).

The percentage of occurrence of subrefraction ($N/\text{km} > 0$) is larger at night (0000 GMT) in February and November at both locations. However, this diurnal trend is much more pronounced at Nicosia, particularly in November when the percentage of night subrefraction is over 30 percent larger than the daytime percentage of occurrence.

5.5. Reliability and Limitations of Ground-Based Refractivity Gradient Data

Because ground-based gradients are so sensitive to local effects, such as terrain and land-water relationships, it was impossible to contour figures C-1 through C-56 for individual small areas. For instance, although Madrid (on the high interior plateau of Spain) experiences little ducting during the year, it is surrounded

by areas of high ducting incidence, and no attempt was made to delineate this small region of nonducting. Also, refractivity gradients calculated from radiosonde observation levels separated by less than 20 m may be seriously affected by instrumental errors, so ground-based layers less than 20 m thick were not included in the analysis. Consequently, very shallow ducting (such as that found at certain times over oceans, under dense jungle canopies, and in

FIGURE 6. Five-year mean vertical refractive gradient profile: Nicosia.

mountain valleys) is not included in the contoured data; however, such layers may be intense enough to create trapping conditions for frequencies down to 600 Mc/s [Jeske, 1964; Baynton et al., 1965; Behn and Duffee, 1965].

The time of day represented by the available observational data must also be considered for any variable which has a definite diurnal trend. Therefore, for a true comparison of worldwide gradient behavior, it would be desirable to use comparable data recorded at least twice a day at standard local or sun-referenced time. How-

ever, because simultaneous data are needed for the preparation of synoptic maps, all stations in the U.S.A. and many in the European countries schedule radiosonde observations at 0000 GMT and 1200 GMT. Many stations in other parts of the world take only one observation per day (usually at either 0000 GMT or 1200 GMT, but there are exceptions, e.g., 0600 GMT at Abidjan, Dakar, and Niamey). Even if all stations had a common GMT hour for taking observations, the diurnal problem would still exist because the *local* time for any designated *GMT*

time would be distributed throughout the day as one traversed the globe. For instance, the following stations (in tropical areas where the occurrence of either subrefractive or superrefractive layers is especially dependent upon the time of day) were used in this report:

<i>Station</i>	<i>Local time</i>	<i>GMT</i>
*Aden, Federation of South Arabia	0300	0000
*Curacao, Netherlands Antilles	2000	0000
Fort Lamy, Republic of Chad	0100	0000
*Hilo, Hawaii	1400	0000
Lae, Territory of New Guinea	1000	0000
Majuro Island, Marshall Islands	1200	0000
Singapore	0700	0000

Those stations marked with an asterisk also take observations at 1200 GMT. However, when evaluating the apparently low level of duct occurrence at some locations (e.g., Majuro) and high occurrence at others (e.g., Fort Lamy), and when checking the subrefraction occurrence at warm, dry continental locations, such as Niamey (where no midday observation is taken), the local time of the radiosonde ascent should be considered.

In addition to the spatial and temporal limitations imposed by the use of available radiosonde data, there are instrument recording limitations (see sec. 2) which must be considered when evaluating *N*-gradients. Although the alternating sequence system of observing the humidity and temperature can put a lower limit on the thickness and thus mask the true gradient of atmospheric layers which can be detected by radiosonde, the response of the radiosonde temperature and humidity elements is a more se-

rious problem in the measurement of the intensity and number of superrefractive gradients at or near the surface. For example, in typical ducting situations during May in a tropical (Saigon) and in a temperate climate (Bordeaux), correction of both humidity and temperature sensor time lags as suggested by Bean and Dutton [1961] would intensify gradients of -293 N/km (Saigon) and -212 N/km (Bordeaux) to -377 N/km and -362 N/km, respectively. This type of correction also would have increased the percentage occurrence of superrefractive and ducting gradients in the majority of cases. Such extensive recalculations were not possible in this study, but the possibility that more intensive gradients may occur in larger percentages at some locations (particularly in temperate, humid climates) should be kept in mind when applying values obtained from any of the figures in appendix C.

Another limitation which applies primarily to the detection of subrefractive layers (figs. C-1 through C-12) in hot, dry regions is the high electrical resistance of the lithium chloride humidity element at very low humidities which causes open-circuit signals ("motorboating"). At stations such as Aoulef, Algeria, where the daytime surface temperature often exceeds 30°C , the relative humidity may be below the motorboating boundary at *all* levels from surface upward, and all relative humidity values (except the surface) are estimated, usually in values which are equal to, or less than, the surface value. However, it is quite probable in these highly convective conditions that the *absolute* humidity remains constant with height, instead of rapidly decreasing (as the estimated relative humidity values would indicate). If it did remain constant, fairly persistent subrefractive gradients would be found in such areas during the hours of most intense solar heating.

6. World Maps of Mean Tropopause Altitudes

Maps have been prepared of the mean tropopause altitudes which were calculated in the course of obtaining the mean *N*-profiles for the 112 station sample, as discussed previously. The maps, for the 4 "seasonal" months, are shown in appendix D. The zone of maximum tropopause altitudes for each month seems to correspond quite well with the mean position of the Intertropical Convergence Zone.

As stated earlier, the criterion for determining the tropopause altitude for each radiosonde ascent was the altitude of the base of the first layer or layers which had a total thickness of at least 2 km and a temperature lapse rate of less than 2°C/km. The mean tropopause altitude for each station and for each month was

determined by a simple average of all of the individual values for the profiles in the sample (usually of 5 years' length). The reliability or consistency of these maps is difficult to assess, since the results of determining tropopause altitudes depend to a great extent on the criteria used for selection of the first stratospheric layer. The criterion used here is the one in most common usage [U.S. Weather Bureau, 1964], but other criteria may be applicable where the results are intended for use in specific atmospheric problems. These maps supplement tropopause data presented in other reports and atlases [For example, Willett, 1944; U.S. Navy, 1955-59; Smith, 1963; Smith et al., 1963; Kantor and Cole, 1965].

7. Appraisal of Results

7.1. Accuracy of $N(z)$ Maps

The general accuracy of the 5-year mean values used in the $N(z)$ study was checked by computing the standard deviation of the year-to-year monthly means and dividing by the square root of 5. This should be a good estimate of the rms (standard) error of the 5-year mean values as compared to the true long-term mean (assuming there are no trends in the data). Table 1 shows the estimated standard error of the 5-year mean N_s values for 40 stations, arranged by climatic classification. The percentage errors should be similar for the $N(z)$ parameters (with the possible exception of scale heights) at various altitudes. The combined (rms) standard error of 5-year mean N_s for the 40 stations for February and August was 2.37 N -units, or about 0.7 percent of the mean N_s . It is significant that even the standard 30-year period recommended (e.g., by the WMO) for standard climatological normals would have a nominal standard error of about ± 1.0 N -unit (2.37 divided by $\sqrt{6}$), or about 0.3 percent of mean N_s values.⁷ The 30-year means would thus

TABLE 1. Standard errors of 5-year mean values of monthly mean N_s for 40 stations.

Climatic type	Number of stations	February* (N -units)	August* (N -units)	12-month estimate (rms of Feb. and Aug.) (N -units)	12-month rms as percentage of mean N_s
Arctic	2	1.6	0.6	1.2	0.4
Subarctic	2	1.2	2.8	2.1	0.7
Marine west coast	4	1.5	1.9	1.7	0.5
Marine (ships)	4	2.2	1.5	1.9	0.6
Continental (cool)	2	1.0	2.9	2.2	0.7
Continental (warm) and subtropical	3	2.2	1.6	1.9	0.6
Semiarid cool, high altitude	2	1.4	3.5	2.7	1.0
Arid and semi-arid tropical	8	2.4	3.8	3.2	0.9
Monsoon	3	3.2	1.3	2.5	0.7
Equatorial	6	(seasons not applicable)		2.7	0.7
All (rms of above)	40	—	—	2.37	0.7

*For stations in the Southern Hemisphere, months were reversed (February was combined with August for northern stations, etc.).

⁷ Thirty-year means are used because there are long-term trends in most climatological series; thus a standard period is desirable for comparison between stations.

have an advantage of only about 50 percent in rms error, as opposed to the 5-year means actually used.

The overall accuracy of the three-part exponential model was checked in two ways. First, a check was made of the accuracy of recovering the $\overline{\Delta N}$ values using the three-part exponential. Here the value of $\overline{\Delta N}$ was calculated, using the wet- and dry-term tropospheric exponentials, and the value obtained was compared with the actual $\overline{\Delta N}$ from the mean N -profile. Figure 7 shows the results of such a comparison for 95 of the 112 stations in the original sample for which coincident data of several types were available. The true value of $\overline{\Delta N}$ from the mean N -profile is the dependent variable, and the value recovered from the wet and dry exponentials is the independent variable. The rms error in recovering $\overline{\Delta N}$ was 9.2 N -units; however, if those stations (points shown as crosses on fig. 7) which are in areas where the three-part exponential model is of questionable validity (as shown in fig. A-30) are eliminated from the sample, the rms error is reduced to 6.4 N -units. The regression line shown in figure 7 is for this reduced sample. The deviation of the regression line from the 45° line (labeled "perfect agreement" in fig. 7: zero intercept and unity slope) is significant at the 5-percent level; thus it would appear that this is not the best usage for the three-part exponential model. Use of the $\overline{\Delta N}$ maps in appendix B is recommended rather than the $N(z)$ maps, for this purpose.

The second check was to use the $N(z)$ maps to recover the values of $N(z)$ for some of the actual station locations, at different heights above the surface, and compare these with the actual values of mean $N(z)$. This would be a check not only on the three-part exponential model but also upon the contouring process. Table 2 shows the results of such an error analysis.

Thirty-two of the original 112 stations were selected on an areal basis, and the corresponding three-part exponential model was constructed for each of these stations, for all 4 months, using the maps in appendix A. These exponential models were then used to calculate $N(z)$ for three heights (3, 8, 16 km) for each month, and the results were compared with the actual mean N -profiles. The mean and maximum values of the absolute errors thus derived are shown in table 2. Stations and seasons in this sample

which are characterized by a high (tropical-type) tropopause showed larger errors at 16 km than at 8 km, the reverse of the usual trend

in table 2. It is apparent from inspection of table 2 that errors in recovering $N(z)$ at altitudes of 3 km or more are likely to be small.

FIGURE 7. Correlation of ΔN : monthly mean N -profiles versus monthly mean exponential model.

TABLE 2. Absolute errors in recovering mean N from map contours for 32 stations (in N -units).

Month	3 km		8 km		16 km	
	Mean	Max	Mean	Max	Mean	Max
Feb.	1.0	2.1	1.6	3.6	0.6	1.7
May	1.3	3.2	1.4	3.3	0.9	2.3
Aug.	1.4	2.1	1.9	3.7	0.8	1.6
Nov.	2.0	4.0	1.3	3.0	1.2	3.0
Year	1.4	4.0	1.6	3.7	0.9	3.0

The total variance, σ_T^2 , in using the maps of $N(z)$ given in appendix A can be estimated in terms of the following error model:

$$\sigma_T^2 \cong \sigma_5^2 + \sigma_M^2, \quad (7)$$

where σ_5^2 is the variance of 5-year mean values (as compared to long-term means), σ_M^2 is the variance of errors in mapping $N(z)$. Random

instrumental errors are included in σ_5^2 . The value of σ_5 can be estimated at about 2.5 N -units (table 1), while σ_M may be estimated at $1.5 \times$ P.E., where the probable error, P.E., is given approximately by the mean absolute errors in table 2. These would yield 2.1 N at 3 km, 2.4 N at 8 km, and 1.4 N at 16 km, for σ_M . A reasonable estimate for σ_M at the surface (0 km) would be 1.0 N -unit. These estimates may be combined to yield approximate σ_T values, as shown in table 3. Minimum and maximum values were obtained by permutations of the values in tables 1 and 2. The standard errors of the 5-year means have been assumed to be a constant percent of mean $N(z)$, independent of altitude.

TABLE 3. Approximate total standard errors, σ_T , for $N(z)$ maps in appendix A.

	0	3 km	8 km	16 km
In terms of N -units				
Average	2.6	1.9	1.8	1.0
Minimum	1.4	1.3	1.3	0.6
Maximum	4.3	2.8	2.2	1.3
As percent of mean $N(z)$				
Average	0.8	1.1	1.5	2.5
Minimum	0.4	0.7	1.1	1.6
Maximum	1.3	1.6	1.9	3.3
Mean $N(z)$	320	175	117	38

It is probable that the percent errors given in table 3 do not increase materially above 16 km; asymptotic values of 3, 2, and 4 percent for average, minimum, and maximum relative standard errors are probably good estimates for altitudes from 20 to 30 km, while above 35 km the standard errors are probably no more than 0.2 N -units.

There are also undoubtedly some bias errors involved in the $N(z)$ maps, although they are probably quite small. Sources of these bias errors would include the equation for N itself (Smith-Weintraub formula), the radiosonde in-

FIGURE 8. Correlation of $\overline{\Delta N}$: monthly mean N -profiles versus monthly mean weather summary data.

strument (where the sensor lag would seem to assure a slight positive bias for all upper-air N values, even over long-term means), and certain peculiarities in the mapping and curve-fitting procedures which might produce bias for some values of z and not others (e.g., the bias due to the sharp "knee" of the D_1 and D_2 exponential terms at the N -tropopause as compared with

the smooth transition of real mean N -profiles; note example in fig. 2). It should be noted that this last type of bias error was (automatically) included in the mean absolute errors given in table 2, since there was no easy way of separating this type of error from the others. Hence table 3 includes an allowance for this particular source of bias error.

7.2 Accuracy of $\overline{\Delta N}$ Maps

As a check on the method used to calculate the $\overline{\Delta N}$ values from which the maps in appendix B were derived, the $\overline{\Delta N}$ values from the weather summary data were obtained for all 90 of the stations which were also contained in the mean N -profile sample; the $\overline{\Delta N}$ values for the months of February, May, August, and November were then compared with the corresponding values from the actual mean N -profiles. However, the period of record involved in the mean N -profile study was not, in general, even partially coincident with the 1960-64 period used for the $\overline{\Delta N}$ study. Thus it was expected that the variance, σ_D^2 , of the differences between the weather summary $\overline{\Delta N}$ values (from which the maps given in appendix B were obtained) and the $\overline{\Delta N}$ values from the mean N -profiles would have two components,

$$\sigma_D^2 = \sigma_R^2 + \sigma_E^2, \quad (8)$$

where σ_R^2 is the variance of the real difference in the two 5-year mean values of ΔN (because they are obtained from different time periods), and σ_E^2 is the variance of the differences which are caused by the interpolation errors inherent in the method used to obtain the $\overline{\Delta N}$ from the weather summary data. Since the real differences (represented by σ_R) would be expected to have a near-zero mean for a worldwide data sample, a regression analysis of the two types of $\overline{\Delta N}$ values should reveal any bias which had been produced by the interpolation method used in the $\overline{\Delta N}$ study. Figure 8 shows the results of such a comparison, with $\overline{\Delta N}$ from the mean N -profiles as the dependent variable, and $\overline{\Delta N}$ from the weather summary data as the independent variable. There is no statistically significant bias shown, since the regression line is almost identical with the "perfect agreement" line (zero intercept and slope of unity).

An evaluation of the relative sizes of σ_R and σ_E was made by calculating the rms difference between the two types of $\overline{\Delta N}$ values for a restricted sample containing only those stations where the mandatory pressure level used to calculate the $\overline{\Delta N}$ values from the weather summary data was within ± 100 m of 1 km above the surface; the rms difference thus calculated was 3.9 N -units. Since any interpolation errors would be expected to be quite small for this restricted sample, it was concluded that the 3.9 N -unit rms represented essentially the value of σ_R as given in (8).

The value of σ_D as given in figure 8 is 5.2 N -units; thus by (8) the value of σ_E is probably on the order of 3.5 N -units. This should be a good approximation to that part of the overall rms error in the $\overline{\Delta N}$ maps which is assignable

to the interpolation method used on the weather summary data.

The overall accuracy of the $\overline{\Delta N}$ maps given in figures B-2 through B-13 depends on several factors: the accuracy of the interpolation method, the variability of the 5-year mean period as compared with a standard WMO 30-year mean period, and the heterogeneous nature of the local observation times included in the data sample. The weather summary data were mostly derived from observations taken at 0000 GMT, although many stations in different parts of the world supplied data taken at 1100 or 1200 GMT, while others supplied data averaged at two, or in a few cases four, times per day. In this study no attempt was made to correct for diurnal variations imposed by the fixed observation times of the various stations; hence diurnal variability must be added to the sources of possible error in the maps. It is reasonable to assume that the actual (unknown) standard error of the maps is not independent of the true value of monthly mean ΔN desired, but that it is more likely a certain percentage of the true value. Since the overall correlation between the contoured and true values is probably quite high, it is plausible to estimate the standard error of the maps as a percentage of the contoured values. On figure 8 it is found that an allowance of ± 10 percent from the perfect-agreement line (in the vertical) will exclude only 23 percent of the 360 data points (40 above the limits, and 44 below the limits); for a normal distribution, 32.5 percent of the points should be excluded by the standard error limits. Therefore, allowing for some added error from diurnal variability, it seems reasonable to estimate the overall standard error of the maps of $\overline{\Delta N}$ as approximately 10 percent of the contoured values.

This is equivalent to assuming an error model,

$$\sigma_T^2 = \sigma_s^2 + \sigma_E^2 + \sigma_t^2, \quad (9)$$

where the terms have the same meaning as those in (7) and (8), with $\sigma_s^2 \cong \sigma_R^2$ (possibly as low as $1/2 \sigma_R^2$) in (8), and where σ_t^2 is the variance assignable to diurnal variations in $\overline{\Delta N}$. The value of σ_t should be on the order of 2 to 4 N -units, which is an estimate based on inspection of the CCIR maps [CCIR, 1965].

There is doubtless some bias error in the $\overline{\Delta N}$ maps; the discussion given for bias errors in the $N(z)$ maps is mostly applicable to the $\overline{\Delta N}$ maps. Here the bias due to the radiosonde is relatively larger, because of the differencing used to obtain $\overline{\Delta N}$ values. This mean bias error may be as high as 1 percent of the $\overline{\Delta N}$ values, but data adequate for checking on this possibility are not available.

7.3. Accuracy of Gradient Maps

It is very difficult to assess the probable errors in the maps of the different kinds of initial gradients given in appendix C. The primary reason for this is that no data are available except those used to prepare the maps. It is likely that the most serious source of discrepancies will arise because of the admixture of data taken

at widely differing local times. In line with the results of the $\overline{\Delta N}$ error analysis, an overall error of about 15 percent of the contoured values seems reasonable, but may be higher or lower, depending on the area being considered. The maps in appendix C are probably best suited for the depiction of climatic tendencies of subrefraction and superrefraction.

8. Conclusions

It seems clear that the most significant conclusion which can be drawn from this study (pertaining to future requirements) is that careful selection of data by local time of observation, and the segregation of these data into types, e.g., nighttime and midafternoon, prior to analysis or mapping, is probably equally as

important as obtaining larger samples. The effects of such an analysis on the results given in this atlas would probably be slight in the case of the $N(z)$ maps, somewhat larger in the case of the $\overline{\Delta N}$ maps, and might well have a profound effect on the ground-based gradient maps of appendix C.

10. Appendix A. World Maps of $N(z)$ Parameters

Data from the weather stations listed alphabetically in table A-1 were used to prepare the maps in this appendix. Each station is preceded by a number to identify its location on figure A-1 and followed by a listing of surface refractivity values at the 1, 5, 50, 95, and 99 percent cumulative distribution levels for the 4 months of February, May, August, and November.

The $N(z)$ parameters (all referenced to sea level) which are necessary to calculate N at any altitude, z , in kilometers, are D_o , W_o , H_1 , H_2 , H_w , and z_t . These are given in figures A-2 through A-25. The z_t chart for any particular month will determine which of the dry-term curves will be used. If the desired altitude (above sea level) of $N(z)$ is *below* the z_t value at the specified location, use the tropospheric equation

$$N(z) = D_o \exp \left\{ -\frac{z}{H_1} \right\} + W_o \exp \left\{ -\frac{z}{H_w} \right\}. \quad (\text{A-1})$$

If the desired altitude is *above* the z_t value, use

$$N(z) = D_o \exp \left\{ -\frac{z_t}{H_1} - \frac{(z - z_t)}{H_2} \right\} + W_o \exp \left\{ -\frac{z}{H_w} \right\}. \quad (\text{A-2})$$

All three scale heights are required for equation (A-2), whereas only two, H_1 and H_w , appear in the tropospheric equation. If the surface altitude of the location is greater than 1 km, it is suggested that the "standard atmosphere" value of 3 km be substituted for H_w (see sec. 3.3).

To illustrate the step-by-step procedure for determining refractivity from the $N(z)$ parameters, the following example (assuming heights of 2 km and 20 km above the surface at a location 200 m above sea level, at latitude 15°N and longitude 0°, in August) is given:

(a) Refractivity at 2 km above the surface:

(1) At the assumed location, interpolate linearly between contours on figures A-19 to obtain z_t (13.8 km) to see whether the altitude above sea level, z (2.2 km), is above or below the z_t value. It is below, so equation (A-1) should be used.

(2) The map values at 15°N and 0° of the parameters needed to calculate (A-1) are:

$D_o = 267.5$ N-units	(fig. A-14)
$W_o = 105.9$ N-units	(fig. A-15)
$H_1 = 9.35$ km	(fig. A-16)
$H_w = 2.19$ km	(fig. A-18)

(3) If these values are substituted in (A-1), $N(z)$ is found to be 249.9 N-units at 2 km above the surface. (Probable errors due to contouring and data restrictions would suggest the use of only three significant figures, i.e., 250 N-units.)

(b) Refractivity at 20 km above surface:

(1) Check to see whether the assumed altitude ($z = 20.2$ km above sea level) is above or below the z_t value. Since it is above, (A-2) should be used.

(2) All the parameters are needed for this calculation. In addition to the four values listed in calculation (a) above, these are required:

$H_2 = 5.90$ km	(fig. A-17)
$z_t = 13.8$ km	(fig. A-19)

FIGURE A-1. Location of $N(z)$ data stations.

(3) If these values are substituted in (A-2), $N(z)$ is found to be 20.7 N -units at 20 km above the surface.

Figures A-26 through A-29 are seasonal maps of the standard prediction error of the exponential fits to the mean wet-term profiles used in the $N(z)$ parameter maps. An rms error in the wet term of more than 5 N -units was considered to be a reasonable limiting criterion for locations where the $N(z)$ model should be used with caution, if at all. Figure A-30 delineates these areas; the cross-hatched areas indicate that the error was in excess of 5 N -units for 2 or more of the seasonal months (February, May, August, and November) and the single-hatching depicts areas where only 1 of the 4 months showed such large errors. Further discussion of the uncertainty in these areas can be found in section 3.4.

11. Appendix B. World Maps of $\overline{\Delta N}$.

The weather stations from which data were obtained for this study are shown in figure B-1. Their locations, elevations and the 5-year mean surface refractivity for each month of the year are alphabetically listed in table B-1.

The monthly $\overline{\Delta N}$ values between the surface and 1 km above the surface are presented in figures B-2 through B-13. If the $\overline{\Delta N}$ at a specific location is desired for a certain month and year for which a monthly mean surface refractivity value, $\overline{N}_s$, is available, the following relationships may be used:

$$\overline{\Delta N} = b (\overline{N}_s - \overline{N}_o) + \overline{\Delta N}, \quad (\text{B-1})$$

where

$$\overline{N}_s = \overline{N}_o \exp^{-0.1(z)}; \quad z = \text{elevation above sea level in km.}$$

World maps of $\overline{N}_o$ (the yearly sea-level value of refractivity), b (the slope of the regression line (B-1)), and $\overline{\Delta N}$ (the mean annual value of the refractivity difference between surface and 1 km) are presented in figures B-14 through B-16.

If the $\overline{\Delta N}$ value were required at a station with an elevation of 300 m and a location of 30°N and 30°E, here is the procedure which would be used. Available surface weather reports indicate that the mean N_s was 314 for a recent month for which a value of $\overline{\Delta N}$ is needed. Therefore, at the assumed location, these values are interpolated linearly from the figures:

$$\overline{N}_o = 320 \quad (\text{fig. B-14})$$

$$\overline{\Delta N} = 48 \text{ N-units} \quad (\text{fig. B-15})$$

$$b = 0.60 \quad (\text{fig. B-16})$$

$$\overline{N}_s = 320 \exp^{-0.1(0.3)} = 311$$

Using the value of 314 for $\overline{N}_s$, $\overline{\Delta N}$ is found to be 50 N-units.

In some areas of the world (e.g., where the assumption of an exponential distribution of the wet term is largely invalid; see sec. 3.4), the use of the regression method to predict $\overline{\Delta N}$ has definite limitations. To delineate these locations, figures B-17, B-18, B-19, and B-20 are presented. The first two figures are world maps of the correlation coefficient and the standard error of estimate of the regression line of $\overline{\Delta N}$ versus $\overline{N}_s$ for the 60 months of station data, and figure B-19 gives the percentage of this standard error to the $\overline{\Delta N}$ value. Areas with correlation coefficients < 0.5 (fig. B-17), standard errors > 5 N-units (fig. B-18), and standard errors > 12 percent of $\overline{\Delta N}$ (fig. B-19) are shaded, but the use of equation (B-1) for any location in these shaded areas may still be valid if:

- (a) a low correlation coefficient occurs with a small standard error (typical of stations with a small seasonal range of variability in both N_s and ΔN), or
- (b) a large error is found with a good correlation (typical of stations with distinct wet-dry seasons).

However, if the coefficient is less than 0.7 (reducing the variance of $\overline{\Delta N}$ to ~ 50 percent) and the standard error is greater than 10 percent of $\overline{\Delta N}$ (as discussed in sec. 7), it would be reasonable to assume that the yearly dependence of $\overline{\Delta N}$ upon N_s is not sufficient to justify the regression prediction method. Areas represented by these criteria are shaded in figure B-20.

12. Appendix C. World Maps and Cumulative Distribution Charts of Gradients of Ground-Based Atmospheric Layers

Initial gradient data, obtained (see sec. 5) for 99 of the 112 stations listed in table A-1, are presented in groups of seasonal world maps which illustrate various aspects of the percentage distribution of gradients in ground-based layers. The specific map groups are given below.

Figures C-1 through C-4: Percent of time gradient ≥ 0 (N/km).

Figures C-5 through C-12: Gradient exceeded 10 and 2 percent of the time for 100-m layer.

Figures C-13 through C-20: Percent of time gradient ≤ -100 (N/km) and percent of superrefractive layers > 100 m thick.

Figures C-21 through C-28: Percent of time gradient ≤ -157 (N/km) and percent of ducting layers > 100 m thick.

Figures C-29 through C-40: Percentage of time trapping frequency is below 3000 Mc/s, below 1000 Mc/s, and below 300 Mc/s.

Figures C-41 through C-56: Lapse rate of refractivity (N/km) exceeded 25, 10, 5, and 2 percent of the time for 100-m layer.

Cumulative probability distribution charts were prepared for 22 climatically diverse locations for the months of February, May, August, and November (figs. C-57 through C-78). The alphabetical listing of these stations in table C-1 includes seasonal median and minimum trapping frequency values when these were available. Distribution data for two separate times of day at Aden and Nicosia are shown in figures C-57 and C-71. The negative gradient of 50 N -units/ km , which is generally considered to be a good normal value for ground-based layers, has been indicated on each of the distributions by a dashed line to provide a common reference for the vertical scale. The circled value on the distribution line represents the *mean* ground-based gradient (of any layer thickness greater than 20 m) for each month.

13. Appendix D. World Charts of Tropopause Heights

Five-year mean tropopause heights obtained in the process of computing $N(z)$ parameters for February, May, August, and November at the 112 stations listed in table A-1 were plotted and contoured. Maps of these heights, given in figures D-1 through D-4, represent the average of all of the individual altitudes which marked the base of the first layer which had a thickness of at least 2 km and a temperature lapse rate of less than $2^{\circ}\text{C}/\text{km}$ (see sec. 6).

FIGURE D-1. Tropopause heights (km), based on temperature lapse rate: February.

FIGURE D-2. Tropopause heights (km), based on temperature lapse rate: May.

FIGURE D-3. Tropopause heights (km), based on temperature lapse rate: August.

FIGURE D-4. Tropopause heights (km), based on temperature lapse rate: November.

14. Appendix E. Sample Listing of the Computer Output for San Juan, P.R., and Amundsen-Scott, Antarctica

A sample listing of the complete computer output of the mean N -profiles for February, May, August, and November at a subtropical and an arctic station is given in the first section of this appendix.

For instance, at station 11636 (San Juan, P. R.) in February (table E-1), the heading gives the number of pieces of data used to compute two types of tropopause height (based on two types of temperature criteria) :

(a) the mean heights where the extreme minimum temperature occurred in 320 individual profiles was $17.56 \text{ km} \pm$ a standard deviation of 0.65 km ,

(b) the mean height of the bottom of the lowest atmospheric layer with a thickness $\geq 2 \text{ km}$ and a temperature gradient $\geq -2^\circ\text{C/km}$ in 307 temperature profiles was $16.44 \text{ km} \pm 0.96 \text{ km}$.

This February profile also gives refractivity information at 40 height levels ranging from 0 to 30 km. Following each height level is a listing of the values of total refractivity, gradient, dry and wet terms, and their respective standard deviations at that height above surface. For example, at 1 km, 383 radiosonde profiles were examined, and the refractivity was found to be 306.7 with a standard deviation of 8.22 N -units; the gradient at that level was -47.66 N/km with a standard deviation of 17.38 N/km ; the dry term was $242.4 \pm 1.19 \text{ N-units}$, and the wet term was $64.3 \pm 8.52 \text{ N-units}$. The correlation coefficients for the data fit, within various height ranges, of the wet term (W) and the tropospheric (D_1) and stratospheric (D_2) dry terms to the line represented by a computed regression equation are found at the bottom of each month's listing. In this example, for the dry term equation (D_1), with a surface value of 271.9 and an exponential decay coefficient of -0.1088 , the correlation coefficient is 0.999 and the standard deviation is 3.01 N -units. (These figures were based on 5 years of data from the surface to 15 km.)

At station 90001 (Amundsen-Scott, Antarctica) the wet-term value is so small at all heights during the months studied that the regression equation from 0 to 3 km becomes meaningless. Because the South Polar region is not shown on the ground-based gradient maps (figs. C-1 through C-56), a complete computer listing for Amundsen-Scott is included in this appendix. This also illustrates the form of the original station data which were used to plot the various values needed for the gradient maps. All gradients are in N -units/km and all frequencies are Mc/s. The "profiles skipped" represents the number of profiles which had gradients $> -100 \text{ N/km}$.
