SUMMARY

The Army is concerned with the problem of unequal load sharing by the engines in its multiengine helicopters. Findings of an engine load-sharing study conducted on the CH-54A Skycrane helicopter in 1965 led to a similar study on the CH-47A Chinook helicopter.

Airspeed, altitude, engine gas producer rpm, engine torque, exhaust gas temperature, main rotor rpm, and outside air temperature were recorded during various flight conditions. The gross weight at takeoff and landing and the barometric pressures were also recorded as supplemental data. The data are presented in a series of histograms and tables showing the variations in engine load sharing as a function of the other aircraft parameters.

It was found that for the CH-47A Chinook, the relative frequency of occurrence of torque splits greater than 20 percent is less than one-half that for the CH-54A Skycrane.

FOREWORD

This report was prepared under Project 1M131201D14415, House-Task 65-29 as a follow-up to an earlier engine load-sharing study performed on the CH-54A Skycrane helicopter.

Acknowledgment is given to Technology Incorporated for acquiring the engine load-sharing data in conjunction with a concurrent operational flight-loads study in Vietnam. Mr. Joseph F. Braun, the project engineer, and Mr. Bob Englehart, a field technician, were primarily responsible for the recording of 346.59 hours of operational flight data on the unarmed CH-47A aircraft.

INTRODUCTION

The U. S. Army Aviation Materiel Laboratories (USAAVLABS) is involved in research and advanced development of multiengine heavy-lift helicopters. An important consideration in the design of these aircraft is the load distribution between the engines. In 1965 a study was conducted of engine load-sharing characteristics of three instrumented twin-engine CH-54A Skycrane helicopters at Fort Benning, Georgia.* As a follow-up to that program, data were collected from four instrumented twin-engine CH-47A Chinook helicopters operating in Vietnam from January 1966 to May 1967.

The same parameters were measured for the CH-47A Chinook as for the CH-54A Skycrane except that two exhaust gas temperature measurements were added to the Chinook instrumentation in order to obtain a more accurate gage of engine performance.

An oscillograph recording system was used to record data on the following parameters: airspeed, altitude, main rotor rpm, engine gas producer rpm, engine torque, outside air temperature, and exhaust gas temperature. Vertical acceleration at the aircraft's center of gravity, barometric pressure, and aircraft gross weight were also measured and recorded as supplemental data.

The data were scanned for significant engine torque splits, and sample points were selected for presentation. The measured parameters were reduced by standard methods, and histograms were drawn to relate the torque splits to the other parameters.

*L. R. Bartek and David Chestnutt, CH-54A SKYCRANE ENGINE LOAD SHARING, USAAVLABS Technical Report 66-47, U. S. Army Aviation Materiel Laboratories, Fort Eustis, Virginia, May 1966, AD 634503.

OBJECTIVES

Following are the objectives of this study:

1. To obtain an estimate of the frequency of occurrence and the severity of unbalanced engine loading conditions on the CH-47A Chinook helicopter.
2. To establish the aircraft flight conditions at which the engine load unbalance is most severe.
3. To compile data to permit a comparison of the engine torque splitting characteristics of the CH-47A Chinook with those of the CH-54A Skycrane previously investigated.

PROCEDURES

INSTRUMENTATION

The engine parameters (exhaust gas temperature, torque, gas producer rpm, and main rotor rpm) were obtained in a manner such that the values recorded were equivalent to cockpit instrument readings. The actual aircraft instrumentation systems were used for signal generators.

Airspeed was measured by attaching a differential pressure transducer to the aircraft pitot system, pressure altitude was measured by tapping the aircraft static pressure system and utilizing an absolute pressure strain-gage transducer, and outside air temperature was measured by gluing a resistance-type thermoribbon to the underside of the aircraft.

This engine load-sharing study was conducted in conjunction with an operational flight-loads measurement program. Parameters recorded but not used in the engine load-sharing study included: vertical acceleration at the aircraft's center of gravity, collective stick position, and longitudinal cyclic stick position. All of the signals generated by the instrumentation systems aboard the aircraft were recorded on a Century Model 409B oscillograph recording unit. A block diagram of the instrumentation and recording system is presented in Figure 1.

DATA REDUCTION

Sample Selection

The data from which samples were collected were grouped into two categories: (1) data in which instrumentation was complete and operating properly, and (2) data in which one or more channels were malfunctioning but the torque instruments were operating as intended. Also included in category 2 were data collected early in the program, when only one exhaust gas temperature and one gas producer rpm were being monitored. Tables I and II constitute the compilation of data samples representing category 1 and category 2, respectively.

Data accumulated totaled 346.59 hours; 202.57 hours were in category 1, and 144.02 hours were in category 2. Data samples were selected by scanning the total 346.59 hours of data and looking for instances in which

the torque difference between the two engines was greater than 10 percent. When this type of condition was located and the data were in category 1, data points were calculated for all pertinent parameters. The data samples included points in the steady-state portions of the record, preceding and following the torque split, as well as points during the peak split period. The 186 samples in category 1 contained a total of 613 data points. This indicates a ratio of 3.32 data points per sample. Thus, most of the torque splits were defined by taking only one or two points at the extreme torque-split portions of a sample. For the data in category 2, only torque was calculated. The data were segregated to promote uniform comparability among data samples. If malfunctioned or incomplete data had been included with category 1 data, the frequency-of-occurrence distributions might have been distorted by the absence of affected parameters.

Whenever a torque split of greater than 10 percent occurred and remained steady, only one sample was selected for calculations. If the torque-split condition was cyclic in occurrence, with splitting and balancing alternating, a sample was selected for each cycle that occurred. Because this method of selecting samples was used, the total time during which torque splits of greater than 10 percent existed is larger than the total time utilized in calculating data points.

The total time represented by the sample points in category 1 is 4.34 hours; this time represents 2.1 percent of the total time from which data were selected.

Data Processing

After the data samples were selected for analysis, the individual points were calculated for tabulation. The oscillograph record contained a reference trace, and measurements were made to establish the deflection existing between each active channel and the reference. This deflection was compared with the amount of deflection present at a zero point or known magnitude level for each channel. A calibration factor was applied to the deflection between an active data point and its respective known reference level in order to calculate the physical magnitude of the quantity being measured. This general method of data reduction was applied to all parameters except gross weight and time.

Initial oscillograph chart speed was set at 4 inches per minute, but the actual speed varied from +23 percent to -11 percent. To correct for fluctuations in paper speed, a time calibration was run for each chart. This was accomplished by turning the voltage channel off for a known time while the recorder chart was running. The ratio of chart length

run in a known time to the distance it should have run at the rate of 4 inches per minute yielded a multiplying factor with which to calculate the correct chart speed. Time was calculated to the nearest 0.1 minute. When a record was edited for processing, a template was used which marked time panels as if the 4-inch-per-minute chart speed were always in effect. Later, when the data were analyzed, the time correction factor was applied. The gross weights were calculated by using a supplemental data sheet which accompanied each record. The takeoff gross weight and the fuel consumption rate were listed by the technician in the field. To calculate the gross weight at any known time, the fuel consumption rate was multiplied by the time from takeoff; this weight was then subtracted from the takeoff gross weight. Any cargo pickups or drops were added to or subtracted from the weight calculated on the basis of fuel consumption rate.

To illustrate, sample calculation 4, point 1, flight 84A follows:

Time

Time panel, 55.4 minutes

Volts off, 60 seconds

Length of deflected voltage trace, 4.46 inches

Theoretical length of trace, 4.00 inches

Time correction factor = $\frac{4.00 \text{ inches}}{4.46 \text{ inches}} = .897$

True time = (time panel) (time correction factor)

True time = (55.4) (0.897) = 49.69 minutes

True time to nearest 0.1 minute = 49.7 minutes

Gross Weight

The takeoff gross weight was listed as 23,087 pounds. The fuel consumption rate was 39.0 pounds per minute for 30.8 minutes; it then changed to 34.0 pounds per minute when a 1200-pound load was picked up by the aircraft. The amount of fuel used in 30.8 minutes, at 39.0 pounds per minute, was 1201 pounds. An additional 643 pounds of fuel was used when flying for 18.9 minutes at a fuel rate of 34.0 pounds. Thus, the gross weight of the helicopter at 49.7 minutes was 22,443 (23,087 - 1201 + 1200 - 643). Since only three significant digits were carried, the value 22,400 pounds appears in the table.

Torque

To calculate the torque on each engine, the deflection of each torque trace from the reference was measured with zero torque applied. In this case, the deflection was 2.32 inches for torque 1 and 2.01 inches for torque 2. At 49.7 minutes, the deflections of torques 1 and 2 from the reference were 2.74 inches and 2.48 inches, respectively. The difference in deflections from the zero loading condition was proportional to the torque applied on each engine. The slopes on the torque-measuring instruments for engines 1 and 2 were 0.770 percent per 0.01-inch deflection and 0.730 percent per 0.01-inch deflection, respectively. From this information, the following calculations were made:

$$\text{Torque 1: } (2.74 \text{ in.} - 2.32 \text{ in.}) (0.770 \text{ pct}/0.01 \text{ in.}) = 32.3 \text{ pct}$$

$$\text{Torque 2: } (2.48 \text{ in.} - 2.01 \text{ in.}) (0.730 \text{ pct}/0.01 \text{ in.}) = 34.3 \text{ pct}$$

$$\text{Torque split: } 34.3 \text{ pct} - 32.3 \text{ pct} = 2.0 \text{ pct}$$

$$\begin{aligned} \text{Average torque} &= \left(\frac{\text{Torque 1} + \text{Torque 2}}{2} \right) \\ &= \left(\frac{32.3 + 34.3}{2} \right) = 33.3 \text{ pct} \end{aligned}$$

Other Engine Parameters

Main rotor rpm, gas producer rpm, and exhaust gas temperature were calculated similarly to the torques.

Airspeed

A slightly varied calculation procedure was adapted for airspeed calculations. The differential pressure of the aircraft's pitot-static airspeed instrumentation system was used in conjunction with a table of differential pressures and airspeeds to calculate airspeed. At 49.7 minutes, the airspeed trace was 1.30 inches

from the reference. The calibration factor for the pressure-measuring instrument in use was 0.4846 inch of mercury. The calibration pulse with a known resistance in the circuit was a 1.66-inch deflection. Therefore, the calibration constant was 0.4846 inch of mercury per 1.66-inch deflection. Following are the steps used to calculate a pressure difference due to airspeed:

$$\text{Pressure differential} = (1.30 \text{ in.} - 0.38 \text{ in.}) (0.4846 \text{ in. Hg} / 1.66 \text{ in. deflection}) = 0.2686 \text{ in. Hg}$$

From a table of differential pressures in inches of mercury and velocities in knots, interpolation will yield the airspeed in knots, as follows:

0.2686 in. Hg corresponds to 74.7 kn

Figure 2 shows a reproduction of the segment of an oscillograph record from which sample 4 was calculated.

RESULTS

For the data sampled, a torque split of 20 percent or less occurs 85 percent of the time (see Figures 3 and 4). Since almost two-thirds of the sample points are the steady values preceding or following the torque split, this distribution appears to be reasonable. The remaining 15 percent of the torque-split points are spread fairly evenly from 20 percent to 100 percent.

The average torque level of more than 85 percent of the data points is between 10 percent and 50 percent (see Figure 5). This figure and all succeeding histograms are based on the category 1 data in which each sample point consists of a complete set of parameters.

Figures 6 through 13 show the ranges of average torque versus frequency of occurrence by 10-percent torque-split brackets up to the 70- to 100-percent range. These histograms illustrate how the torque splits are distributed by average torque level.

Figures 14, 15, and 16 show frequency of occurrence versus average torque ranges in percent for torque splits of greater than 10 percent during descent, steady-state, and high-power conditions (ascent, hover, and maneuver), respectively. During descent, more than 70 percent of the points fell in the category of less than 30 percent average torque. The bulk of the data in the steady-state and high-power distributions was between 20 percent and 70 percent. It would be expected that the average torque for torque splits in descent would be lower than in the other operational conditions since descent is ordinarily a low-power flying condition.

Table III lists the sample points and indicates which flight-mode category each falls into. Nearly two-thirds of the 186 data samples are in the descent mission segment. This indicates that most torque splits occur at low-power conditions and are necessarily of small magnitude.

Frequency of occurrence versus ranges of torque splits for torque splits of greater than 10 percent for various mission segments is plotted in Figures 17, 18, and 19; these figures can be used in conjunction with Figures 14, 15, and 16 to show the distribution of torque splits by descent, steady-state, and high-power operating conditions, respectively. These histograms also give an indication of how much power the aircraft were using during the torque splits. The significance of a given

magnitude torque split is dependent upon average torque of the two engines as well as absolute magnitude

Figures 20, 21, and 22 show exhaust gas temperature splits versus frequency of occurrence for descent, steady-state, and high-power mission segments with torque splits of greater than 10 percent. In all three operating conditions, 75 percent of the exhaust gas temperature splits were 200°F or less. Figure 23 shows exhaust gas temperature splits versus frequency of occurrence for the 618 sample points; 92 percent of them are less than 200°F. Since the torque-split sample points of less than 10 percent are included in these data, one would expect exhaust gas temperature splits to be smaller on a percentage basis. Figures 24 through 32 break down frequency of occurrence of exhaust gas temperature splits by 10-percent torque split, with brackets from 0 to 80 percent; the last bracket extends from 80 to 100 percent.

Frequency of occurrence versus variation in gas producer rpm between two engines for the total 618 sample points is plotted in Figure 33. At 80 percent of the points, the difference in rpm between the engines is less than 4,000. These data correlate well with torque-split data, since torque is a function of gas producer rpm. Figures 34 through 43 display the variation in gas producer rpm between two engines versus frequency of occurrence over the range of torque splits from 0 to 100 percent.

Nearly 70 percent of the torque-split sample points occurred at gross weights of 20,000-24,000 pounds (see Figure 44). This is to be expected, as the aircraft takeoff weight with crew and a full load of fuel with no cargo is 23,087 pounds. In Figures 44 through 53, gross weight is plotted versus frequency of occurrence of sample points at torque-split brackets of 10 percent from 0 to 80 percent; the last bracket extends from 80 to 100 percent.

In Figures 54, 55, and 56, gross weight versus frequency of occurrence is plotted for each category of operating conditions. The 20,000-24,000-pound gross weight range still dominates the figures.

Two-thirds of the torque-split samples occurred in descent mission segments (see Figure 57). The fewest torque splits occurred during high-power mission segments.

Ninety-four percent of the torque-split sample points occurred at main rotor rpm's between 225 and 240 (see Figure 58). This distribution could be expected, since the normal operating rpm for this helicopter is between 230 and 233.

In Figures 59 through 67, main rotor rpm is plotted versus frequency of occurrence for torque-split brackets covering the full range of torque splits.

The histogram of airspeed versus frequency of occurrence of sample points (Figure 68) shows that one-fourth of the data points occurred at less than 10 knots' airspeed and 70 percent at less than 70 knots' airspeed. Since so many of the torque splits occurred during descents and ascents, one would expect the low-airspeed data points to dominate the distribution of data.

Figures 69 through 77 show distribution of airspeed versus frequency of occurrence by ranges of torque splits; Figures 78, 79, and 80 show distribution of airspeed versus frequency of occurrence by mission segment.

CONCLUSIONS

It is concluded that:

1. Torque splits of greater than 10 percent for the CH-47A Chinook occur about once per flight hour. (During the 346.59-hour sample period, momentary torque splits of greater than 100 percent were experienced five times.)
2. Torque splits occur most frequently in the descending mode of flight. High-power conditions are least susceptible to unbalanced engine loading.
3. The CH-47A Chinook encountered torque splits of greater than 20 percent on 15.6 percent of the sample points in the study. (The CH-54A Skycrane encountered torque splits of greater than 20 percent on 36.5 percent of the sample points.)
4. Engine torque splits are not a significant problem at high-gross-weight flying conditions.

13. ABSTRACT		
The Army is concerned with the problem of unequal load sharing by the engines in its multiengine helicopters. Findings of an engine load-sharing study conducted on the CH-54A Skycrane helicopter in 1965 led to a similar study on the CH-47A Chinook helicopter. Airspeed, altitude, engine gas producer rpm, engine torque, exhaust gas temperature, main rotor rpm, and outside air temperature were recorded during various flight conditions. The gross weight at takeoff and landing and the barometric pressures were also recorded as supplemental data. The data are presented in a series of histograms and tables showing the variations in engine load sharing as a function of the other aircraft parameters. It was found that for the CH-47A Chinook, the relative frequency of occurrence of torque splits greater than 20 percent is less than one-half that for the CH-54A Skycrane.
