12

The following conclusions appear to be valid for the shock over-pressure range 5-20 psi.

1. A room entrance without a baffle allows the incoming flow to create a high speed flow of several hundred feet per second along the centerline of the entrance. The jet probably does not extend past a half entrance width to either side of the entrance. However, the distance the high speed flow extends into a room varies with the pressure of the external shockwave. For example, an input shock of 20 psi level caused the jet to extend 10 - 15 entrance widths along the centerline with dynamic pressure still above a safe (3.7 psi, Ref. 8) value.

2. An entrance baffle placed one entrance width inside successfully deflected the incoming jet from the centerline of the room without adding to the overall unsafe area.

3. By the addition of an entrance baffle, about the same safe floor space was available in the model when exposed to a shock over-pressure of 20 psi as was available when the model was exposed to 5 psi without an entrance baffle.

SUMMARY

A. Introduction:

The work reported here is the third part in a study of the filling processes of rooms when exposed to blast and shockwaves in the range of 5-20 psi overpressure.

The earlier work treated the expansion of the free field blast wave into a room and the increase in the internal pressure caused by pressure falling throughout the entire room volume. The experiments reported here describe a third part of the filling problem - the creation of a high speed air jet caused by the incoming air from the external blast wave. The purpose of this work is to determine the velocity of the air flow in the jet and the area it covers.

Results obtained in the study allow estimates to be given of the unsafe area of a full-size shelter room with and without a baffle inside the entrance. The estimates are given for free field blast waves of 5-20 psi overpressure range.

B. Experiments:

Two- and three-dimensional models were exposed to step shock waves in the BRL Shock Tubes. Two-dimensional air flow was observed inside models by movement of smoke grid tracers photographed by a high speed framing camera. Stagnation and side-on fill pressures were measured with transducers inside three-dimensional models to determine the dynamic pressure inside.

C. Results and Conclusions:

The Appendices of the report contain computer program flow predictions for simple models with and without an entrance baffle, tables of flow calculated from the smoke grid tracer method, and the pressure-time records obtained inside the three-dimensional models.

FLOW IN MODEL ROOMS CAUSED BY AIR SHOCK WAVES

ABSTRACT

Experimental results and two-dimensional computer code predictions are shown which illustrate the internal air flow inside model rooms when loaded externally by air shock waves in a 5-20 psi range. Stagnation and side-on fill pressure records are presented for three-dimensional models which indicate that flow patterns similar to those observed in the two-dimensional study are present inside the three-dimensional models. Baffles were placed inside the entrances of the models which re-directed the air flow to positions off the entrance centerline and gave more safe floor area.

I. INTRODUCTION

The work reported here is the third part in a study of the filling processes of rooms and chambers when exposed to blast and shock waves. The work was sponsored by the Office of Civil Defense under contract, Work Order No. DAHC-20-67-W-0153, with the Ballistic Research Laboratories (BRL).

The purpose of this work is to study the incoming flow field inside a room and the related damage potential of the flow caused by the filling process. The earlier work was reported in References 1-4*.

The present study was broken into two parts. One was done with two-dimensional models in which the flow was monitored photographically with smoke grids as tracers. The second group of experiments was done with three-dimensional models. In this study stagnation and side-on fill pressure-time records were obtained from the outputs of pressure transducers to determine the dynamic pressure of the flow from the jet in the model entrance.

The data from both groups of experiments are placed in the Appendices. The results from the two-dimensional study are in Appendix A, the flow calculations from the smoke grid tracers are listed in Appendix B, and the pressure-time records from the three-dimensional models are given in Appendix C.

II. EXPERIMENTS

High speed air flows have been predicted (Reference 1, 5, and 6) for areas of flow on or near the entrance centerline of a room or shelter which is being filled by the exterior shock overpressure to which the shelter is exposed. Since high speed air flow may cause translocation of persons in a room or shelter, it is necessary to determine the magnitude of the flow parameters and the area over which they exist.

*References are listed on page 75 Preceding page blank

The present experiments were carried out to determine if the predicted flows (several hundred feet per second for an input pressure of $P_s = 5$ psi) existed, and the distance the flows extended into a room. A second goal was to deflect and reduce, if possible, by an entrance baffle, the incoming flow so a greater "safe" floor space would be available in the room or shelter.

Table I summarizes the type models and orientation of the models to the shock waves used in the experiments. The type of filling (front or side-on) is noted.

A. Two-Dimensional Models

Computer predictions (RIPPLE program, Reference 7) were made by Dr. V. Kucher and Mr. J. Harrison; Applied Mathematics Division, BRL; for the first two models shown in Figure 1. Again, high speed flows were predicted along the centerline of the entrance to the model and near the baffle. No computer predictions were made for the remainder of the two-dimensional models.

Figures 1-C, 1-D, and 1-E show the two-dimensional models used for the present study. Air flow patterns were observed inside each model by smoke grid tracers. Just before the shock tube is fired, smoke grids are established as shown in Figure 2. A high speed framing camera followed smoke grid movement and calculations were made from these data.

B. Three-Dimensional Models

A short coming of the smoke grid tracer method is the fact that the grids move out of the high speed flow area. Less and less information is obtained as the flow continues and the grids leave the areas of interest.

Accordingly, to obtain data in the high speed flow areas near the entrance, for the three-dimensional study, stagnation pressure transducers were placed inside the model rooms to measure the effect of the speed of the jet. The recording system channels consisted of Susquehanna ST-2 ceramic pressure transducers, Kistler 566 charge

Figure 2. Smoke Grid Technique

amplifiers, Tektronix 502 or 564 oscilloscopes equipped with Polaroid cameras.

Figures 3 - 5 show the three-dimensional models with the transducer locations.

III. RESULTS

The results are presented in two parts: two-dimensional and three-dimensional models.

A. Two-Dimensional Models

Vector plots of the results of the computer program calculations are shown as Figures 6 - 14. Figures 6 - 10 show the vector flow field generated when an input shock wave of $P_s = 5$ psi is reflected on the outside front of an entrance to a room. High speed flows of several hundred feet per second are predicted along the axis of the entrance. The flow trying to turn the corner at the entrance causes a rotation of the flow throughout the room. At the edge of the room entrance the result is a vortex.

The second set of the computer plots (Figures 11 - 14) show how a similar model with an entrance baffle re-directs the incoming flow during the time the model is being filled. Large flow velocities (>1000 ft/sec) are predicted to exist between the baffle and the front wall. However, they do not appear to extend beyond the baffle. A listing of axial and radial components of the airflow velocity vectors for both models are given in Appendix A.

Table II presents a numerical comparison of the experimental data (Reference 2, Model XIV-D) with the computer program predictions. A time correction to the computer data was made to adjust time zero to be shock arrival inside the model. This was time zero for the experiments of Reference 2. The overall patterns of flow are similar for the computer program predictions and for the experimental cases. If there is a time or position error in either, large differences in flow-magnitude and direction - may occur at areas of rapid flow changes

														model.

such as near the vortex. Overall, the computer program probably gives sufficiently accurate predictions for one to understand what flow pattern to expect in a room for a given entrance-baffle combination.

Table III gives a summary of the flow calculations made with the smoke grid method from Models 35, 35 with baffle, and 36. Appendix B contains the more complete flow tables and plots. All three models were exposed to the 5 psi shock wave in a side-on position so as to simulate the entryway flow conditions set up in an underground room such as a basement.

Flows of 200-300 ft/sec were observed near the entryway exit of Model 35 without a baffle. A circular flow continued around the interior of the model, moving away from the entryway exit.

In contrast, Models 35 with baffle and Model 36 seemed to contain the higher flows to an area near the baffles. The flows generally were not as high as for Model 35. Shot 342, Model 36, appears to be an exception to this, with flows of 414-463 ft/sec listed. These appear isolated in the flow tables (Appendix B) and probably do not represent the general flow properties.

B. Three-Dimensional Models

Tables IV, V, and VI summarize the data from Models 27-A, 27-A with baffle, and Model 25-A, respectively. The complete series of pressure-time records from the models are given in Appendix C.

Records from positions on the entrance centerline, typical of all the shots, are shown in Figures 15 and 16. The position numbers refer to locations of transducers as shown in Figure 5, Model 25-A. A great many pressure oscillations may be seen on all the stagnation records obtained in areas of high speed flow such as near the entrance.

Pressure calculations were made from the records by averaging through the oscillations. The dynamic pressure was calculated by a subtraction of the side-on fill overpressure values from the stagnation overpressure values for equal times after arrival at a transducer

Figure 16. (Continued) Typical Records from Model 25-A, Positions off Centerline.

position. This gives them an indication of the air flows ability to cause translation. For a prototype shelter room, this damage potential can be related to translation of the occupants of the shelter. These calculated pressure differences are shown for Model 27-A (without baffle) in Figures 17 - 19 as a function of the input pressures and the transducer locations. At times early in the filling process, the stagnation pressure is large and the side-on fill is still small. The result is a large dynamic pressure approaching a value equal to the stagnation pressure of the entering flow. As the model fills, the pressure difference becomes less.

The maximum dynamic pressure decreases with distance from the entrance of the model. Position 3 shows perhaps 20% of the maximum dynamic pressure at Position 1. Addition of a baffle one entrance width inside the model causes the incoming flow to be diverted. Figures 20 - 25 show the dynamic pressure curves for positions inside Model 27-A with baffle.

Figure 26 summarizes the maximum values of dynamic pressure from 27-A. For about two entrance widths away from the entrance (no baffle) the dynamic pressure equals that of the stagnation pressure of the shock wave outside. These values decayed in about 12 entrance widths to values equal to the dynamic pressure of the shockwave outside at that time. All values of maximum dynamic pressure were reduced, with the baffle, to values below 3 psi; the majority were below 2 psi. A similar procedure of calculations of the dynamic pressure was followed for the records obtained from inside Model 25-A.

Figures 27 - 29 show the values calculated for the entrance centerline positions (no baffle). Figures 30 - 32 show very much reduced values of dynamic pressure at positions off the centerline. The same result is found for positions on the centerline behind the baffle (Figures 33 - 35).

Figure 35. Dynamic Pressure - Model 25-A, with Baffle
 $P_s = 20.7 \text{ psi}$.

A re-direction of the flow by the baffle causes Pos. 1-B (off centerline) to show an increase in dynamic pressure (Figures 36 - 38) over the pressures calculated from the previous shots without the baffle. At the other positions off the centerline (2-B and 3-B) the dynamic pressure still remains low as before.

Figure 37 shows plots with dynamic pressure apparently going below zero. Since the graph is a plot of stagnation pressure minus side-on fill, a negative value means that there is no component of air flow which strikes the transducer face-on to add a dynamic value to the side-on value the transducer measures. If a time-space fluctuation in side-on fill pressure occurs at the probe and gives less pressure than the flush mounted side-on fill transducer, then the subtraction will appear to give a negative dynamic pressure.

Figure 39 summarizes the maximum values of dynamic pressure for Model 25-A. Again, the curves are similar to those obtained from Model 27-A. After about two entrance widths, all positions with the baffle in place showed pressure below a safe level of 3.7 psi (Reference 8).

IV. SUMMARY AND CONCLUSIONS

A. Model Study

The authors of References 2, 6, and 8 have predicted areas of high speed flows on or near the centerline of the entrance of a room or shelter in which an exterior blast or shock wave is causing the air flow. Similar predictions were obtained from the two-dimensional computer program (RIPPLE) at BRL.

The results from the BRL computer program indicated high speed flows of several hundred feet per second were predicted along the entrance centerline. For the 5 psi input used, the high speed flows rapidly decay below 200 - 300 ft/sec at a distance of about two entrance widths into the model. The high speed flow does not appear to exist much past the entrance edges in a side direction off-axis.

OUTSIDE SHOCK WAVE
 $P_s = 4.76 \text{ PSI}$, $P_{stag} = 5.29 \text{ PSI}$

Figure 36. Dynamic Pressure off Centerline - Model 25-A,
 with Baffle - $P_s = 4.8 \text{ psi}$.

Figure 37. Dynamic Pressure off Centerline - Model 25-A,
 with Baffle - $P_s = 10.6 \text{ psi}$.

Figure 38. Dynamic Pressure off Centerline - Model 25-A,
 with Baffle - $P_s = 21 \text{ psi}$.

Figure 39. Maximum Dynamic Pressure as a Function of Distance From the Entrance - Model 25-A

The limit might extend to a half entrance width either side of the entrance. With the baffle inside the entrance (one entrance width away), the computer program predicts high speed flows of several hundred feet per second between the front wall and the baffle. Again, the high speed does not appear to extend much beyond the baffle.

Experimentally, both Models 27-A and 25-A showed flows existed of the predicted configuration and magnitude. Dynamic pressures were measured in both models without baffles which approached stagnation pressure values of 5.8, 13.0, and 30 psi for average input shock overpressures of 5.2, 10.5, and 20.8 psi. The maximum dynamic pressure approximately equaled the stagnation pressure of the external shock wave used in each shot. If densities of about 0.003 slugs/ft^3 are used as predicted in the two-dimensional experiments (Reference 2), then air flow speeds corresponding to dynamic pressures of 5.8, 13.0, and 30 psi would be 746, 1120, and 1700 ft/sec. The value 746 ft/sec compares favorably with the trends shown in Figure A-2, Appendix A. The axial velocities shown for the open model range from 723 - 625 ft/sec near the entrance for the 5 psi input shock wave. The transducer measurements are consistent with the smoke tracer experiments and the predicted flow trends of the computer program.

B. Application to Full-Size Rooms

The curves of Figures 26 and 39 may be used to predict the unsafe area in the corresponding full-size shelter rooms. For example, if a safe value of dynamic pressure is chosen to be $<3.7 \text{ psi}$ (Reference 8), points on the curves may be found corresponding to positions in entrance widths which represent pressure values below 3.7 psi.

It should be noted this limiting value of dynamic pressure from Reference 8 is based upon statistics obtained from pilots that were ejected from their aircraft into the airstream. Long duration flow is assumed and the damage is probably caused by the high rate of acceleration when the airstream hits.

SHOCK WAVE DIRECTION →

Figure 41. Full-Size Room for Model 25-A

To illustrate the use of Figure 39 for this given limiting value, a line is drawn across the graph at 3.7 psi. The line crosses the 5, 10.5, and 20.9 psi input curves at distances of 4, 8.5, and 10 entrance widths, respectively. These are the axial limits for the 3.7 dynamic pressure level into the room. If the influence to the side of the jet is bounded by about one-half entrance width to each side, unsafe areas are defined for the room. For quick comparison, the unsafe areas are given in percentages of total available floor space. Figures 40 and 41 illustrate the use of this procedure from the curves of Figures 26 and 39.

The addition of a baffle inside the entrance allows the external shock wave pressure to be increased from 5.2 to 20.8 psi while still maintaining the approximate same safe area.

The room volume to entrance area ratio, V/A , in Figures 40 and 41 largely determines the total room filling time and therefore, the total duration of the incoming flow with its potential for damage by translation. The factor $2L/A_1$ shown represents approximately two shock wave crossing times (for the weak internal shock wave). This factor represents an approximate time one may expect high dynamic pressure (about equal to a stagnation value) since very little over all side-on pressure increase has occurred as yet during this period.

To summarize, the initial high values of dynamic pressure continues with little decrease until the side-on pressure increase causes the difference between stagnation and side-on pressure to become smaller and smaller. At the time the entire room volume is filled to the maximum value of side-on pressure, the dynamic pressure approaches a minimum value. The dynamic pressure apparently follows the outside conditions pretty much for the remaining shock wave duration.

ACKNOWLEDGEMENTS

The author wishes to thank Dr. V. Kucher and Mr. J. T. Harrison for their expert programming of the two-dimensional models with the RIPPLE Code, and also to thank Mr. W. T. Matthews for the design of the intricate models used with the smoke grid technique.

APPENDIX A

RIPPLE PROGRAM VELOCITY PREDICTIONS FOR
TWO-DIMENSIONAL MODELS

Preceding page blank

USE OF APPENDIX A

Comparisons of air flow components, predicted by the BRL RIPPLE computer program, are given for a 4 x 4-inch two-dimensional model with and without a baffle inside the entrance. Radial and axial components of flow are shown in separate figures. The values shown are for discrete readout times beginning when the input shock wave ($P_s = 5$ psi) was about 78 μ sec away from the outside of the front of the model. The sign convention for the flow components is shown on each figure.

APPENDIX B
AIR FLOW TABLES AND VECTOR PLOTS

USE OF APPENDIX B

The first part of Appendix B consists of tables of calculations made from the smoke grids and the second part consists of plots of air flow vectors (scale 1 in. = 200 ft/sec) computed for several grid intersections for discrete frame times which illustrate the many flow directions. Also given, is a time-space plot of the first row of four grid intersections. These start at an initial time labeled "start" to end times "T".

The tables list the frame time in microseconds measured from time of shock exit from entryway, the x - y coordinates in inches as measured from an origin at the inside, lower left bottom of the model, the average velocity of a particular smoke grid intersection (positions in frames behind and ahead of the given frame in time are used to find the average for the known camera framing speed), average angle of flow direction measured from a horizontal axis, the density obtained from the grid size and undisturbed grid area (density), and Q (equal to one-half the density times the velocity squared).

13. ABSTRACT Experimental results and two-dimensional computer code predictions are shown which illustrate the internal air flow inside model rooms when loaded externally by air shock waves in a 5-20 psi range. Stagnation and side-on fill pressure records are presented for three-dimensional models which indicate that flow patterns similar to those observed in the two-dimensional study are present inside the three-dimensional models. Baffles were placed inside the entrances of the models which re-directed the air flow to positions off the entrance centerline and gave more safe floor area.
