ABSTRACT

Equivalent headwinds or equivalent winds are computed using Sawyer's method for approximately 4400 strategic world air routes contained in Volumes I & II. The seasonal mean equivalent wind and its standard deviation and the annual 50-, 75-, and 85- percent reliability equivalent winds are tabulated. Route winds are computed for the 5000-, 10,000-, and 18,000 foot levels. An IBM 360/65 program was used to compute the equivalent winds. Input data for the program consist, for each level, of a grid composed of the mean vector wind and the standard vector deviation at the intersection of each 5° of latitude with each 10° of longitude between 60°S and 60°N and at the intersection of each 5° of latitude and each 20° of longitude south and north of 60°S and 60°N respectively. In addition to the equivalent winds, great circle distances are computed and tabulated for each route.

FORWARD

Ten years ago, The Boeing Company published documents on equivalent route winds for upper altitudes for domestic, international and military air routes for use in the airline industry: "Equivalent Winds for North American Air Routes," D6-9176; "Equivalent Winds for World Air Routes," D6-9177; and "Great Circle Equivalent Route Winds for Military Application," D6-9175. Since then, the helicopter industry has had a need for lower altitude wind data for helicopter routes and speeds.

Tables of winds for the lower altitudes were prepared and the computer program used for the earlier documents was modified to incorporate minor improvements in technique in order to correct inaccuracies which could occur for lower speed aircraft and to operate on the IBM 360/65 system.

Airfield bases listed in this document are only a sample of the total number available and are not chosen on major importance. It should be noted that one airfield may represent other stations within a radius of 50 miles, since the difference in the azimuths of the flight routes would be nominal, thus reflecting little if any changes in the calculated results of equivalent headwinds. Additional air routes may be requested by writing to the Boeing Vertol Company in care of the author.

EQUIVALENT WINDS FOR HELICOPTER AIR ROUTES
AT HEIGHTS OF 5,000, 10,000 and 18,000 FEET

1.0 INTRODUCTION

The increasing ability (usually with aerial refueling and/or auxiliary tanks) for helicopters to deploy over long distances has established a requirement for route wind statistics with which to make long-term estimates of the economic and strategic capabilities of these aircraft. To meet this need for route-wind data, Boeing-Vertol analysts have computed seasonal and annual equivalent winds for principal air routes.

2.0 DEFINITIONS

2.1 Equivalent Route Wind

The equivalent wind for an air route may be defined as a uniform wind, which when directed along the track at all points, results in the same average ground speed as that actually attained. Alternately, the equivalent route wind is the difference between the average airspeed and the average groundspeed throughout the flight.

2.2 Reliability Equivalent Route Wind

The reliability equivalent wind is the equivalent headwind which is not exceeded (a route wind which can be relied upon) a given percent of occasions or time during a given period.

3.0 COMPUTATIONS

3.1 Equations

3.1.1. Equivalent Route Wind

Sawyer's theory of equivalent headwinds has been applied extensively to the computation of equivalent route winds ¹⁻⁹. This method involves use of the mean vector wind and the standard vector deviation, two parameters which completely define the circular normal distribution of winds generally found in the free atmosphere. Charts and tabulations of the mean vector wind and the standard vector deviation are available in many meteorological publications 10-19.

The principal assumptions of Sawyer's theory are (1) the wind speed does not exceed the speed of the aircraft and (2) the distribution of winds in the free atmosphere during a given season can be approximated by the circular normal distribution. Based on these and other assumptions, the basic equation for the average equivalent headwind, EW, over a route and expressed in terms of the mean vector wind and the standard vector deviation, σ , at points along the

3.1.1. Equivalent Route Wind (cont'd.)

route is:

$$EW = \frac{\sum_{i=1}^N z_i}{\sum_{i=1}^N t_i} - A$$

 z_i = length of i-th segment of route t_i = time to fly z_i A = airspeed of aircraft over route

$$\text{but } t_i = z_i / \bar{g}_i$$

where $\bar{g}_i$ = mean ground speed on i-th segment

$$= A - \frac{1}{2A} (\bar{v}_i^2 + \frac{u_i^2}{2}) + \bar{u}_i$$

 $\bar{v}_i$ = mean vector wind component
normal to track

 $\bar{u}_i$ = mean vector wind component parallel
to track

$$\text{and } z_i = Z/N$$

 Z = great circle route distance N = number of equal length segments z_i

$$EW = \frac{Z}{\sum_{i=1}^N \frac{Z/N}{\bar{g}_i}} - A$$

$$EW = \frac{Z}{\sum_{i=1}^N 1/\bar{g}_i} - A$$

3.1.1. Equivalent Route Wind (cont'd.)

or, equivalent headwind is the harmonic mean* of the ground speeds less airspeed. By convention, when mean ground speed is less than airspeed, equivalent wind is a headwind and will be negative.

*The earlier Boeing documents used the arithmetic mean for headwind. Since the airspeed in their case was much greater than windspeed, error would be small. The harmonic mean is technically correct, and for lower airspeed, required to eliminate overestimates.

3.1.2. Route Standard Deviation

Correlation studies and physical considerations reveal that vector winds at points along a route are related to one another^{1,21}. For this reason, the mean vector wind and the standard vector deviation at points along a route while sufficient to determine the average value of the route equivalent wind, are insufficient to determine its variability. For example, strong winds at points along a route may or may not occur simultaneously. If they do not occur together, there is a tendency for the headwind components to average out such that the average value of the extreme winds is less than the values of the extreme winds at individual points over the route. Sawyer¹ has shown this to be the case.

The route standard deviation provides a measure of the variability of the equivalent route wind. The relationship between the route standard deviation and the average value of the standard vector deviation at points along the route is:

$$\sigma_t = S \sqrt{\frac{\sum_{i=1}^N \sigma_i^2}{N}}$$

where:

σ_t = Route standard deviation (tabulated value)

S = Factor to convert root mean square standard vector deviation of wind over a route, into the route standard deviation of the equivalent route wind. The value of S decreases with increasing route length and exhibits some variation with season, latitude and route orientation¹.

The values of S used in preparing Table 3 are those listed in Graystone⁶.

3.1.3. Great Circle Distance

Route lengths in nautical miles are computed over the great-circle

3.1.3. Great Circle Distance (cont'd.)

course, i.e., the least distance on a sphere, between terminals. The expression used to compute great circle distances is:

$$S = 60 \cos^{-1}(\sin \psi_1 \sin \psi_2 + \cos \psi_1 \cos \psi_2 \cos (\lambda_1 - \lambda_2))$$

where:

S = Great circle distance
in nautical miles

ψ = Latitude

λ = Longitude

$\cos^{-1}$ = Angle expressed
in degrees

Fig. 1

Great Circle Distance

South latitudes and east longitudes are considered negative and north latitudes and west longitudes are considered positive.

3.2 Annual Equivalent Route Winds

Annual equivalent route winds for the 50%, 75%, and 85% level are computed from the seasonal mean values of equivalent route winds and their standard deviations. The technique involves an iterative procedure by which wind speeds are found such that 50, 75, and 85 percent of the total area under the four seasonal wind distribution curves, lies to their right. With reference to Figure 2, the 50, 75, and 85 annual equivalent winds are estimated to be -5, -11, and -13 knots respectively. (From the

Fig. 2. Hypothetical Seasonal Wind Distribution

3.2 Annual Equivalent Route Winds (cont'd.)

definition, these are the headwinds - headwinds are negative - which will not be exceeded X% of the time. If the distribution of winds are entirely positive (tailwinds) the technique is the same. To assure a headwind value which will not be exceeded, one must get the lowest value of tailwind which meets the reliability level.

3.3 Input Data

The most recent and internally consistent summaries of statistical wind data available were used. Wind statistics were obtained primarily from Crutcher⁵ and the NAVAIR publications while the airfield coordinates were obtained from standard reference sources. The mean vector wind and the standard vector deviation together with the coordinates of each terminal form the input data for an IBM 360/65 program. The wind parameters for the four seasons and for the 5000 (850 mb), 10,000 (700 mb), and 18,000 (500 mb) foot levels, were obtained by computing them at the intersection of each 5° of latitude with each 10° of longitude between 60°N and 60°S and at the intersection of each 5° of latitude with each 20° of longitude north of 60°N and south of 60°S.

3.4 Method

Equivalent route winds are computed by first dividing the route into an integral number of segments of 200 miles or less in length and then calculating the segment flight time resulting from the wind vectors at the mid-points of these segments. This is accomplished by weighing the four nearest wind values (at grid points) in proportion to their proximity to the point on the route. The times are summed for the entire route, and resulting average ground speed is calculated. Equivalent wind results by subtracting average airspeed from the average ground speed.

By convention, a positive sign denotes a tailwind; a negative sign, a headwind.

3.5 Tabulations

Equivalent winds for the 5,000-, 10,000-, 18,000- foot levels are tabulated for routes between selected airfields (Table 3). The route wind tabulations are organized alphabetically by the terminals that identify each route. In the index, each route is referenced under both of its terminals (Table 4). Included in the data are:

3.5 Tabulations (cont'd.)

1. The direct and return seasonal mean equivalent route wind and its standard deviation and the annual 50-, 75-, and 85- percent reliability equivalent route wind in knots.
2. The great circle distance in nautical miles.

An alphabetical listing of terminals with their geographical coordinates is provided in Table 3.

4.0 USE OF TABLES

4.1 Normal Curve

Brooks¹⁰ et al found that in any one season the distribution of equivalent route winds about the mean closely approximates the normal law of errors. According to this law, the mean and its standard deviation completely define the distribution of winds about the mean. In turn, this error distribution very nearly approximates the normal or Gaussian frequency distribution defined as:

$$Y = \frac{1}{\sigma \sqrt{2\pi}} e^{-x^2/2\sigma^2}$$

where:

Y = The frequency ordinate at distance x from the mean

σ = The standard deviation

4.2 Estimating Reliability Equivalent Route Winds

Computation of reliability equivalent route winds deserves special attention since deviations of the relative frequency of extreme wind speeds from the assumed normal law of errors may be appreciable, particularly at levels and in regions affected by jet streams. The frequency of extreme values is probably higher than that predicted from the assumed model. For this reason, reliability equivalent winds for percentages less than 5 and greater than 95 are likely unreliable.

Two methods for estimating equivalent winds for reliabilities other than for the tabulated mean values involve use of error factors and secondly, use of arithmetic probability paper.

4.2.1. Error Factor Method

For a given route, reliability equivalent winds are computed by subtracting the product of k times the standard deviation from the

4.2.1. Error Factor Method (cont'd.)

mean equivalent wind, where k is a factor derivable from the error function. Values of k are given in Table 1 or can be found from tables of the normal curve of error. These methods are accurate only for estimating seasonal reliabilities. The seasonal curves approximate the normal law of errors, but the annual curve does not. Therefore, to get an annual reliability requires an iterative technique as described in 3.2.

The error factors method is illustrated by computing the 85 percent reliability equivalent route wind over the great circle - Ft. Rucker to Ft. Eustis air route, in winter at 5,000 feet.

TABLE 1. ERROR FACTORS

Reliability Percent (Area under normal curve to $+k$)	$+k$ (Number of standard deviations from the mean)
50	0.0
60	0.25
70	0.52
80	0.84
85	1.04
90	1.28
95	1.65

From Table 1, the error factor is 1.04.

- a. The DIRECT reliability equivalent headwind which should not be exceeded on 85 percent of occasions is a wind of -23 knots:

$$-11 - (1.04 \times 12) = -23 \text{ knots.}$$

or, Mean - $1.04 \sigma_t$ (See 3.2)

- b. The RETURN reliability equivalent headwind which can be relied on 85 percent of occasions is a wind of -2.5 knots;

$$10 - (1.04 \times 12) = -2.5 \text{ knots.}$$

or, Mean - $1.04 \sigma_t$ (See 3.2)

4.2.2. Arithmetic Probability Paper Method

As previously stated, in any season the distribution of equivalent route winds about the mean closely approximates the normal law of errors and the normal or Gaussian frequency distribution defined in (4). Arithmetic probability paper is arranged with the percent cumulative frequency scale printed on the ordinate such that the integral of the normal

4.2.2. Arithmetic Probability Paper Method (cont'd.)

$$Q(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^x e^{-x^2/2} dx \quad (5)$$

frequency curve plots as a straight line while the abscissa has a linear scale. The sign convention is followed for equivalent wind speeds (+ for a tailwind and - for a headwind). These two lines give the frequency distribution of equivalent winds over the route.

4.3 Variation in Airspeed

The tabulated equivalent wind data were computed for a 120-knot airspeed. For airspeeds much above this value, the new values may be approximated by assuming the wind speed is the result of the arithmetic mean of the ground speeds.

Expressions to use are:

$$D' = 1/2 (D - R) + \frac{62.5}{A} (D + R) \quad (6)$$

$$R' = -1/2 (D - R) + \frac{62.5}{A} (D + R) \quad (7)$$

If D and R are of equal value and of opposite sign, the tabulated values are the same for any airspeed. If $D \perp R$, i.e., a cross wind component is present, D' and R' will differ slightly from D and R.

Caution should be exercised when attempting to use airspeeds less than 120 knots, because simplifications used in the basic Sawyer method will cause increasing error as wind speeds at any segment approach aircraft speed.

Percent reliability equivalent headwinds computed for the new airspeed, A, will differ by the same amount as the mean values, i.e., $D - D'$, because standard deviations are not sufficiently affected by changes in airspeed².

4.4 Great Circle Route Length

The route length in nautical miles is computed over the great-circle course, i.e., the least distance on a sphere, between terminals (Fig. 3). For completeness, a great circle may be defined as the intersection of the surface of a sphere and a plane which passes through the center of the sphere. A nautical mile is the length

4.4 Great Circle Route Length (cont'd.)

on one minute of arc along a great circle on the earth's surface, i.e., the earth's circumference is $360 \times 60 = 21,600$ n. mi. In terms of statute miles, 1 n. mi. = 1.1508 miles.

Figure 3 Great Circle Route Length

4.5 Equivalent Route Length

The equivalent route length, for a given reliability equivalent wind, is the distance that an aircraft would have flown in still air on a flight having the same duration as that required with given percent equivalent wind. The equivalent route length may be expressed as

$$L_x = \frac{DA}{A + W_x} \quad (11)$$

where:

L_x = Equivalent route length in knots for x percent reliability equivalent wind W_x

D = Great circle distance in nautical miles

A = Airspeed in knots

5.0 OCCURRENCE OF HEADWINDS ON BOTH DIRECT AND RETURN FLIGHTS

Over routes characterized by prevailing light winds or by strong winds perpendicular to track the direct and return route winds can both appear as a headwind. This situation occurs when the contribution to the mean equivalent wind from the wind components at right angles to the track exceeds the contribution from the wind components along the track. The effect of winds at right angles to track on the ground speed becomes apparent when it is realized that an

5.0 OCCURRENCE OF HEADWINDS ON BOTH DIRECT AND RETURN FLIGHTS (cont'd.)

airplane could make no progress along the intended track with a wind at right angles to the track and equal to its airspeed.

Reliability equivalent headwinds for some routes appear as headwinds for the direct and return flight. The situation can occur over routes where the mean equivalent wind is about the same magnitude as its standard deviation. For example, a route having a mean equivalent wind of 12 knots, and a standard deviation of 15 knots, has an 85 percent reliability wind of -3 knots. In this example a tailwind has not become a headwind, but rather a headwind of 3 knots is not likely to be exceeded on 85 percent of occasions and a tailwind of 12 knots can be relied on 50 percent of occasions.

6.0 RELIABILITY OF RESULTS

The reliability of the tabulated equivalent headwinds as being representative of the actual route winds over great circle routes depends largely upon the assumption that wind distributions in the free atmosphere can be treated by the circular normal distribution. This distribution requires that the zonal and meridional components of wind be uncorrelated and that their standard deviation be equal. From physical considerations, however, some degree of ellipticity must be present, otherwise there would be no mean transport of energy in the atmosphere as is observed. For most conditions, the degree of ellipticity is small and the assumed circular normal distribution acceptable. Brooks¹⁰ pointed out that the assumption of circularity is likely to be weakest in frontal zones, in the vicinity of jet streams and in areas characterized by distinct seasonal wind variation such as the boundary region between a monsoon circulation and the circulation above.

The tabulated values are intended as long term estimates of enroute winds and as such the actual winds in any one season may differ appreciably from them. This condition particularly occurs where all routes closely parallel the mean position of the jet stream. Where air routes routinely traverse normal to the jet stream, however, only small differences between the tabulated and observed route winds should occur.

7.0 CONCLUSION

The application of equivalent winds can aid agencies concerned with the problems of aircraft logistics to estimate the long term capabilities of helicopters to deploy over long distances. Considerable effort has been expended by Boeing-Vertol since 1965 to display temperature probability variations with altitude. Many government agencies are using our data on that subject. By combining that data with the wind data of this document, one can estimate fairly accurately the effects on helicopter performance.

HEADWINDS--COMPUTED FOR A 10-KNOT AIRSPEED.

000--CIRCLES ARE EQUIVALENT HEADWINDS FOR INDICATED PER CENT RELIABILITIES.
PLUS SIGN LEAVES HEADWINDS.

EQUIVALENT MEASUREMENTS AND STANCARE DEVIATION IN ANGLES FOR GREAT CIRCLE AIR ROUTES

HEIGHT IN FEET	EQUILIBRIUM MEASUREMENTS												STANCARE DEVIATION

HEADWINDS—COMPUTED FOR A 120-KT AIRSPEED.

0005C—DENOTES ANNUAL EQUIVALENT HEADWINDS FOR INDICATED PER CENT RELIABILITIES.
MINUS SIGN DENOTES HEADWINDS.
