

Advanced Fabrication Processes for Superconducting Very Large Scale Integrated Circuits

Sergey K. Tolpygo, Vladimir Bolkhovsky, T.J. Weir, Alex Wynn, D.E. Oates, L.M. Johnson, and M.A. Gouker

Abstract—We review the salient features of two advanced nodes of an 8-Nb-layer fully planarized process developed recently at MIT Lincoln Laboratory for fabricating Single Flux Quantum (SFQ) digital circuits with very large scale integration (VLSI) on 200-mm wafers: the SFQ4ee and SFQ5ee nodes, where “ee” denotes the process is tuned for energy efficient SFQ circuits. The former has eight superconducting layers with 0.5 μm minimum feature size and a 2 Ω/sq Mo layer for circuit resistors. The latter has nine superconducting layers: eight Nb wiring layers with the minimum feature size of 350 nm and a thin superconducting MoN_x layer ($T_c \sim 7.5$ K) with high kinetic inductance (about 8 pH/sq) for forming compact inductors. A nonsuperconducting ($T_c < 3$ K) MoN_x layer with lower nitrogen content is used for 6 Ω/sq planar resistors for shunting and biasing of Josephson junctions (JJ). Another resistive layer is added to form interlayer, sandwich-type resistors of m Ω range for releasing unwanted flux quanta from superconducting loops of logic cells. Both process nodes use Au/Pt/Ti contact metallization for chip packaging. The technology utilizes one layer of Nb/ AlO_x -Al/Nb JJs with critical current density, J_c of 100 $\mu\text{A}/\mu\text{m}^2$ and minimum diameter of 700 nm. Circuit patterns are defined by 248-nm photolithography and high density plasma etching. All circuit layers are fully planarized using chemical mechanical planarization (CMP) of SiO_2 interlayer dielectric. The following results and topic are presented and discussed: the effect of surface topography under the JJs on their properties and repeatability, I_c and J_c targeting, effect of hydrogen dissolved in Nb, MoN_x properties for the resistor layer and for high kinetic inductance layer, technology of m Ω -range resistors.

Index Terms—Josephson junctions, high kinetic inductance, MoN_x , Nb/ AlO_x /Nb Josephson junctions, ERSFQ, RSFQ, RQL, superconducting integrated circuits

I. INTRODUCTION

SUPERCONDUCTING DIGITAL electronics is considered for applications in high performance-computing due to a potential for much higher clock rates and lower energy dissipation than those offered by the current CMOS technology. In order to become competitive with semiconductor electronics, superconducting circuits must reach a very large scale of integration (VLSI) that would enable circuit functionalities and complexities required for computing. At present, superconducting digital circuits have

about 5 orders of magnitude lower integration scale than the typical CMOS circuits. E.g., the largest demonstrated Single Flux Quantum (SFQ) circuits have only about 10^5 switching elements, Josephson junctions, [1]–[3] whereas CMOS circuits routinely have over 10^{10} transistors.

There are several reasons for this gigantic disparity: insufficient funding and lack of profit-driven investments in superconductor electronics (SCE), immaturity of the fabrication processes and integrated circuit design tools, and physical limitations on the size of SFQ logic cells. The present work is devoted to development of advanced fabrication processes for making superconducting VLSI circuits and, thus, reducing this disparity.

II. EIGHT-NB-LAYER PROCESS NODE SFQ4EE

In our previous works [4],[5] we introduced a fabrication process with eight Nb layers and full planarization of all layers including the layer of Josephson junctions. This process node was termed SFQ4ee, where “ee” denotes that the process is tuned for making energy efficient circuits for the IARPA Cryogenic Computing Complexity, C3 Program [6]. The cross section of the process is shown in Fig. 1; the target parameters of the layers as they appear in the processing and minimum feature sizes (critical dimensions) are given in Table 1.

TABLE I
CRITICAL DIMENSIONS AND LAYER PARAMETERS OF SFQ4EE PROCESS

Physical layer	Photolithography layer	Material	Thickness (nm)	Critical dimension Feature (nm)	Space (nm)	I_c^a or R_s^b
M0	M0	Nb	200 $\pm$ 15	500	700	20
A0	I0	SiO_2	200 $\pm$ 30	700	700	20
M1	M1	Nb	200 $\pm$ 15	500	700	20
A1	I1	SiO_2	200 $\pm$ 30	700	700	20
M2	M1	Nb	200 $\pm$ 15	500	700	20
A2	I2	SiO_2	200 $\pm$ 30	700	700	20
M3	M3	Nb	200 $\pm$ 15	500	700	20
A3	I3	SiO_2	200 $\pm$ 30	700	700	20
M4	M4	Nb	200 $\pm$ 15	500	700	20
A4	I4	SiO_2	200 $\pm$ 30	1000	1000	20
M5	M5	Nb	135 $\pm$ 15	700	1000	20
J5	J5	AlO_x/Nb	170 $\pm$ 15	700	1100	100 ^c
A5a	I5	anodic oxide ^d	40 $\pm$ 2	700	700	
A5b	I5	SiO_2	170 $\pm$ 15	700	700	20
R5	R5	Mo	40 $\pm$ 5	500	700	2 $\pm$ 0.3
A5c	C5	SiO_2	70 $\pm$ 5	700	700	20
M6	M6	Nb	200 $\pm$ 15	500	700	20
A6	I6	SiO_2	200 $\pm$ 30	700	700	20
M7	M7	Nb	200 $\pm$ 15	500	700	20
A7	I7	SiO_2	200 $\pm$ 30	1000	1000	n/a
M8	M8	Au/Pt/Ti	250 $\pm$ 30	2000	2000	n/a

^a I_c is the minimum critical current of metal lines or contact holes (vias) of the critical dimensions (CD) in mA, R_s is the sheet resistance of resistor layer R5 in Ω/sq .

^c Josephson critical current density of Nb/ AlO_x -Al/Nb trilayer in $\mu\text{A}/\mu\text{m}^2$.

^d Mixed anodic oxide (AlNb) O_x formed by anodization of Al/Nb bilayer of JJ bottom electrode.

Fig. 1. Scanning electron microscope (SEM) image of a wafer cross section made by focus ion beam (FIB). The wafer was fabricated by SFQ4ee process. Labels of metal layers correspond to notations in Table I. Vias corresponding to the physical and lithographical layers A# and I# are labeled V0,...,V6. The vias are formed by etching contact holes in the interlayer dielectric and covering them by Nb of the next wiring layer.

A. Fabrication and Measurement Details

All metal layers (Nb, Al, Mo) were deposited on 200 mm Si wafers by magnetron sputtering using a multi-chamber cluster tool (Endura from Applied Materials, Inc.) with base pressure of 10^{-8} Torr. SiO_2 interlayer dielectric (ILD) was deposited at 150°C , using a Plasma Enhanced Chemical Vapor Deposition (PECVD) system Sequel from Novellus (Lam Research, Inc.) Thickness uniformity of the deposited oxide was $\sigma = 2\%$, where σ is standard deviation (normalized to the mean value). Photolithography was done using a Canon FPA-3000 EX4 stepper with 248 nm exposure wavelength, UV5 photoresist, and AR3 bottom antireflection coating. Etching of all metal and dielectric layers was done in a Centura etch cluster (Applied Materials, Inc.), using Cl-based chemistry for metals and F-based chemistry for dielectrics. Planarization of the metal layers was done by a chemical mechanical planarization (CMP), using the following steps: **a**) deposition of a $\sim 2.5\times$ times thicker SiO_2 over the patterned metal layer; **b**) polishing SiO_2 to the required level, using a CMP tool Mirra from Applied Materials, Inc. **c**) measuring the remaining dielectric thickness in 49 points on the wafer, using an ellipsometer; **d**) redeposition of SiO_2 , if needed, to achieve the target ILD thickness in Table 1. Etched vias I0, I1, etc. are filled by Nb of the following metal layer. JJ fabrication was described in detail in [4].

For the process characterization and electrical testing we used a Process Control Monitor (PCM) set of reticles with sixteen $5\text{ mm} \times 5\text{ mm}$ chips containing ~ 3600 structures for testing JJs, wires, vias, inductors, resistors, dielectric integrity, and other process parameters. For purely process development fabrication runs, this $22\text{ mm} \times 22\text{ mm}$ PCM was stepped all over the wafer on a 7×7 grid using labels A,B,...,G for the x-coordinate and 1,2,...,7 for the y-coordinate. For runs with SFQ digital circuits, the PCM was stepped only over nine locations (A4, B2, B6, D1, D4, D7, F2, F6, G4) whereas a different set of reticles, containing only digital circuits, was

used for the other 40 locations.

About 3300 test structures (TS) per each location were tested at room temperature by using a semi-automated wafer prober. All JJs for room- T testing were designed in a cross-bridge Kelvin resistor (CBKR) configuration to measure the tunnel barrier resistance. A smaller subset of TS, including JJs, wires, vias, resistors, and inductors, were tested at 4.2 K after dicing the wafer and wire bonding the individual chips. A procedure for estimating the Josephson critical current density J_c and JJ parameter spreads from room- T measurements of JJ conductance was described in [4]. Briefly, a junction conductance G at room- T is directly proportional to the tunnel barrier conductance G_N at 4.2 K and to I_c of the JJ through the Ambegaokar-Baratoff relation ($I_c R_N$ product, $R_N = 1/G_N$) [7]. Accordingly, the relative standard deviation of conductances σ_G (normalized to the mean conductance value) of a set of nominally identical JJs is a very good measure of the relative standard deviation of the critical current σ_{I_c} in the set, for details see [4].

Except when specifically noted, all JJs were designed such that Nb leads connecting their base and counter electrodes to $100\text{ }\mu\text{m} \times 100\text{ }\mu\text{m}$ Au/Pt/Ti/Nb contact pads were interrupted by $50\text{ }\Omega$ molybdenum resistors, $25\text{ }\mu\text{m}$ long and $2\text{ }\mu\text{m}$ wide. The purpose of these resistors was to interrupt a diffusion path from the JJs to contact pads through Nb wires by a material with much lower diffusion coefficient of impurities such as hydrogen, oxygen, nitrogen, etc. These impurities may dissolve in Nb during various steps of wafer processing and affect junction tunnel conductance and Josephson critical current [8]-[12]. Molybdenum resistors work as a diffusion barrier preventing out-diffusion of impurities from JJs to contact pads and thus fixing the true impurity state of JJs by the end of wafer processing [10]-[12].

B. Layer Topography Effects on Josephson Junctions

An accurate targeting of the critical currents I_c of JJs and minimization of their variations (standard deviation σ_{I_c}) are of prime importance for yielding operational SFQ digital circuits because of their narrow design margins with respect to deviations of I_c from the target values. One of the possible sources of I_c variations is surface topography created by patterned wiring layers under JJs as a result of planarization imperfections, e.g., SiO_2 dishing between metal lines, etc. For instance, Fig. 2 - Fig. 4 show a few examples of JJs placed over the edges of etched wires in Nb layers below the JJs. Electric properties of such JJs (tunnel barrier conductance G at room- T) have been measured and compared with a control group of JJs placed over the flat surface formed above M4, M2, and M0 ground planes with no patterning under and in proximity to the JJs.

As a ground plane we refer to a multiply-connected metal layer with average metal density of $\geq 80\%$ on a scale of $5\text{ mm} \times 5\text{ mm}$ chips. It typically serves for returning all bias currents in circuits. Since electric signals coming from the bottom layers should pass through the ground planes in order to reach JJs, these planes have multiple etched openings (holes), moats, and short wires whose edges may be located under JJs,

e.g., as shown in Fig. 2. Wiring layers typical have 25% to 65% metal density. JJ density was typically from 4% to 6%.

Fig. 2. SEM images of the FIB cross sections through a JJ and Nb layers below it: (a) 1 μm circular JJs above the coincident edge of wires in four metal layers M0, M1, M2, and M4 below the junction; (b) a zoom in showing only the JJs and the edge of the upper layer M4. Layers M0, M2, and M4 were ground planes with average metal density $\sim 80\%$ on the chip scale. Please note, FIB samples are tilted $\sim 55^\circ$, so the vertical scale is not equal to the horizontal scale.

The surface of the I4 dielectric after planarization and the surface of the bottom electrode (M5) of the JJ look very flat in Fig. 2, despite the presence of the coincident edge of four wires in the layers below right in the middle of the JJ. Fig. 3 gives another example of possible topography under a JJ. Here, multiple wires of the minimum allowed width (Table 1) are placed under the JJs. Zoomed image Fig. 3(b) does not reveal noticeable changes in the flatness of the bottom electrode of the JJ, M5. However, the tunnel barrier is only ~ 1 nm thick and thus can potentially be affected by surface imperfections not visible at this magnification or in these particular cross-sections. Therefore, only electric testing can reveal if the presence of wire edges in the layers under the junction layer and topography they create affect the JJs.

Fig. 3. (a) FIB cross section showing a 1 μm circular JJ above topography created by multiple 0.5- μm -wide M4 wires stacked on 0.5- μm -wide M3 wires above M2 and M0 ground planes; (b) a zoom in showing the JJ and the M4 layer under it. Globally, M4 layer was a ground plane with the metal density about 80%. The M4 wires shown are about 20 μm long in the perpendicular to the cross-section direction and separated from the ground plane.

Fig. 4 gives an example when the planarization does not look this perfect. In this case a few 0.7- μm -wide parallel wires in layer M3 were placed below a much wider wire in M4 under a JJ. Since the metal density of the M3 layer near the JJ was low, there was a noticeable dishing of the dielectric between the wires. As a result, M4 wires sagged a little bit between them, and a clear step in M4 can be seen projecting up from the edge of the M3 wire right under the JJ, see Fig. 4(b).

The control group had 24 JJs per chip, 196 JJs per wafer, placed above M4, M2, and M0 ground planes, as shown in Fig. 1 but with layers M1 and M3 etched away under the JJs.

The edges of patterns in M1 and M3 layers were about 50 μm away from the JJs in the control group.

Fig. 4. (a) FIB cross section showing a 1 μm circular JJ above topography created by multiple 0.7- μm -wide M3 wires under a 20- μm -wide M4 wire and above M2 and M0 ground planes; (b) a zoom in showing the JJ and the M4 layer under it. Layer M4 clearly has a step right in the middle of the JJ, resulting from sagging in (dishing of the dielectric between two wires in M3 under the JJ. It appears though that this step does not affect the planarity of the bottom electrode of the JJ, but only electric testing can reveal if this JJ differs in any way from a JJ placed on the flat surface with no wires below it.

Another group consisting of sixty six JJs per chip, 594 per wafer, was placed over the topographies shown in Fig. 2 – Fig. 4 and a few other combinations of layers and wires, e.g., single wire, crossing wires, etc. All JJs in both groups were Manhattan-shaped junctions defined on a 5 nm grid with an effective diameter of 1000 nm. The typical aggregate distributions of conductance of the JJs in both groups are shown in Fig. 5.

Fig. 5. Distribution of conductance of Josephson junctions on a wafer: (a) junctions above ground planes M4, M2 and M0 with no patterning under and near the junctions, (b) junctions above various patterns in M4 and/or M3, and M2 layers described in the text. The mean values $\langle G_{0l} \rangle$ and $\langle G_{0gr} \rangle$ as well as second moments of the distributions, σ_{0l} and σ_{0gr} , are shown. Solid lines show fits to a Gaussian distribution. The distribution of conductance characterizes the distribution of the critical current. Note the scale difference between (a) and (b).

From the point of view of SFQ circuits, the important parameters are the difference in the mean values of these distributions $\langle G_{\text{tpgr}} \rangle - \langle G_{\text{flt}} \rangle$ and the difference of their second moments $\sigma_{\text{tpgr}} - \sigma_{\text{flt}}$, where subscripts “tpgr” and “flt” refer to the group over various topographies and the control group above the nominally flat SiO_2 surface above the ground plane, respectively. These parameters were tracked for all wafers made by the process. Hereafter we will refer to the second moments of conductance and I_c distributions as standard deviations without implying that they are strictly Gaussian.

Fig. 6. (a) Relative difference of the mean conductance of JJs on topographies $\langle G_{\text{tpgr}} \rangle$ with respect to the junctions on the flat dielectric above M4 ground plane, $\langle G_{\text{flt}} \rangle$. (b) Difference of the standard deviations of these two groups of JJs. Parameters of aggregate distribution of JJs on 9 dies per wafer are shown by squares and of distributions excluding the central die, D4, are shown by stars.

Fig. 6 shows the normalized difference of the mean values $(\langle G_{\text{tpgr}} \rangle - \langle G_{\text{flt}} \rangle) / \langle G_{\text{flt}} \rangle$ for the 24 most recently made wafers. It can be seen that there is a small statistical difference between the mean values of conductance of JJs over various topographies and the control group, from about 0.5% to 2.5%, and a somewhat larger difference in the standard deviation. On average, JJs over topographies have a bit higher conductance and, hence, higher critical current and a bit wider statistical distribution than JJs above the ground plane, Fig. 6(b). However, a die-by-die comparison shows that the main difference is confined to just one die, the central die D4, on all

the wafers. Excluding this central die from the analysis shows that there is about 1% increase in the average conductance of JJs over topographies, see Fig. 6(a). From Fig. 6(b) it is also clear that there is no statistically important increase in the width of their distribution, given that the estimated uncertainty of σ determination using JJ resistance measurements on a wafer prober is about $\pm 0.3\%$.

The observed increase in JJ conductance can be explained by an increase in JJ average area resulting from purely geometric factors such as (macroscopic) surface roughness. For instance, assume that near the edge of metal lines shown in Fig. 2(a) and Fig. 3(a) a step h in the dielectric forms as a result of SiO_2 dishing during the CMP, as shown schematically in Fig. 7(a). For small steps $h \ll t$, where t is Nb layer thickness, a deposited Nb/ AlO_x -Al/Nb trilayer covers such steps likely without changes in the tunnel barrier properties. The step causes an increase of the junction area with respect to the flat JJ of about $\delta A_{\text{tpgr}} = 2h(r^2 - a^2)^{1/2}$, where a is the distance between the step and the center of the circular junction with radius r . The relative increase in tunnel conductance due to this area increase is $\delta G_{\text{tpgr}} / G_{\text{flt}} = \delta A_{\text{tpgr}} / A_{\text{flt}} = (2h/\pi r)(1 - (a/r)^2)^{1/2}$.

Fig. 7. (a) A sketch of a junction placed over a step formed in the interlayer dielectric as a result of imperfect planarization, e. g., dishing of SiO_2 near the edges of wires in metal layer M3 and M4 below the junction base electrode layer M5. A bend of the base electrode and AlO_x -Al barrier with height h could be formed, increasing the effective area of the junction. (b) Dishing of interlayer dielectric between two metal lines. Due to the surface curvature, a JJ placed between these lines has larger area than the one on the flat surface.

The observed increase in the mean conductance of JJs with $r = 500$ nm is $\sim 1\%$, see Fig. 6. It can be explained by the presence of steps with the mean height of about 8 nm. They would hardly be seen in SEM images, Fig. 3 and Fig. 4. The maximum step height h_{max} we observed after CMP was ~ 35 nm, which could result in the maximum relative increase in conductance of 1000 nm JJs of $\sim 4\%$. We note that randomness in step locations and step heights, i.e., the surface roughness, would cause random variation of JJ areas and increase the width of JJ conductance distribution. This

increase of the normalized σ_G can be estimated as $2\sigma_h/\pi r$, where σ_h is the width of the step heights distribution. Then, σ_h can be estimated as $h_{\max}/6 \approx 6$ nm, giving $\sigma_G \approx 4/r$ about 0.4% for 1000 nm JJs; r is expressed in nm. This surface-roughness-caused contribution to JJ variability is of the same magnitude as the contribution of the so-called mask errors estimated in [4]. For a full comparison with the results of [4], a relationship between the actual (on wafer) radius of JJs r and the designed radius r_d should be used, as done in [4].

Another example is SiO₂ dishing between two metal lines during the CMP, forming a curved surface with radius R and depth h , see Fig. 7(b). A JJ formed on this curved surface will have larger area than on the flat surface. Depending on the length of the wires, the dishing can be approximated by either a cylindrical or a spherical surface with radius R . In both cases the JJ area can be approximated by the area of a spherical sector with height h , $A_{\text{tpr}} = 2\pi R h = \pi(r^2 + h^2)$, resulting in the increase in the JJ area and the JJ conductance by a factor $1 + (h/r)^2$. For 1000 nm JJs and $h = 35$ nm, the increase is about 0.5%.

These simple estimates demonstrate how macroscopic nonuniformities (surface roughness) of the dielectric surface under the JJs may affect their parameters, even without taking into account possible changes in the microscopic properties of the tunnel barrier.

JJs located near the very center of 200 mm wafers show, on average, larger parameter spreads and more outliers than JJs located more than ~ 1 cm away from the center. Usually these outliers have much larger conductance than the mean, indicating some type of damage to the tunnel barrier rather than the geometric effects considered above. E.g., such an outlier JJ with high conductance can be clearly seen in Fig. 5(b). At present we do not have an explanation for this behavior and its cause.

C. Critical Current and J_c Targeting

For accurate targeting of I_c in SFQ circuits, Josephson critical current density J_c is a convenient design parameter. However, being a differential characteristic, its accurate determination requires the accurate measurements of I_c and the accurate knowledge of the actual size of JJs. Also the cryogenic measurements on a 200 mm wafer scale are somewhat involved. The full procedure was described in [4]. For the purpose of this paper, we looked at the targeting of the critical current (tunnel conductance) of JJs with design diameter of 1000 nm because it is perhaps the most frequently used size of JJs.

Fig. 8 shows the wafer-averaged conductance of 1000 nm JJs on 64 wafers fabricated from the beginning of 2014 until August 2015. A set of 216 JJs per wafer at the nine PCM locations described before was used. The second moment of the distributions (standard deviation) σ_G of conductance in the group is shown as an error bar. For JJs of this diameter, tunnel barrier conductance of 50 mS corresponds approximately to the target J_c of $100 \mu\text{A}/\mu\text{m}^2$.

A $\pm 10\%$ margin band is shown by the dashed lines, which is assumed to be the acceptable margin for SFQ circuits. It is easy to count that 33 out of the 64 studied wafers were within

this margin, giving a J_c targeting wafer yield Y of 52%. Since the control of the JJs area and its run-to-run repeatability in our process is very tight, the changes in JJ average conductance in Fig. 8 are fully attributable to changes in the tunnel barrier transparency and J_c from run to run. We continue investigating the factors affecting J_c targeting in our process, beyond the oxidation time and pressure, and how this targeting can be significantly improved.

Fig. 8. Tracking of the wafer-averaged conductance of junctions at room temperature. JJs were designed as manhattans on a 5-nm grid and were circularly shaped with the effective diameter of 1000 nm. Red circles correspond to the JJs with molybdenum resistors in Nb wires leading to the contact pads and black squares to the JJs without the resistors. Mo resistors work as diffusion barriers and do not allow hydrogen dissolved in the base and counter electrodes of JJs and in the top Nb wire to escape into the contact pads. The changes observed reflect the run-to-run variation of the tunnel barrier transparency and J_c .

D. Hydrogen Effect on Critical Current and J_c Targeting

It is well known that many impurities, especially hydrogen, can dissolve in Nb during wafer processing and reduce J_c and conductance of JJs due to their effect on the tunnel barrier height [10],[12]. A convenient method of monitoring the degree of hydrogen contamination of JJs is based on comparing two groups of JJs: JJs directly connected to Au/Pt/Ti/Nb contact pads by Nb wires and JJ connected through molybdenum resistors, which are a diffusion barrier for hydrogen. Hydrogen can escape from the JJs to the contact pads in the first group but stays inside the JJs in the second group. This leads to a higher conductance and higher J_c of JJs in the first group than in the second [12]. The diffusion path from the JJs to the contact pads is short, no more than 50 μm . So hydrogen out-diffusion happens during a very short time period after the contact pad deposition [12]-[14].

Fig. 8 shows the wafer-averaged conductance for these two groups of JJs for 64 wafers studied. We use notations $\langle G_{\text{wt}} \rangle$ and $\langle G_r \rangle$ for the mean conductance of the group without the resistors and the group with resistors, respectively. Their normalized difference $(\langle G_{\text{wt}} \rangle - \langle G_r \rangle) / \langle G_r \rangle$ gives the relative difference in the mean values of I_c and J_c in these two groups and is shown in Fig. 9. Knowing this difference may be important for designing circuits which have junctions directly connected to the contact pads by their counter electrodes or other types of connections that may create a difference in the

hydrogen content and hence create bi-modal distributions of nominally identical JJs within the circuit.

Fig. 9. The relative difference of JJ conductance of junctions without hydrogen dissolved in Nb (without molybdenum diffusion barrier), G_{nr} , and with hydrogen dissolved in Nb during the processing (and preserved by the presence of molybdenum resistors), G_{wr} . This quantity gives also the relative difference of the critical currents of JJs in these two groups: without dissolved hydrogen in Nb and with dissolved hydrogen. JJ conductance data are wafer-averaged. The same set of wafers as in Fig. 8 was used.

It can be seen from Fig. 9 that the level of hydrogen contamination varies from wafer to wafer. We have many indications that the source of hydrogen contamination is PECVD interlayer dielectric which, due to the low deposition temperature, has high concentration of Si-OH and Si-H bonds and can also absorb H_2O molecules during the processing. Some of the loosely bonded hydrogen can diffuse into Nb during processing steps taking place at elevated temperatures. However, this needs further investigating as well as finding the methods of eliminating this contamination. We note here that hydrogen diffusion barriers proposed and implemented in [11] do not eliminate hydrogen contamination of Nb but simply fix the hydrogen content by preventing hydrogen migration between the circuit layers. As can be seen, the difference between the JJs with hydrogen and without hydrogen can reach $\sim 10\%$. Therefore, we continue investigating all possible ways of minimizing hydrogen contamination of Nb in our process.

III. SFQ5EE PROCESS NODE

In comparison with the SFQ4ee features listed in Table 1, a more advanced SFQ5ee node offers the following improvements:

- a) the minimum linewidth and spacing for all metal layers, except M0 and R5, is reduced to $0.35 \mu m$ and $0.5 \mu m$, respectively;
- b) the minimum size of etched vias and their metal surround is reduced to $0.5 \mu m$ and $0.35 \mu m$, respectively;
- c) the sheet resistance of the resistor layer is increased to $6 \Omega/sq$ by utilizing a nonsuperconducting MoN_x film, offering a choice of either $2 \Omega/sq$ (Mo) or $6 \Omega/sq$ (MoN_x) planar resistors for JJ shunting and biasing;
- d) an additional thin superconducting layer with high kinetic inductance is added below the first Nb layer M0 in order to enable compact bias inductors;

e) an additional resistive layer is added between Nb layers M4 and M5 in order to enable interlayer, sandwich-type resistors with resistance values in the $m\Omega$ range for minimizing magnetic flux trapping and releasing unwanted flux from logic cells.

Fig. 10. Cross section of a wafer fabricated by the SFQ5ee process. The labels of metal layers and vias are the same as in Table I. New features of the SFQ5ee are shown: a high kinetic inductance layer under M0 and a layer of $m\Omega$ -range resistors between M4 and M5 layers.

A cross-section showing these new features of the SFQ5ee node is given in Fig. 10. Below we will discuss new features c), d), and e) and the motivation for having them in some detail, leaving the details of the fabrication processes involved and the detailed results of parameter characterization for a separate publication.

A. High-Shee- Resistance Layer

Shunt resistors in the SFQ4ee process occupy a considerably larger area than JJs, restricting circuit integration scale. It may seem easy to decrease the area of resistors by increasing the sheet resistance of the resistor layer. Indeed, a thin-film resistor with $R = (l/w)R_s$ occupies area $A_R = w^2 R / R_s + 2A_c$ where R_s is the sheet resistance, w and l are the resistor width and length between two superconducting contacts through the dielectric (vias), and $2A_c$ is the area of these contacts, see the top of Fig. 11. So, increasing R_s should decrease A_R .

The expression above assumes that the length l can be made arbitrarily small in order to get small values of R . However, this is not the case. The superconducting vias to the resistor cannot be placed arbitrarily close to each other. They should be separated by the minimum distance l_{min} equal to the minimum spacing, s between Nb wires plus twice the minimum required surround, sr of the via by the wire. In the SFQ4ee process, $sr = 0.5 \mu m$ and $s = 0.7 \mu m$, making $l_{min} = 1.7 \mu m$. This sets the minimum value of the resistor that can be made using the minimum allowed width in the process, w_{min} , and hence, with the minimum possible area as $R = (l_{min}/w_{min})R_s = 6.8 \Omega$ in the SFQ4ee node. For getting the smaller values, the resistor length cannot be reduced below l_{min} . Therefore, the width needs to be increased with respect to the minimum allowed. In this regime, the resistor area is given by $A_R = (l_{min})^2 R_s / R + 2A_c$ and increases with increasing R_s .

Fig. 11 shows dependences of the resistor active area

(without the area of vias) as a function the resistor value for $R_s = 2 \Omega/\text{sq}$ and $6 \Omega/\text{sq}$. The minimum achievable area ($l_{\min}w_{\min}$) does not depend on R_s and is reached at $R = (l_{\min}/w_{\min})R_s$.

Fig. 11. Shunt resistor area (without the area of Nb contacts) for different values of the resistor: SFQ4ee process with $R_s = 2 \Omega/\text{sq}$, $w_{\min} = 0.5 \mu\text{m}$, and $l_{\min} = 1.7 \mu\text{m}$ (black solid curve), and SFQ5ee with $R_s = 6 \Omega/\text{sq}$, $w_{\min} = 0.5 \mu\text{m}$, and $l_{\min} = 1.2 \mu\text{m}$ (top, blue solid curve). The regime shown by the dashed lines cannot be realized because the length l of the resistor cannot be decreased below $l_{\min}$. The dotted curve corresponds to a future SFQ6ee process with $R_s = 6 \Omega/\text{sq}$, $w_{\min} = s = 0.35 \mu\text{m}$ and $l_{\min} = 0.95 \mu\text{m}$. The top scale shows the area of the critically damped junction with shunt resistor value R . A sketch of the resistor cross section is shown on top.

For the $J_c = 100 \mu\text{A}/\mu\text{m}^2$ processes, the critical damping of JJs corresponds to the characteristic voltage $V_c = I_c R_n$ of $\sim 700 \mu\text{V}$, where R_n is a parallel combination of the shunt resistor R and junction subgap resistance R_{sub} . The latter is about 10x times larger than the junction normal-state resistance R_N and can be neglected for the estimates here. Then, the shunt resistor (in ohms) is given approximately by $R = 7/A_J$, where A_J is the junction area in μm^2 . Hence, all JJs with areas $A_J > 7/(3R_s)$ have shunts limited by the minimum spacing and therefore increasing the sheet resistance of the shunt material without reducing $l_{\min}$ will only increase the resistor area. For the SFQ4ee process this corresponds to $A_J \geq 1.17 \mu\text{m}^2$ ($I_c \geq 117 \mu\text{A}$), covering nearly the whole range of JJs used in RSFQ [15] and ERSFQ [16] circuits.

If we increase R_s to $6 \Omega/\text{sq}$, keep the same minimum wire spacing $s = 0.5 \mu\text{m}$ and reduce the surround to $sr = 0.35 \mu\text{m}$ as in the SFQ5ee process, all resistors with values below 8.31Ω will still increase in area. This will affect resistive shunts of all JJs with $A_J > 0.84 \mu\text{m}^2$, $I_c > 84 \mu\text{A}$, i.e., all junctions used in

RSFQ and ERSFQ circuits. Other types of logic, which use smaller JJs and larger shunts, e.g., RQL [17] may still benefit from the increase in R_s . If in the next process node we also reduce the minimum spacing to $0.35 \mu\text{m}$, the shunt area savings will take place for the entire range of resistor values and JJs used in SFQ circuits, as shown by a dotted line in Fig. 11.

Despite the absence of resistor area savings in SFQ5ee node for resistors with $R \leq 8.31 \Omega$, we have developed MoN_x resistors with the target $R_s = 6 \Omega/\text{sq}$ for the use in the future process nodes with smaller resistor linewidth and wire spacing $w_{\min} = s = 0.35 \mu\text{m}$ and $0.25 \mu\text{m}$, and also for the nodes with higher J_c such as $200 \mu\text{A}/\mu\text{m}^2$ and $500 \mu\text{A}/\mu\text{m}^2$. Higher J_c junctions require larger shunt resistors and increasing R_s may be beneficial.

Amorphous MoN_x films with a broad range of sheet resistances and superconducting critical temperatures were obtained by changing N_2/Ar ratio during Mo sputtering [18]–[20]. Fig. 12 shows a dependence of T_c on R_s for amorphous MoN_x films with 40 nm thickness, deposited on thermally oxidized Si wafers at room- T . For the R_s range of interest, the resistance ratio $RRR = R_{300}/R_{4.2}$ is from 1.2 to 1.3, so we target the films with about $7.5 \Omega/\text{sq}$ at 300 K for the shunt resistor layer in the SFQ5ee process.

Fig. 12. Critical temperature of amorphous MoN_x films deposited on SiO_2/Si wafers at room temperature by reactive sputtering of Mo in Ar/N_2 mixture. Films with T_c below about 3.5 K can be used for the high sheet resistance resistor layer. High- T_c (high sheet resistance) region can be used for a layer of inductors with high kinetic inductance L_k in the range from about $4 \text{ pH}/\text{sq}$ to about $16 \text{ pH}/\text{sq}$ at 40 nm film thickness. Dashed line is to guide the eye only.

Sheet resistance uniformity of unpatterned MoN_x films of better than 2% on 200-mm wafers was achieved by rotating the wafer during the film deposition. Four-probe measurements were done in 49 points. On the fully processed SFQ5ee wafers, the patterned resistor uniformity (1σ standard deviation) was measured using 9 PCM locations and found to be 2.3%.

B. High-Kinetic-Inductance Layer

It can be easily shown that inductors occupy most of the space in SFQ circuits of any type RSFQ, RQL, AQFP, etc. Making energy efficient ERSFQ circuits requires particularly large, $\sim 100 \text{ pH}$, bias inductors instead of bias resistors in

order to eliminate the static power dissipation [16]. A 100 pH inductor in the SFQ4ee process node occupies more than $100 \mu\text{m}^2$ area, which severely limits the integration scale of ERSFQ circuits. In order to alleviate restrictions related to the size of inductors and enable increasing the integration scale of ERSFQ circuits, we suggested and implemented in SFQ5ee node an additional (the 9th) superconducting layer with high kinetic inductance. It is well known that kinetic inductance of thin superconducting films $L_k = \mu_0 \lambda^2 / t$ is much larger than their geometric inductance if $\lambda \gg t$ and $\lambda^2 / t \gg w$, where λ is magnetic field penetration depth, t and w are the film thickness and width, respectively.

Many high-kinetic-inductance materials such as NbN_x , TiN_x , and TiSi_2 have been extensively studied for applications in detectors of photons and particles [21]. Usually such detectors require only one superconducting layer and operate below the LHe temperature, so very thin films with $t \sim 5 \text{ nm}$ can be used giving very large values of L_k . In our case we needed to integrate a thin superconducting film into a multilayer process and prevent a significant degradation of its critical temperature T_c in comparison with T_c of Nb. Also we need to keep the deposition temperature relatively low and would like to minimize the number of different materials used in the process because each additional material requires an additional vacuum chamber and a sputtering gun.

In SFQ4ee process we use pure molybdenum thin films for the $2 \Omega/\text{sq}$ resistor layer. In SFQ5ee process we add nitrogen impurities to molybdenum to form an amorphous MoN_x with low nitrogen content [20] in order to increase the sheet resistance to $6 \Omega/\text{sq}$. Therefore, we decided to investigate and implement thin superconducting MoN_x films in the high-sheet-resistance region of Fig. 12 (with high nitrogen content) as high kinetic inductors [22]. The advantage of this approach is that the same vacuum chamber and Mo target can be used for reactive sputtering of both the high-sheet-resistance layer for resistors and the high-kinetic-inductance layer for inductors simply by adjusting the N_2/Ar ratio in the mixture.

The high-kinetic-inductance layer was placed as the first layer in the process as shown in Fig. 10. We used a 40 nm thick MoN_x film. After patterning it was covered by a 60 nm layer of SiO_2 to isolate it from the first Nb layer M0. Superconducting vias were made by etching contact holes in SiO_2 . Due to its low thickness, the layer of kinetic inductors was not planarized by CMP.

Sheet inductance of the unpatterned films was measured using a dielectric resonator technique [23],[24]. On the fully processed wafers, kinetic inductors of various widths from $0.5 \mu\text{m}$ to $2 \mu\text{m}$ and various lengths were included in the arms of the test SQUIDS described in [5]. The inductance was determined from the period of the SQUID modulation. Sheet inductance values in the range from about $4 \text{ pH}/\text{sq}$ to $16 \text{ pH}/\text{sq}$ for 40-nm-thick films were obtained by varying the MoN_x deposition parameters. Higher-kinetic-inductance films have lower superconducting critical currents. The target value for the kinetic inductance in the SFQ5ee process node was set as $8 \text{ pH}/\text{sq}$ in order to satisfy the critical current requirements for bias inductors in ERSFQ circuits, $I_c > 0.5 \text{ mA}$ per inductor.

The details of MoN_x high kinetic inductor fabrication and characterization will be given elsewhere.

C. Interlayer, Sandwich-Type $m\Omega$ -Range Resistors

One of the main reliability problems of SFQ circuits is the sensitivity of their operation margins to magnetic flux trapping inside and near the logic cells. The flux is caused by the residual magnetic field and the field produced by bias currents. Single flux quanta are also produced as a result of cells normal operation. If trapped in superconducting loops, some types of cells may not operate correctly as a result. In order to minimize both types of the flux trapping, it would be helpful to break some of the superconducting loops by resistors allowing magnetic flux to decay. The typical decay time τ is L/R , where L and R are the loop inductance and the breaking resistance. Most of the inductors in SFQ circuits are on the order of 10 pH. The decay time should be much longer than the circuit clock period $1/f_{cl}$ to allow SFQ information processing. On the other hand it should be short enough to prevent memory effects, i.e., to reset the cell to a zero flux state before the next logic operation. At 1 GHz clock frequency, these requirements result in $0 \ll R \ll 0.1 \Omega$.

Due to the limitations described in III.A, it is not possible to make planar resistors with such small resistance values and reasonably small area by using conventional thin films having $\sim 1 \Omega/\text{sq}$ sheet resistances. However, if a resistive film is sandwiched between two superconducting layers, its resistance in the direction perpendicular to the film plane can be utilized, giving $R = R_s t^2 / A$, where t is the film thickness and A is the contact area. For any $t < 0.1 \mu\text{m}$ and $R_s < 10 \Omega/\text{sq}$, RA is less than $0.1 \Omega\mu\text{m}^2$ and the required compact resistors can be realized. The main trick is to prevent the formation in this manner of a sandwich-type SNS Josephson junction with critical current larger than Φ_0/L .

In this work, a resistive film was sandwiched between Nb layers M4 and M5 as shown in Fig. 10. In order to achieve this, the vias between these layers were made as Nb pillars (studs), as can be seen in Fig. 10, by using a double-etch and planarization (DEAP) technology of stud-vias described in [25],[26]. After the CMP to the level of Nb pillars, the resistive layer was deposited over and patterned to leave it only on the studs where a resistive contact is required. After that the next Nb layer M5 was deposited, completing the sandwich. In this structure, the contact area A is determined by the area of the Nb pillar (stud-via). More details on the materials used, processing, and characterization of vertical, sandwich-type resistors will be given elsewhere due to a lack of space here.

ACKNOWLEDGMENT

The authors would like to thank Vasili K. Semenov, Alex F. Kirichenko, Marc A. Manheimer, and D. Scott Holmes for useful discussions, Scott Zarr and Corey Stull for help in the SFQ5ee process development.
