14. ABSTRACT

The overall goal of the project was to gain an overview of the PFAS problem within representative DoD sites by performing detailed, systematic investigations on the nature and extent of PFAS contamination at three sites. The purpose was to develop improved general Conceptual Site Models that site managers can use to inform cost-effective PFAS management decisions across the DoD portfolio of PFAS-impacted sites. As part of this objective, this project also aimed to provide verification of PFAS fate and transport processes that have been increasingly documented in controlled lab settings but have yet to be comprehensively investigated at field scale.

High-resolution characterization field efforts, along with state-of-the-art analytical methods provided a detailed and unique set of results for three sites: i) NAS Jacksonville, FL; ii) NBVC Pt. Mugu, CA; and iii) NALF Fentress, VA. The spatial patterns in PFAS data were used to develop a Conceptual Site Model for each of the three sites that identifies the relevant transport processes, the potential for migration, and active natural attenuation mechanisms at the site. This can include retardation due to various mechanisms, as well as biodegradation of polyfluorinated compounds which may serve as precursors to PFAAs.

The results showed that PFAS distribution within the source area and downgradient plume reflected site conditions such as soil parameters, as well as expected fate and transport processes. Mechanisms such as retardation due to the

partitioning of PFAS to solid-phase surfaces from hydrophobic and electrostatic interactions were consistently observed, along with slow advection and diffusion into shallow lower-permeability soils. For example, at NAS Jacksonville, these processes were particularly evident for zwitterionic/cationic precursors, which were strongly retained within source area soils with low permeability. Here, the groundwater plume was largely comprised of PFAAs, and the presence of intermediates of suspected biotransformation pathways confirmed that this mechanism was active within the plume. At NBVC Pt. Mugu, retention within the source area could also be attributed to enhanced electrostatic interactions due to the presence of high salinity groundwater. At NALF Fentress, PFAS concentrations were generally highest in shallow unsaturated soils within the source area and then decreased with depth and distance downgradient. This retention could be partially attributed to the enhanced partitioning of PFAS at the air-water interface within the vadose zone. Collectively, these processes contribute to attenuation of PFAS concentrations moving away from the source, with decreases in concentration of several orders of magnitude observed between the source area and the farthest downgradient locations. Given that the approach used during this project is data intensive, costs associated with a similar level of effort at another site would be expected to be several hundred thousand dollars.

ABSTRACT

Introduction and Objectives: The overall goal of the project was to gain an overview of the PFAS problem within representative DoD sites by performing detailed, systematic investigations on the nature and extent of PFAS impacts at three sites. The purpose was to develop improved general Conceptual Site Models that site managers can use to inform cost-effective PFAS management decisions across the DoD portfolio of PFAS-impacted sites. As part of this objective, this project also aimed to provide verification of PFAS fate and transport processes that have been increasingly documented in controlled lab settings but have yet to be comprehensively investigated at field scale.

Technology Description: High-resolution characterization field efforts, along with state-of-the-art analytical methods provided a detailed and unique set of results for three sites: i) NAS Jacksonville, FL; ii) NBVC Pt. Mugu, CA; and iii) NALF Fentress, VA. The spatial patterns in PFAS data were used to develop a Conceptual Site Model for each of the three sites that identifies the relevant transport processes, the potential for migration, and active natural attenuation mechanisms at the site. This can include retardation due to various mechanisms, as well as biodegradation of polyfluorinated compounds which may serve as precursors to PFAAs.

Performance and Cost Assessment: The results showed that PFAS distribution within the source area and downgradient plume reflected site conditions such as soil parameters, as well as expected fate and transport processes. Mechanisms such as retardation due to the partitioning of PFAS to solid-phase surfaces from hydrophobic and electrostatic interactions were consistently observed, along with slow advection and diffusion into shallow lower-permeability soils. For example, at NAS Jacksonville, these processes were particularly evident for zwitterionic/cationic precursors, which were strongly retained within source area soils with low permeability. Here, the groundwater plume was largely comprised of PFAAs, and the presence of intermediates of suspected biotransformation pathways confirmed that this mechanism was active within the plume. At NBVC Pt. Mugu, retention within the source area could also be attributed to enhanced electrostatic interactions due to the presence of high salinity groundwater. At NALF Fentress, PFAS concentrations were generally highest in shallow unsaturated soils within the source area and then decreased with depth and distance downgradient. This retention could be partially attributed to the enhanced partitioning of PFAS at the air-water interface within the vadose zone. Collectively, these processes contribute to attenuation of PFAS concentrations moving away from the source, with decreases in concentration of several orders of magnitude observed between the source area and the farthest downgradient locations. Given that the approach used during this project is data intensive, costs associated with a similar level of effort at another site would be expected to be several hundred thousand dollars.

Implementation Issues: No major procurement or permitting issues are anticipated. This approach can be implemented with standard field equipment but may require specialty analytical lab services. Some data (e.g., non-target analytes) may not be applicable to compliance programs.

Publications: Three published papers that were directly or partially funded by this project: 1) Nickerson et al., 2020) ("Enhanced extraction of AFFF-associated PFASs from source zone soils", ES&T); 2) Nickerson et al., 2020 ("Spatial trends of anionic, zwitterionic, and cationic PFASs at an AFFF-impacted site", ES&T); 3) Adamson et al., 2020 ("Mass-Based, Field-Scale Demonstration of PFAS Retention within AFFF-Associated Source Areas", ES&T). Two

manuscripts are currently in preparation: 1) Comparison of relevant processes impacting PFAS fate and transport; and 2) Modeling of PFAS plume behavior over time.

EXECUTIVE SUMMARY

E.1 INTRODUCTION

This study was conducted as part of project ER-201633 *The Characterization and Nature of Per- and Polyfluoroalkyl Substances (PFAS) in Environmental Media at DoD Site for Informed Decision-Making*. This project was performed in collaboration with Environmental Security Technology Certification Program (ESTCP) and the Naval Facilities Engineering Command (NAVFAC), along with GSI Environmental Inc. (GSI), Oregon State University (OSU), Colorado School of Mines (CSM), and University of Notre Dame (UND). The following summarizes the approach and key results of the project.

E.2 OBJECTIVES

The overall goal of the project was to gain an overview of the PFAS problem within representative DoD sites and to perform detailed, systematic investigations on the nature and extent of PFAS impacts at three sites for the purpose of developing improved general Conceptual Site Models that DoD site managers can use to develop cost-effective PFAS management strategies across the DoD portfolio. In part, this project also aimed to provide verification of PFAS fate and transport processes that have been increasingly documented in controlled lab settings but have yet to be comprehensively investigated at field scale.

To achieve these goals, the following technical objectives were addressed:

1) Conduct state-of-the art, high-spatial resolution sampling at three DoD firefighter-training areas, or areas where AFFF was known to have been used in quantity, and to apply state-of-the-art analytical techniques for the determination of total fluorine in groundwater and individual PFAS in soil, sediment, groundwater, and surface water.
2) Conduct in-depth spatial analysis of data on total fluorine and individual PFAS to delineate plume boundaries, identify source zones, differentiate sources, and to estimate field retardation factors and in-situ transformation rates.

The primary tasks that were performed to meet the objectives of the project, as follows:

- Task 1: Development of an overall Demonstration Plan (as well as site-specific plans) by leads from NAVFAC and GSI;
- Task 2: Detailed field investigations were conducted by GSI, with lab analyses performed by Colorado School of Mines, University of Notre Dame, Oregon State University, and a commercial laboratory.
- Task 3: Data analysis, interpretation, and development of PFAS conceptual models by the entire team.
- Task 4: Reporting and technology transition.

E.3 TECHNOLOGY DESCRIPTION

This project focused on combining several high-resolution approaches and implementing these methods at three DoD site with known PFAS detections:

- Site 1: NAS Jacksonville FL
- Site 2: NBVC Pt. Mugu
- Site 3: NALF Fentress, VA

Each field program was designed to collect high-resolution groundwater and soil data. Specific sampling methodology used during this project involved:

1) High-resolution vertical stratigraphic profiling;
2) Depth-discrete collection of groundwater samples; and
3) Depth-discrete collection of soil samples.

Specifically, multiple locations were characterized at each site with the focus on source areas, several downgradient locations, and a minimum of one upgradient (background) location. The following analyses were completed on groundwater and/or soil samples collected during the field program:

- ***PFASs***. Aqueous-phase samples were primarily analyzed for PFAS at Oregon State University using a combination of LC-MS-MS and LC-QTOF-MS in both ESI- and ESI+ modes. This detailed PFAS analysis of groundwater by OSU can determine the distribution and concentrations of hundreds of individual PFASs. All analyses of solid-phase samples for PFAS were completed at Colorado School of Mines using LC-QTOF-MS in both ESI- and ESI+ modes with appropriate dilutions. The PFAS analyte list was designed to be as similar as possible to that performed for groundwater at OSU. The method quantifies all the analytes listed in US EPA Method 537 and the latest DoD QSM list (40 as of the date of this report) but expands beyond this list by including a wider range of homologs and unique chemistries. The absence of appropriate stable isotope surrogate and internal standards precluded quantitative analyses of some compounds. Specifically, non-target analysis was performed on all samples to determine if a larger set of compounds (identified through suspect screening) were present, along with an estimated concentration for each.
- ***Total Fluorine.*** A state-of-the-art analytical method for Total Fluorine was employed by the University of Notre Dame. The PIGE (Particle Induced Gamma-ray Emission) spectroscopy method has the potential to be a cost-effective method of using total fluorine to guide characterization locations for more expensive analysis for individual PFASs. This analysis was primarily used for groundwater samples but a subset of soil extracts were also analyzed.
- ***Field Parameters, Volatile Organic Compounds (VOCs) + methane***. Groundwater field parameters such as pH, redox, temperature, electrical conductivity, and dissolved oxygen were obtained using a YSI probe (or similar) in the field and recorded on designated field forms. VOCs via EPA Method 8260B were analyzed in a subset of groundwater samples by a commercial lab, and a subset of groundwater samples were analyzed for methane via EPA Method RSK-175.
- ***Fraction of Organic Carbon and Cation Exchange Capacity***. Total organic carbon via EPA Method 9060A were analyzed in a subset of soil samples by a commercial lab. Cation exchange capacity via EPA Method 9081 were also analyzed in a subset of soil samples by a commercial lab.

E.4 OVERVIEW OF RESULTS

The following graphical representations of the Conceptual Site Models for the three field sites were based on data collected during this project.

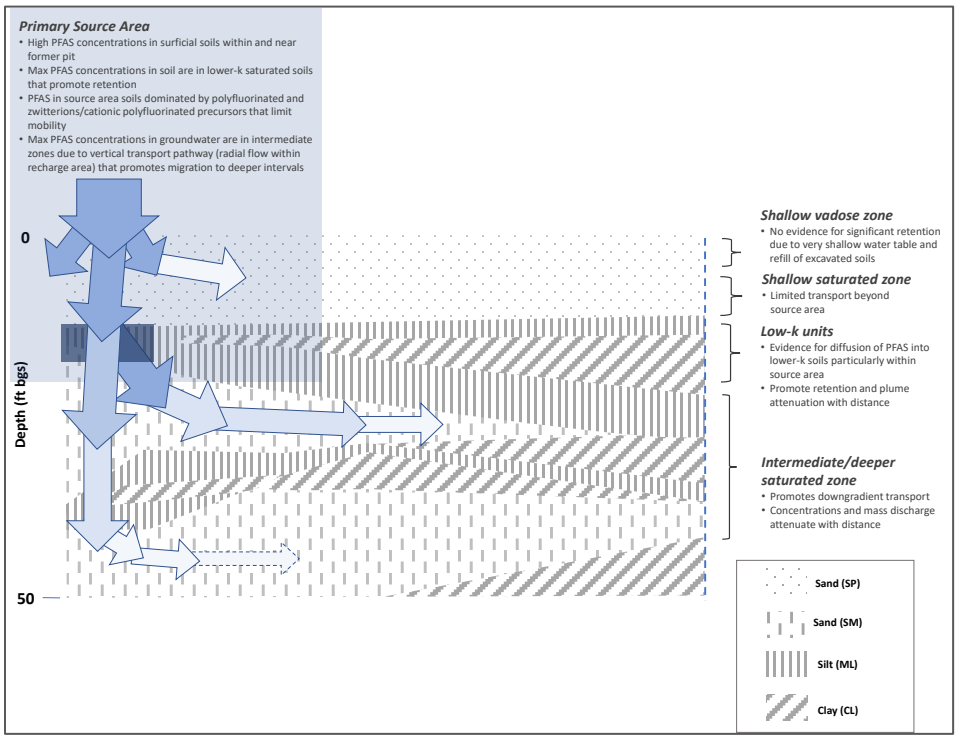

Figure E-1. Conceptual Site Model for NAS Jacksonville Site. *Shows representative cross section (A-A'; approximatley 920 ft), with groundater flow direction from left to right (northeasterly).*

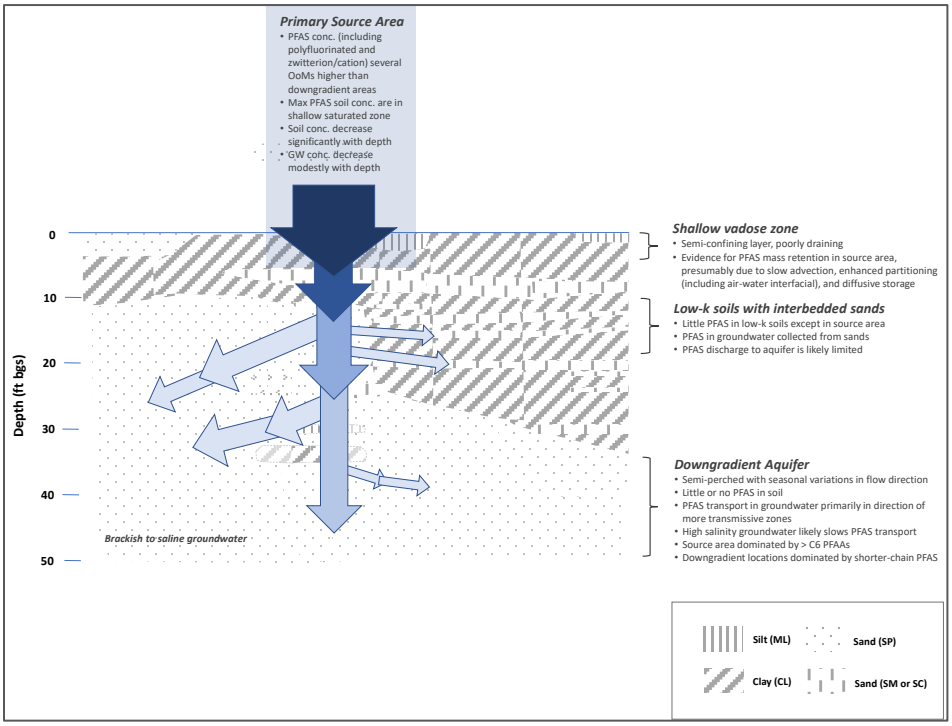

Figure E-2. Conceptual Site Model for PFAS Source and Fate and Transport at Pt. Mugu. *Shows representative cross section (A-A'; approximatley 3400 ft), with groundater flow direction varying seasonally from southwesterly (right to left) to northeasterly (left to right).*

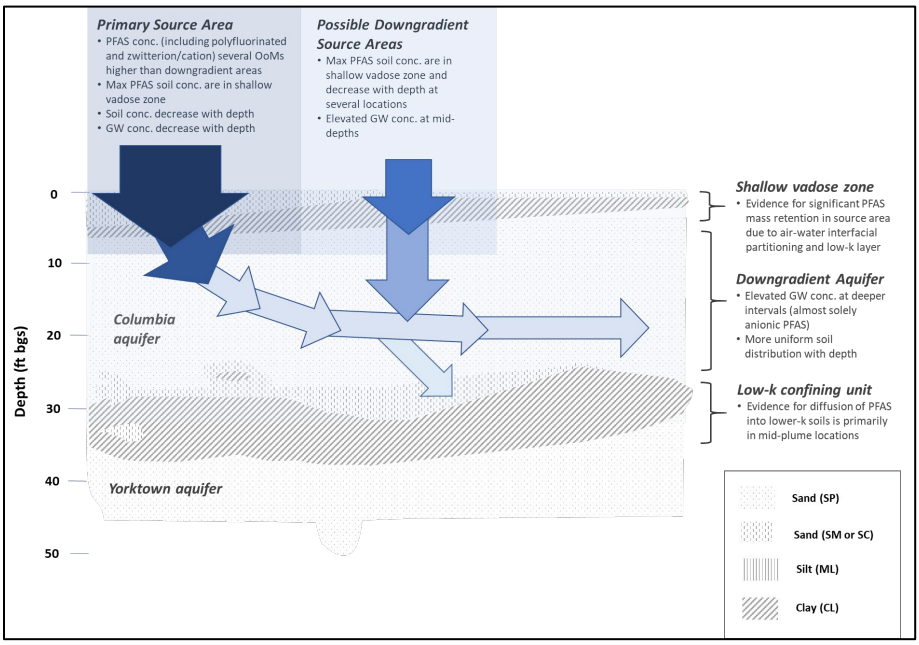

Figure E-3. Conceptual Site Model for PFAS Source and Fate and Transport at NALF Fentress. *Shows representative cross section (A-A'; approximatley 1480 ft), with groundater flow direction from left to right (easterly).*

E.5 PERFORMANCE ASSESSMENT

Presence of Source Zones

The project objective of high-resolution spatial characterization of PFAS was completed, with the overall goal of establishing the PFAS distribution and compositional differences associated with the source zone vs. downgradient locations.

Site 1: NAS Jacksonville, FL

A representative average carbon chain length for all PFAS at each location was estimated by weighting the concentration of individual PFAS. As expected, the PFAS chain length generally decreased with distance from the source due to preferential sorption (retardation) of longer-chain compounds, but these chain length differences could not be established as statistically significant. In part, this reflects the relatively narrow range of representative carbon chain lengths at these site locations (all were between 5.8 and 6.8). The concentrations of zwitterionic/cationic PFAS were higher in the source area than at downgradient locations, and this difference was statistically significant ($p=0.01$). These compounds are expected to be more strongly retained within the source area due to favorable electrostatic interactions, and this was confirmed by the data.

In addition, a number of other lines of evidence (discussed in detail in Section 5.7.2) confirmed that the former firefighter training area was serving as the primary PFAS source area, including: 1) highest total PFAS concentrations in both soil and groundwater were found in the immediate vicinity of the former firefighter training area; 2) highest PFAS concentrations in surficial soils were observed within the same general area; 3) relative abundance of PFAS precursors within source area; 4) usage of ECF-based AFFF based on site history and high concentration of PFOS typically at or above expected branching percentage; 5) usage of telomer-based AFFF based on

abundance of fluorotelomer substances and low PFOA branching percentages; and 6) PFAS concentrations decrease rapidly in the direction of groundwater flow.

Site 2: NBVC Pt. Mugu, CA

At this site, the PFAS chain length decreased with distance from the source (firefighter training facility) due to preferential sorption (retardation) of longer-chained compounds, and the difference between source vs. far downgradient locations was statistically significant. The range for these representative carbon chain lengths were between 4.7 and 6.2 at this site. Based on aggregated data, the concentrations of zwitterionic/cationic PFAS were higher in the source area than at downgradient locations, and the results were statistically significant ($p=0.001$). For example, the shallow unsaturated soil sample from location L5 exhibited the highest concentration of zwitterionic/cationic PFAS (1,013 ng/g). In addition, zwitterionic and cationic PFAS were largely absent from site groundwater. When coupled with several other site-specific lines of evidence (discussed in detail in Section 5.7.3), the former firefighter training area was serving as the primary PFAS source area at this site.

Site 3: NALF Fentress

The PFAS chain length generally decreased with distance from the source due to preferential sorption (retardation) of longer-chained compounds, and the shortest representative value (5.86) was observed in the farthest downgradient location. However, these chain length differences could not be established as statistically significant. This site had the highest chain length values within the source and near source area (7.00 – 7.03) of any of the three sites that were investigated as part of this project. The percentage of zwitterionic/cationic PFAS could not be established as higher in the source area than at downgradient locations. In part, this reflects the relatively low concentrations of these charged compounds in downgradient locations, particularly in groundwater. Like the other sites, the highest concentrations of zwitterionic/cationic PFAS were consistently measured in the source area at this site, particularly within shallow soils. However, a distinguishing characteristic at this site was data showing relatively high PFAS concentrations, including zwitterionic/cationic compounds, in shallow soils at mid-plume locations. These results suggest that surface releases and/or runoff of AFFF at downgradient locations may be serving as a secondary source of PFAS to groundwater. Regardless, the preponderance of data indicates the AFFF Storage and Transfer Area was the primary PFAS source area at this site, as detailed in Section 5.7.4

Differentiate AFFF and Non-AFFF Sources

The distributions of PFAS in groundwater and soil from the suspected source area were compared to those in locations where historic AFFF use is not suspected based on the site history. This evaluation provides information on the nature of PFAS sources at DoD sites, as well as concentrations and compounds potentially associated with background PFAS sources (that may impact source and plume delineation efforts).

Site 1: NAS Jacksonville, FL

PCA results demonstrated that PFAS composition in samples from specific source area locations (Location 3) formed a distinct group that was different from those formed by the two background locations (Locations 16 and 17). The presence of zwitterionic/cationic PFAS in the source area

and relative absence of zwitterionic/cationic PFAS in background locations serves as a secondary line of evidence for differentiating between the AFFF source and other diffuse sources. Specifically, this provides further evidence that the PFAS present in these locations derives from a non-AFFF source, potentially through a different application or transport route.

As described in detail in Section 5.7.2, PFAS compositional data and isomer branching patterns are consistent with the use of both ECF-based foams as well as telomer-based foams in the source area. Background locations were dominated by non-PFAAs compounds in both soil and groundwater, and compounds identified during non-target analysis that were unique to the background locations included several longer-chain hydrido-perfluorosulfonates in soil (e.g., H-PFPeDA, H-PFTeDA, H-PFTrDA). The presence of these compounds suggests that other PFAS sources may have contributed to the observed PFAS in the background locations, though a source cannot be readily identified. Compounds that have been proposed to be largely associated with non-AFFF sources such as shorter chain fluorotelomer intermediates that have been proposed to be diagnostic of landfill leachate (e.g., 5:3 FTCA for landfill; MeFOSA and EtFOSA for industrial/commercial products) were generally not detected in soil and groundwater from any location. In addition, the variability in PFAS compositions observed at individual locations or within proximate areas (as reflected in the low amount of variability that could be described by PC1+PC2 during PCA) would complicate assigning the PFAS from background locations to any specific non-AFFF source.

Site 2: NBVC Pt. Mugu

The data collected at this site suggested that the PFAS signatures in samples from the background locations may be different than those in the primary source area. However, the data do not provide strong evidence that the PFAS at these locations would have derived from non-AFFF sources. The PCA results generally showed that data from background locations clustered within a tight confidence interval, although the boundaries still overlapped with those that were based on data from the source area. The two background locations were located cross gradient to groundwater flow but relatively near (800 ft) to the farthest downgradient location. As a result, PFAS from AFFF releases in the firefighter training pits could have been the primary or sole contributor to the observed PFAS in the study area. Background locations were dominated by non-PFAAs compounds in both soil and groundwater, though they were largely similar to those detected in the source area groundwater. Compounds that were unique to the background locations were non-target analytes, including several longer-chain hydrido-perfluorosulfonates in soil (e.g., H-PFPeDA, H-PFTeDA, H-PFTrDA). Like the other sites investigated as part of this project, there was little or no contribution from compounds that are generally considered indicative of non-AFFF PFAS sources (e.g., 5:3 FTCA, MeFOSA, EtFOSA) at these background locations.

The PCA results also established that there was overlap between source area data and the data from near source and both downgradient directions, which supports that these areas represent similar PFAS sources, even accounting for transport-related compositional shifts. There were several other lines of evidence confirming that the former firefighter training area was the primary source of PFAS at this site, including the use of both ECF-based AFFF and telomer-based AFFF.

Site 3: NALF Fentress

At this site, the PCA results showed a clear distinction between specific source area locations and the two background locations, with no overlap in the confidence intervals. These analyses also suggest that the PFAS present in surface soils located downgradient of the AFFF Storage and Transfer Area are also highly similar in composition to those in the primary source area and thus likely associated with AFFF usage. There were several other lines of evidence that indicate usage of both ECF-based AFFF and telomer-based AFFF were the primary sources of PFAS in the source area locations and downgradient, and that these were not directly contributing to PFAS observed in background locations.

PFAS was detected at up to 900 ng/kg and 16,000 ng/L in soil and groundwater samples from the background locations. PFOS was absent in all soil samples and all but one groundwater sample from these locations. Compounds unique to the background locations were detected in groundwater samples but several unique compounds were detected in soil samples (e.g., UPFOS, H-PFPeA). The presence of these compounds suggests that alternative PFAS sources may have contributed to the observed PFAS at background locations, although a source could not be readily identified. No other known or suspected sources of PFAS were reported in site documentation, and compounds indicative of non-AFFF source (e.g., 5:3 FTCA, MeFOSA, EtFOSA) were detected only sporadically and only at trace levels.

PIGE as a Cost-Effective Guidance Tool

PIGE analysis was completed by the University of Notre Dame on the majority of aqueous samples and a subset of soil samples to determine how the total fluorine measurements generated by the method compare to the total PFAS concentrations generated by LC-MS/MS. While the latter method quantifies (targeted compounds) and semi-quantifies (non-targeted compounds) individual PFAS and thus can be used forensically, PIGE has the potential to provide a quick, low-cost option to understand relative PFAS levels at a site, including the sum of targeted and non-targeted compounds. However, contributions from inorganic fluorine may confound results where PFAS concentrations are low.

Site 1: NAS Jacksonville, FL

Using data from 43 aqueous samples, the PIGE results showed that there was a statistically significant relationship with the LC-MS/MS data based on the non-parametric test results, but linear regression yielded an r^2 value (0.57) that was slightly below the selected performance threshold. In part, this was due to non-linear distribution of the data, particularly at the lower-end PFAS concentrations where PIGE appeared to provide less resolution. These data suggest that PIGE provides a reasonable indication of the relative PFAS levels in these groundwater samples but may be better suited as a screening tool to characterizing higher-concentration areas (i.e., source zones).

Site 2: NBVC Pt. Mugu

At this site, there was sufficient data to evaluate correlations between PIGE groundwater data and LC-MS/MS measurements of total PFAS in groundwater as well as in co-located soil samples. In both cases, a statistically significant relationship could be established using the non-parametric test. This is consistent with the expectation that soil and groundwater PFAS concentrations in co-

located samples should be similar, such that PIGE results would demonstrate some similarity to soil result despite the different matrices being analyzed. However, only the groundwater datasets demonstrated a correlation that was strong enough to meet the success criteria ($r^2 > 0.7$ from linear regression). The correlation coefficient between PIGE and soil data was low (0.13), such that the ability to actually predict soil concentration using PIGE appears to be low. There were a number of samples where PIGE did not detect PFAS even though the total PFAS through the higher-resolution techniques was greater than 4000 ng/L in all samples. This was a result of the high limit of quantification for PIGE at this site (approximately 5,000 ng/L) which was influenced by the high ionic strength of the groundwater. These data provide confirmation that PIGE is likely better suited for source area characterization efforts at sites where the water is not highly saline.

Site 3: NALF Fentress

A statistically significant relationship between the PIGE groundwater data and the LC-MS/MS groundwater was established at this site using Spearman's Correlation test. Linear regression also resulted in a high r^2 value that met the success criterion. In addition, there were no false negatives using PIGE. At this site, the correlation in lower-end range of concentrations (1000 to 100,000 ng/L) was relatively strong and likely to provide more predictive value than the higher-end range of concentrations. This is because one PIGE-based measurement was several orders of magnitude higher than any other measurements, such that it may not be representative. Regardless, the correlation was reasonable within a concentration range that might be expected within a source area.

Evidence of Natural Attenuation

PFAS compositional data were generated, and spatial patterns were used to provide both qualitative and quantitative evidence for active natural attenuation mechanisms at the site. This includes retardation due to sorption, as well as biodegradation and transformation of polyfluorinated precursors.

Site 1: NAS Jacksonville, FL

Soil adsorption coefficients and retardation factors were calculated for key PFAAs using co-located soil and groundwater data. Overall, values of K_d varied significantly with distance, both with depth and distance downgradient. Additionally, K_d values generally increased with increasing PFAS chain length and were higher for PFSAs than PFCAs, as expected. Retardation factors by soil type were between 1.7 and 10.4, and even shorter-chain PFAAs like PFBA and PFBS exhibited values that were consistently above 2.0. For most PFAAs, a positive correlation between K_d and organic carbon could be established, indicating the importance of hydrophobic sorption as a mechanism for retardation. Little effect was observed for pH or EC, suggesting that partitioning due to electrostatic interactions may have been limited relative to hydrophobic sorption at this site. In contrast to the expected inverse relationship, cation exchange capacity (CEC) was positively correlated with K_d, but this is likely due to the increased organic carbon associated with soils with higher CEC.

The relevance of various retention mechanisms was established at this site, including the higher contribution of less mobile cationic/zwitterionic species to the total PFAS measured in the source area relative to downgradient areas. Matrix diffusion was also confirmed to be a key process at

this site, with high concentrations of PFAS present in soils with relatively limited permeability. This contributed to decreases in the PFAS mass discharge with distance from the source.

Confirmation that precursor transformation was occurring at this site was based on several lines of evidence, including trends in the percentage of PFAA end-products relative to other PFAS, with the assumption that the latter group represents all potential precursors. If biodegradation of precursors was occurring, the percentage of PFAA end-products would be expected to increase moving downgradient from the source area, which was observed. The percentage of degradation end-products (i.e., PFAAs) relative to precursors is higher in the groundwater samples from downgradient locations relative to both groundwater and soil samples from the source area. Additionally, suspected biodegradation intermediates (e.g., Spr-FHxSA) have been identified in downgradient samples that are absent from source area samples. There are several other lines of evidence for biodegradation, including the identification of specific biodegradation intermediates and high concentrations of intermediates (e.g., fluorotelomer sulfonates) that are not known to be present in large quantities in AFFF sources.

Note that the dataset from this site was part of parallel study that performed a PFAS mass balance across the site (Adamson et al., 2020). That evaluation established that PFAS precursors were being converted to PFAAs at an annual rate of 2% or less, and that the relative contribution from precursors on a mass basis was decreasing with distance from the source.

Site 2: NBVC Pt. Mugu

Soil adsorption coefficients and retardation factors were calculated for key PFAAs. As expected, K_d values generally increased with increasing PFAS chain length and were higher for PFSAs than PFCAs. Retardation factors ranged from 1.7 to 46 for the various PFAS, confirming significant retardation relative to the seepage velocity for groundwater at the site. Soil adsorption was generally greater in sands (SP) as compared to clays (CL) for the key PFAAs, presumably due to the lower CEC of these soils. This trend indicated that electrostatic forces were a significant factor contributing to the adsorption onto sands compared to hydrophobic forces. Similarly, trends of f_{oc} and other anions detected in groundwater (e.g., chloride, fluoride, sulfate), indicated that groundwater collected in clayey soils typically had significantly higher concentrations of other anions, despite these soils also having greater f_{oc} values as compared to sands. As such, the high salinity of this site likely influenced adsorption due to electrostatic processes. It should be noted that only a limited number of groundwater samples from clayey soils could be obtained.

The high salinity and the abundance of lower-permeability soils apparently contributed to significant attenuation of PFAS concentrations that were observed with distance from the source area. In addition, the relatively high concentrations in shallow unsaturated soils provided evidence for vadose zone retention due to air-water interfacial sorption. Despite these factors, total PFAS concentration remain well above 1000 ng/L across the site.

Site 3: NALF Fentress

Like the other two sites, retardation factors for key PFAAs estimated at this site generally increased with increasing chain length and were greater for PFSAs than PFCAs. One exception was an anomalously high R of 48 for PFPeA in sands. The retardation factors for the remaining compounds ranged from 1.8 to 18. Given that these estimates are based on a relatively limited

number of co-located samples where compounds were detected in both matrices (soil and groundwater), some anomalous values can be expected. At this site, the limited number of K_d values meant it was not possible to establish correlations with other site characteristics such as soil organic carbon. The K_d values for sands were generally higher than those for clays despite the higher f_{oc} values for the latter soil type. While the dataset is small, this suggests that electrostatic interactions are playing a major role in the observed partitioning patterns. The retardation factors also indicate that the PFAAs are moving at a slower rate than site groundwater. In particular, retention within the vadose zone due to air-water interfacial partitioning was evident based on vertical profiling that showed that PFAS concentrations decreased significantly between shallow unsaturated soils and the top of the saturated zone.

The compositional data also support the assumption that in situ transformation of PFAS has occurred at this site. Several suspected transformation intermediates (e.g., fluorotelomer sulfonates, FHxSA) were observed at increasing relative concentrations moving away from the source. In contrast, precursors to these intermediates were detected primarily in the source area. The source area location with the highest total PFAS concentrations also had the highest precursor concentrations, including three unsaturated soil samples that exhibited the highest precursor concentrations measured across the site. The majority of these precursors were anionic, but their relative abundance in the source area is consistent with retention in the vadose zone due to air-water interfacial partitioning, along with slow transformation to other intermediates and PFAAs that may be more readily transported.

E.6 COST ASSESSMENT

The costs of implementing this technology are a function of the level of characterization performed at a site. The key cost drivers are the number of locations characterized per site, and the number of soil and groundwater samples collected per location. For example, this demonstration included high-resolution characterization at up to 11 locations per site. For a site with unconsolidated water-bearing unit that could be characterized using direct push methods (e.g., total depth < 40 ft bgs), it is estimated that collecting 60 depth-discrete groundwater samples and 120 soil samples would provide sufficient resolution. Costs for this type of effort would be on the order of $350,000. This cost estimate assumes that analysis would be performed by a commercial lab and necessitate the use of an assay to measure precursors and other non-targeted PFAS such as TOF or TOP if non-target MS analysis is not possible.

E.7 IMPLEMENTATION ISSUES

Methods for obtaining samples are relatively conventional and unlikely to be subject to additional regulatory oversight or permitting other than those associated with standard site investigations. Investigation-derived waste disposal may require special attention to account for the presence of PFAS. In this project, academic research labs provided innovative high-resolution analytical capabilities for both soil and groundwater. This included analysis of a large suite of PFAS (including non-target analytes) that are otherwise not commercially available at this time. To evaluate this large suite of analytes at a generic site, a research lab would need to be identified that could provide a similar level of high-resolution data capabilities, although it is anticipated that commercial laboratories would also be able to provide this service in the near future. In lieu of this, an assay measuring total organofluorine such as TOF, or an estimate of total oxidizable

precursors (TOP) can provide an estimation of the total PFAS mass at a site. Since none of these methods – high resolution (including non-targeted analytes) LC-MS/MS (or LC-QTOF/MS), TOF or TOP - is currently a method available from any NELAP-accredited laboratory, the use of such non-accredited methods is currently in the realm of research projects only. Further, high resolution MS analytical methods are currently costly to implement, particularly for a large amount of soil and groundwater samples. DoD Environmental Restoration projects use methods that have been approved by USEPA and that meet DoD QSM requirements (and are provided by NELAP-accredited laboratories) meaning that analyses would be performed by commercial labs with the more limited, targeted, analyte list. Consequently, some loss in data resolution should be expected when using only standard methods. Therefore, this approach may be of greatest value where data collection can be considered a research effort until such time standard methods are published and offered as NELAP-accredited laboratory methods for targeted compounds for which standards are readily available. Finally, PIGE analysis has high quantitation limits in the configuration used in this project, especially in areas where the water composition indicates high TDS or salinity. This may be a shortcoming with respect to the application of PIGE with variable geochemical composition, though as PIGE sample preparation methods are refined these limitations can likely be overcome.

1.0 INTRODUCTION

This Final Report summarizes the approach and results of project ER-201633 *The Characterization and Nature of Per- and Polyfluoroalkyl Substances (PFAS) in Environmental Media at DoD Site for Informed Decision-Making*. This project was performed in collaboration with Environmental Security Technology Certification Program (ESTCP) and the Naval Facilities Engineering Command (NAVFAC), along with GSI Environmental Inc. (GSI), Oregon State University (OSU), Colorado School of Mines (CSM), and University of Notre Dame (UND).

1.1 BACKGROUND

Per- and polyfluoroalkyl substances (PFAS) are anthropogenic chemicals that contain highly fluorinated carbon chains. The carbon-fluorine bond is among the strongest known chemical bonds, which confers an unusually high degree of stability to PFAS. This stability, along with some unusual chemical properties (such as being both hydrophobic – water repelling, and oleophobic – oil repelling) makes PFASs uniquely suited for a wide variety of applications, including textile water and stain repellants, non-stick coatings, and aqueous film forming foam (AFFF) used for fighting hydrocarbon-based fuel fires (Class B fires). Their widespread use in industrial processes and products, as well as consumer products, has made them ubiquitous throughout the world, including human blood, tissue, and breast milk. Due to their stability, perfluorinated forms persist for long times in the environment, and the longer-chain forms (e.g., C8) can bioaccumulate in animals.

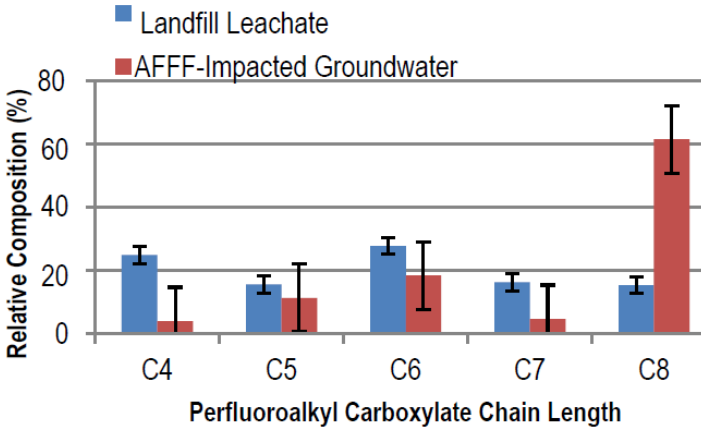

Figure 1-1. Similar distributions of C4-C8 perfluoroalkyl carboxylates in landfill leachates and AFFF-impacted groundwater.

Because of their ubiquity, persistence, and potential toxicity, some PFAS are designated as emerging chemicals by the Department of Defense (DoD). Historically, the DoD regularly trained with PFAS-based AFFF in fire-fighter training exercises and used PFAS to extinguish fires. This practice resulted in releases of PFAS to the environment and levels of PFOA and PFOS in groundwater that, in some cases, exceed the United States Environmental Agency's health advisory levels (70 ng/L combined) by several orders of magnitude. Further, because of their persistence and widespread use in other applications, PFASs have "background" concentrations in most environmental media and biological tissues, in both urban and remote areas (Ahrens, 2011; Brusseau et al., 2020). This complicates the determination of AFFF-based PFAS plume boundaries, particularly as other point sources of PFASs (i.e., landfills, wastewater treatment plants, etc.) are often in close proximity to many DoD installations. Finally, because some PFAS are very mobile, while others are considerably less mobile, there is the potential for continual release from source zones, an issue that has not, to date,

been adequately addressed for AFFF-impacted sites: if such source areas contribute to plumes, it is necessary to identify and remediate these areas as well as to identify mitigation strategies for plumes that emanate from these source areas.

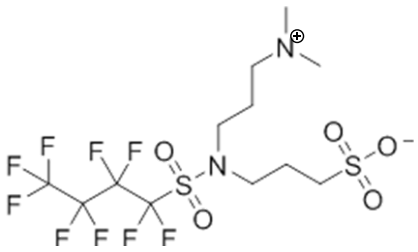

Figure 1-2. Zwitterionic polyfluorinated substances found in NAS Jacksonville groundwater.

For the purposes of characterizing or "fingerprinting" sources of PFAS impacts, a broader suite of PFAS analytes must be analyzed, including those that are unique to AFFF. Identification of additional PFASs when combined with what is currently known about aerobic (Yamada et al., 2005; Zhang et al., 2020) and anaerobic (Yi et al., 2014) transformation pathways will further elucidate the nature and extent of PFAS, thus leading to a more comprehensive management approach at DoD sites.

An early (pre-project) application of these analytical tools to groundwater from NAS Jacksonville revealed a zwitterionic substance that can only be attributed to 3M AFFFs (Figure 1-2): these chemicals are not likely to be derived from other PFAS sources (i.e., landfill leachate). Despite a molecular weight exceeding that of PFOS or PFOA, zwitterionic chemicals are likely to be readily transported due to the anionic moieties that impart water solubility. In addition, GAC systems optimized for PFOA and PFOS removal would not necessarily effectively capture this zwitterionic chemical due to its significantly greater water solubility. Understanding the chemical nature of the highly water-soluble PFASs in groundwater is essential for designing effective systems for treating potential drinking water sources for base and civilian populations.

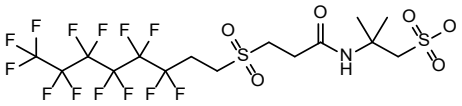

Figure 1-3. Biodegradation intermediate of polyfluorinated substance in Ansul AFFF (oxidized sulfoxide - center S atom) in NAS Jacksonville groundwater.

A potential transformation product (Figure 1-3) (Harding-Marjanovic et al., 2015) of the active ingredient in Ansul AFFF also was found in NAS Jacksonville groundwater. The presence of this chemical form may signal that *in situ* transformation is occurring. When combined with firefighter-training records and site hydrology, documenting the spatial trends in biodegradation intermediates will assist in determining the extent to which conversion of PFAS to terminal perfluorinated species has already occurred and to estimate rates. Transformation rates are critical to estimate how long PFAS residues will persist at sites. The chemical forms shown in Figures 1-2 and 1-3 are examples of the polyfluorinated compounds that can account for part of the missing mass identified by higher-resolution analytical methods. Monitoring for only a small fraction of known PFAS may lead to inaccurate Conceptual Site Models and misidentification of sources.

1.2 OBJECTIVE OF THE DEMONSTRATION

The overall goal of the project was to gain an overview of the PFAS problem within a "typical" DoD site and to perform detailed, systematic investigations on the nature and extent of PFAS impacts at three sites for the purpose of developing an improved general Conceptual Site Models and risk guidance that DoD site managers can use to develop cost-effective PFAS management

strategies across the entire DoD complex. In part, this project also aimed to provide verification of PFAS fate and transport processes that have been increasingly documented in controlled lab settings but have yet to be comprehensively investigated at field scale.

To achieve these goals, the following technical objectives were addressed:

1) To conduct state-of-the art, high-spatial resolution sampling at three DoD firefighter-training areas, or areas where AFFF was known to have been used in quantity, and to apply state-of-the-art analytical techniques for the determination of total fluorine in groundwater and individual PFAS in soil, sediment, groundwater, and surface water.

2) To conduct in-depth spatial analysis of data on total fluorine and individual PFAS to delineate plume boundaries, identify source zones, differentiate sources, and to estimate field retardation factors and in-situ transformation rates.

The primary tasks that were performed to meet the objectives of the project, as follows:

- Task 1: Development of an overall Demonstration Plan (as well as site-specific plans) by leads from NAVFAC and GSI;

- Task 2: Detailed field investigations were conducted by GSI, with lab analyses performed by Colorado School of Mines, University of Notre Dame, Oregon State University, and a commercial laboratory.

- Task 3: Data analysis, interpretation, and development of PFAS conceptual models by the entire team.

- Task 4: Reporting and technology transition.

1.3 REGULATORY DRIVERS

The United States Environmental Protection Agency (US EPA) in May 2016 set a non-enforceable health advisory level (HAL) of 70 ng/L for the sum of PFOA and PFOS. While there has been increased focus on developing enforceable federal standards based on regulatory determinations, there are no existing federal regulations enforced by the US EPA for PFAS as of the date of this report. Regardless, the introduction of the HAL has led to individual states to take regulatory actions by initiating or establishing health guidelines to address the emerging issue of PFAS prevalence in drinking water (ITRC 2020). Significant DoD-funded PFAS research and PFAS assessment work at DoD facilities was already underway by the time the US EPA HAL was issued, with the understanding that focused research would aid future characterization efforts (Leeson et al., 2021).

On February 20, 2020, the US EPA proposed a preliminary regulatory determination for PFOA and PFOS (US EPA 2020). On February 22, 2021, the US EPA issued Final Regulatory Determinations for PFOS and PFOA under the Safe Drinking Water Act (SDWA) (US EPA, 2021). This implied that the Agency is deciding whether to start the process to propose and promulgate a national primary drinking water regulation for an unregulated chemical. In addition to issuing the final regulatory determinations for PFOA and PFOS, the EPA also reissued

a proposed rule to address 29 PFAS in the list of unregulated chemicals under the SDWA's Unregulated Contaminant Monitoring Rule (UCMR 5, US EPA 2021).

In addition to the development/establishment of PFAS regulation, the EPA is currently developing toxicity assessments for other PFAS. On April 8, 2021, the US EPA announced the release of the final Human Health Toxicity Values for PFBS while other PFAS such as PFHxA, PFHxS, PFNA, PFDA and HFPO-DA (GenX chemicals) are undergoing toxicity assessment.

Federal and state regulations, public concern, and the prevalence of PFAS in drinking water, groundwater, wastewater, and surface water sources are key drivers for assessment and remediation of PFAS impacts and development of innovative technologies for treatment.

2.0 TECHNOLOGY

2.1 TECHNOLOGY DESCRIPTION

For Task 2, detailed field investigations were conducted at three sites selected from a review of available site data of Navy sites with known PFAS presence in the environment: i) NAS Jacksonville, FL; ii) NBVC Pt. Mugu, CA; and iii) NALF Fentress, VA. Consideration was given to sites that appeared to offer the most potential to delineate plumes, identify source areas, differentiate sources, evaluate PFAS transport and potential transformation, and evaluate surface water impacts if possible.

State-of-the-art analytical methods for total fluorine (Notre Dame) and individual PFAS by liquid chromatography tandem mass spectrometry (LC-MS/MS) (Colorado School of Mines, CSM and Oregon State University, OSU) were applied to demonstrate the cost-effectiveness of total fluorine for guiding well drilling and for prioritizing field samples for LC-MS/MS analysis for individual PFAS. The PIGE (Particle Induced Gamma-ray Emission) spectroscopy method was used by the University of Notre Dame research group to screen all groundwater and surface water samples for total fluorine. High-spatial resolution characterization of the PFAS in soil and groundwater provided a unique dataset on the nature and extent of PFAS impacts at "typical" AFFF-impacted sites (Objective 2).

2.2 TECHNOLOGY DEVELOPMENT

Most published information on AFFF-impacted site characterization efforts have involved a relatively limited scope that focused on a small subset of PFASs. High resolution mass spectrometry (HRMS), specifically liquid chromatography Quadrupole Time of Flight Mass Spectrometry (LC-QTOF-MS), is a valuable method that can provide data on a broader suite of PFAS. This includes semi-quantitative approaches for individual PFAS that do not have commercial standards and PFAS that can be ionized by positive mode electrospray ionization (ESI+). These approaches should help improve quantitative assessments of these compounds' contribution to the total environmental PFAS load (McDonough et al., 2019). In addition, bulk methods for assessing total PFAS have begun to be tested to determine if they provide adequate data for field characterization purposes. This includes total fluorine by particle induced gamma ray emission (PIGE) spectroscopy, which has been used to assess the potential presence of PFAS in a variety of matrices (Ritter et al., 2017).

As noted above, existing site characterization performed to date have included perfluoroalkyl acids (PFAAs) and possibly a few additional fluorotelomer sulfonates, carboxylates, and anionic precursors such as FOSA. Studies that include zwitterions and cations are limited. For example, Mejia-Avendaño el al. (2017) included some cations and zwitterions in analysis of soils from a relatively small number of sampling locations (n=5) that were subjected to a single fluorotelomer AFFF input. Firefighter training areas are subjected to AFFF releases of various formulations over decades-long timeframes. In addition, site characterization data are typically limited to a single matrix (e.g., groundwater) and do not always provide adequate spatial resolution to assess trends with depth or lateral transport. Soils can act as long-term source inputs of PFASs into groundwater, and thus represent an important compartment for understanding source distribution and transport potential.

PFAS fate and transport is a function of site-specific characteristics and release scenarios, but it is also strongly influenced by the wide-ranging physical chemical properties within this class of compounds. One distinguishing characteristic of AFFF-based source areas is that relatively high volumes of PFAS are periodically released at the ground surface compared to other type of PFAS releases. In these cases, the primary influences are the slow rates of advection that occur within the subsurface (relative to surface water or the atmosphere) and the important interactions between PFAS, soil particles, and the air/water present in the pore spaces of the unsaturated and saturated zones. This includes partitioning of PFAS to the air-water interfaces due to the surfactant properties of PFAS, hydrophobic sorption of PFAS to natural organic carbon within soils, and electrostatic interactions between soil particles and PFAS functional groups with varying charges (Anderson et al., 2019; Schaefer et al., 2019; Higgins and Luthy, 2007; Guelfo and Higgins, 2013; Li et al., 2018; Mejia-Avendano et al., 2020; Hellsing et al., 2016; Pereira et al., 2018; Barzen-Hanson et al., 2017; Xiao et al., 2019).

These processes should promote retention of some PFAS within the area where they are released and retard their rate of migration downgradient. PFAS that would be more subject to retention include various zwitterionic and cationic PFAS that are known to be present in AFFF and serve as polyfluorinated precursors to perfluoroalkyl acids (PFAA) due to their enhanced electrostatic attraction to soil particles that are typically negatively charged. Biotransformation may influence the extent that PFAS are retained by converting these precursors to anionic forms that are likely more mobile and (ultimately) more persistent. As a result, the effect of these fate and transport processes on the distribution of PFAS following AFFF releases has significant implications for site-specific decision making, including understanding short-term and long-term exposure risks and/or priorities for site management (e.g., applicability of Monitored Natural Attenuation, Newell et al., 2021a, 2021b).

Most studies have examined the possible relevance of these processes in lab-scale systems under controlled conditions that cannot capture the complexity of field-scale releases. The field-based studies published to-date have primarily relied on comparing groundwater concentration data (and occasionally soil data) from a few locations. The more comprehensive approach employed during this project is valuable for evaluating trends in concentration, composition, isomeric distributions, and potential transformation of specific PFAS. It also provides a clear picture of PFAS distribution and the relative importance of retention mechanisms, including the quantification of the impact of permeability (e.g., sands vs. clays) within an aquifer, which is possible only with extensive soil data.

2.3 ADVANTAGES AND LIMITATIONS OF THE TECHNOLOGY

The technology couples a detailed site characterization with state-of-the-art analytical methods for quantifying PFAS concentrations. The advantages and limitations of this approach should be evaluated in terms of its ease of use, applicability, and the knowledge gained following implementation. Table 2.1 summarizes the advantages and disadvantages within this context.

Steps to minimize cross-contamination were included in the demonstration design. The demonstration involved a relatively passive technology with minimal potential for short-term site disruption or long-term negative impacts on subsurface conditions.

Table 2-1. Advantages and Potential Limitations of the Technology

Advantages	Limitations
Investigation is minimal in footprint and requires no permanent installations	Collection of high-resolution data can be costly at sites with complex geology or deep impacted media
Increased understanding of chemical fate and transport at a site is provided through co-located soil/groundwater samples along distinct transects	High-resolution data from non-commercial (or non-accredited) labs provides high-value insights but may not be suitable for regulatory purposes
State-of-the-art analytical methods for total fluorine via PIGE method and individual PFAS by liquid chromatography tandem mass spectrometry (LC MS/MS) with QTOF provides data that might otherwise be missed through more conventional analyses	PIGE method is relatively new and limited results exist on relationship between total fluorine vs. individual PFAS
Fingerprinting sources, identify source zones, and estimate retardation factors and transformation rates adds to the growing body of literature on site-specific data	Lack of comprehensive understanding of all site activities as well as lack of accurate background levels may result in overlooking other contributing source areas within a site boundary as well as misrepresentation of a source area as part of input into PCA for fingerprinting purposes, resulting in faulty interpretations

3.0 PERFORMANCE OBJECTIVES

For the purposes of evaluating the cost and performance of the field demonstration, the following performance objectives for this phase were addressed (Table 3.1). A full description of the various components of the approach listed in Table 3.1 is provided in Section 5.0 (Test Design).

Table 3-1. Performance Objectives

Performance Objective	Data Requirements	Success Criteria	Performance Objective Met?
Quantitative			
1 Determine presence of source zone(s)	High-resolution spatial PFAS characterization of soil and groundwater at 3 sites Spatial trends in PFAS composition	Using Wilcoxon rank sum test, demonstrate that 1) median and/or average chain length of source soils are longer than groundwater samples in the downgradient locations; 2) concentrations of cationic and zwitterionic PFAS are higher in the source zone soils compared to soils in the downgradient locations.	**Partially** Statistically significant differences observed in data from 2 of 3 sites Multiple additional lines of evidence obtained to support identification of source area at all 3 sites
2 Differentiate AFFF and non-AFFF sources	Compare groundwater and/or soil PFAS composition to background (upgradient) locations	Cluster analysis and/or PCA show differences between source zone composition and concentrations vs. background locations and/or expected non-AFFF PFAS compositions.	**Partially** Distinct clustering with largely non-overlapping PCA confidence intervals at 2 of 3 sites
3 PIGE as cost-effective guidance tool for drilling and plume footprint	Sum of Individual PFASs by LC-MS/MS and total fluorine measurements by PIGE in groundwater samples	Linear regression of datasets from each site yield $r^2 > 0.70$ Statistically significant relationship between site-specific datasets based on Spearman's Correlation test ($p<0.05$)	**Partially** $r^2 > 0.7$ at 2 of 3 sites Significant positive correlation using Spearman's Correlation test ($p<0.05$) at 3 of 3 sites
Qualitative			
4 Natural attenuation - evidence from retardation factors, PFAS fingerprints, and spatial distributions	Spatial trends in PFAS fingerprint Soil/aquifer properties Hydrogeologic factors (direction and velocity of groundwater flow)	Retardation factors estimated for PFAS (charge, C-length, branching) are consistent with aquifer properties and physical-chemical properties Lines of evidence that attenuation mechanisms (e.g., retardation) are relevant (e.g., PFAS concentrations decrease with distance) Lines of evidence that PFAS transformation mechanisms are relevant (e.g., PFAS identified as biodegradation intermediates are present, shift in precursor/PFAA contributions with distance, favorable field conditions).	**Yes** Retardation factors followed expected patterns Multiple additional lines of evidence obtained to support relevance of several different attenuation mechanisms at all 3 sites, including transformation

3.1 PERFORMANCE OBJECTIVE: DETERMINE PRESENCE OF SOURCE ZONES

High resolution spatial characterization of PFAS was conducted to determine the presence of source zones and downgradient impacts.

3.1.1 Data Requirements

The sampling protocol focused on characterizing differences in PFAS fingerprint and mass distribution at source zones vs. mid-plume vs. downgradient locations. A combination of groundwater and soil samples (primarily in source areas) were collected using high-resolution sampling techniques.

Collected samples underwent total fluorine analysis using PIGE spectroscopy by University of Notre Dame and for PFAS fingerprinting by Oregon State University (groundwater and surface water) and Colorado School of Mines (soil). Conventional geochemical parameter analyses were also performed to provide context for the interpretation of PFAS spatial distributions and fingerprints via a commercial laboratory and field measurements.

3.1.2 Success Criteria

Using Wilcoxon Rank Sum test, the median PFAS chain length of samples from source area should be longer than groundwater samples in the downgradient locations. Additionally, the proportion of cationic and zwitterionic PFAS should be higher in the source zone samples compared to samples in the downgradient locations.

3.1.3 Outcome

The success criteria for this performance objective were partially achieved.

At all three sites, the representative PFAS chain length (after weighting by concentration) was higher in the source area groundwater samples than in downgradient samples. However, this difference was statistically significant at only 1 of the 3 sites (Pt Mugu).

At all three sites, the concentrations of zwitterionic/cationic PFAS were higher in the source area than at downgradient locations, and the results were statistically significant ($p<0.05$) for 2 sites out of 3 (NAS Jacksonville and Pt. Mugu).

3.2 PERFORMANCE OBJECTIVE: DIFFERENTIATE AFFF AND NON-AFFF SOURCES

PFAS compositional data from the high-resolution characterization, along with site-specific fate and transport information, was used to differentiate between PFAS related to AFFF usage at the suspected source area and PFAS at locations outside of the expected source area that could be related to non-AFFF sources.

3.2.1 Data Requirements

At each site, distributions of PFASs in groundwater and soil sampling locations were compared to PFAS distributions in background (upgradient) locations.

3.2.2 Success Criteria

This performance objective was considered achieved if statistically significant differences between source area PFAS concentrations/composition profiles and those from background locations could be established using one or more statistical methods (e.g., Principal Component Analysis [PCA]).

3.2.3 Outcome

The success criteria for this performance objective were partially achieved.

At 2 of the 3 sites (NAS Jacksonville, Fentress), a clear distinction between samples from background locations and the source area could be obtained. This included statistically significant differences (clustering with different confidence intervals) during PCA, as well as the presence of multiple compounds that were unique to the source area locations and/or background locations. Filtering data to reduce the number of analytes and/or locations generally improved the ability to distinguish between samples from different areas.

At 1 of the 3 sites (Pt Mugu), the PFAS compositional data from the background locations was only slightly distinguishable from the source area locations. At this site, the data from background locations clustered tightly during PCA, but the confidence interval overlapped with those associated with other locations.

Collectively, these analyses supported other site data that suggest that the PFAS detected at the background locations at these sites are likely unrelated to the releases associated with the primary source areas (where AFFF was known to have been released). As such, the PFAS at these background locations may have come from non-AFFF sources, although an alternative source could not be identified due to the lack of distinguishing compounds and the variability in the datasets.

3.3 PERFORMANCE OBJECTIVE: PIGE AS TOOL FOR PFAS SITE CHARACTERIZATION

PIGE analysis (conducted by University of Notre Dame) was conducted on all groundwater and samples obtained in the field as a cost-effective method for measuring bulk PFAS and as a possible supplement and/or alternative to higher-resolution methods.

3.3.1 Data Requirements

Groundwater samples obtained during the sampling program were analyzed for individual PFASs by LC-MS/MS, as well as total fluorine measurements by PIGE.

3.3.2 Success Criteria

This performance objective will meet success criteria if groundwater sample concentrations from PIGE correlate with LC-MS/MS measurements with an r^2 of 0.7 based on linear regression. This was evaluated individually for each site. A secondary criterion was based on establishing a statistically significant positive correlation between the two datasets using a non-parametric test (Spearman's Correlation; $p<0.05$).

3.3.3 Outcome

The success criteria for this performance objective were partially achieved.

At 2 of the 3 sites (Pt. Mugu with $r^2 = 0.98$; Fentress with $r^2 = 0.98$), the r^2 values for regression of the PIGE and LC-MS/MS data met the target threshold. The r^2 value for the remaining site (NAS Jacksonville with $r^2 = 0.57$) did not meet this threshold.

At all three sites, a statistically significant relationship could be established between the PIGE groundwater data and the LC-MS/MS groundwater data using Spearman's Correlation test (non-parametric).

3.4 PERFORMANCE OBJECTIVE: NATURAL ATTENUATION EVIDENCE FROM RETARDATION FACTORS, PFAS FINGERPRINTS, AND SPATIAL DISTRIBUTIONS

3.4.1 Data Requirements

Spatial trends in PFAS composition and site properties as well as hydrogeologic factors (direction and velocity of groundwater flow) were evaluated to determine transport parameters such as retardation factors and patterns in spatial distributions of PFASs to identify relevant degradation pathways.

3.4.2 Success Criteria

The primary success criteria were based on: 1) determining that retardation factors for individual PFASs are consistent with aquifer properties and physical-chemical properties (functional groups, ionic charge, C-length, branching); 2) documenting one or more lines of evidence that attenuation and biodegradation pathways for PFAS are occurring at individual sites.

3.4.3 Outcome

The success criteria for this qualitative performance objective were achieved.

Retardation factors were estimated for a variety of individual PFAS at all three sites using Kd values estimated from co-located soil and groundwater samples, and these followed the expected relationships with respect to carbon chain length (longer-chain PFAS had higher R values than shorter-chain PFAS), functional group (PFSAs exhibited higher R values than PFCAs). R values were consistently higher than 2 for all PFAS that could be evaluated.

In addition, the apparent Kd values showed a relatively strong positive correlation with the organic carbon content, as well as a strong negative correlation with CEC (presumably due to the higher organic carbon in the high CEC soils) at one site (NAS Jacksonville). However, apparent Kd and R values were often higher in sandy soils than in clayey soils, reflecting the complex influences of soil type on various retention mechanism.

Multiple lines of evidence supported that retention-based attenuation was occurring at all three sites, including electrostatic attraction, hydrophobic sorption, matrix diffusion (particularly at NAS Jacksonville), and air-water interfacial sorption (particularly at Fentress).

Evidence for PFAS transformation was also obtained at all three sites, specifically through spatial patterns in particular compounds. These trends were used to develop possible transformation pathways involving specific precursors, intermediates, and presumed end-products. At all sites, the contribution of precursors to the total PFAS concentration decreased with distance from the primary source area.

4.0 SITE DESCRIPTION

Three sites were selected for this demonstration project, namely Naval Air Station (NAS) Jacksonville in Florida, NBVC Pt Mugu in California, and NALF Fentress in Virginia. AFFF was used at all three sites for firefighter training activities. As such, these sites likely contain PFASs in both the source zone and downgradient environmental media. Other AFFF sources, known and unknown, are also present as a result of use in emergency response, spills, equipment washout and wastewater treatment, among others. The following sections provide a site history, hydrogeological characteristics, and extent of known PFAS impacts.

4.1 SITE 1: NAS JACKSONVILLE, FL

4.1.1 Site History and Location

Naval Air Station (NAS) Jacksonville is a large site located within the city limits of Jacksonville, Florida with at least eight operable units (OUs) that are part of extensive investigation and cleanup efforts under Superfund. The area being investigated as part of this ESTCP project is part of OU-2 and is designated the "Petroleum Contaminated Area" 15 Fire Fighting Training Facility (PCA 15) FFTF). This area is located in the northern part of the facility, north and west of the primary flight line. It lies immediately east of a golf course and immediately north of the wastewater treatment facility for the base. The area contains few structures or roads and is not heavily trafficked (Figure 4-1).

Firefighting training occurred within this area between approximately 1968 to 1991. Activities were largely performed within a shallow unlined pit approximately 120 ft in diameter. Vehicles and other large equipment were set afire using JP-5, gasoline, and/or waste oil, and then foams were used to train personnel on proper firefighting techniques. It has been estimated that 6000 gallons per year of fuel were used during this 25-year training period, but the amount of foam used has not been reported.

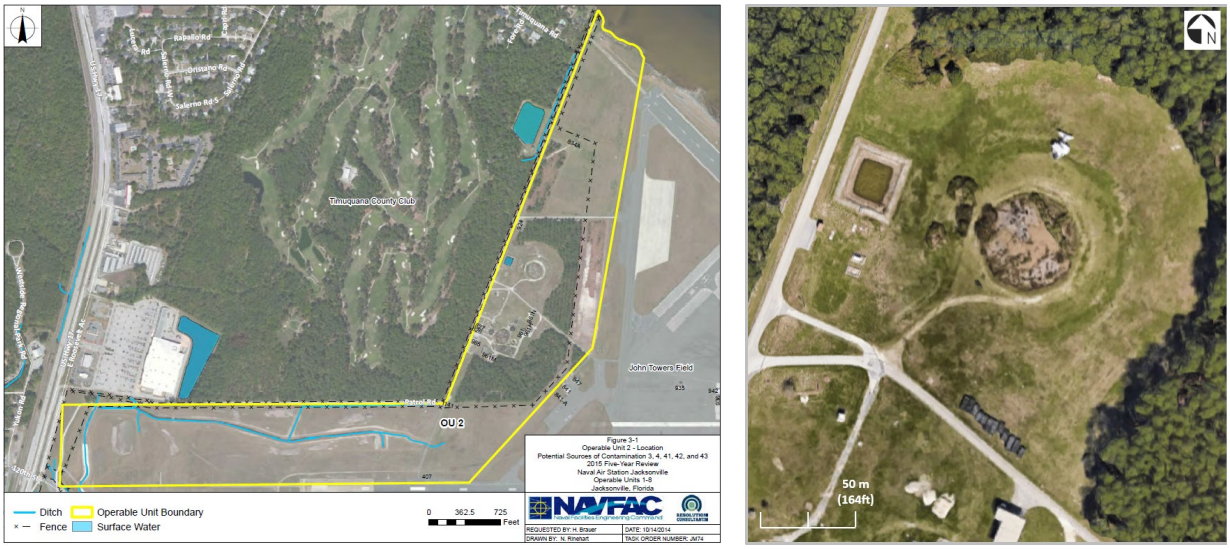

Figure 4-1. Operable Unit 2 (Left Panel) and Former Fire Fighting Training Facility (Right Panel) at NAS Jacksonville (source: CH2M, 2016).

Environmental characterizations began in 1983 with an Initial Assessment Study that identified the FFTF as a potential source of fuel impacts. Petroleum-impacted soil and free product were identified in 1994 and attributed to firefighting training activities. The Interim Record of Decision for OU-2 in 1994 mandated an Interim Remedial Action for the FFTF that was also completed in 1994. This action consisted of the collection and off-site disposal of free-product, as well as the excavation of approximately 2,400 cubic yards of petroleum-impacted soils. These excavated soils were processed through a mobile low-temperature thermal desorption treatment unit. After treatment, this soil was then used to backfill the former FFTF pit. There is no reason to believe significant removal of PFAS occurred in the low-temperature thermal desorption unit.

Characterization in 1998 (as part of a follow-up Remedial Investigation) encountered free product in several groundwater monitoring wells within the site and identified what was described as a "small" BTEX plume. In 1999, a Remedial Action Plan (RAP) for the site listed air sparging/soil vapor extraction (AS/SVE) as the preferred remedial alternative. The AS system became active in 2001, but the SVE system was never constructed. Active free-product removal was performed in monitoring well FFF-MW-13 in 2002 through 2005. Operation of the AS system operation was halted in 2004 following FDEP approval; site personnel reported that the above-ground components of the AS system were removed in 2013 (the below-ground components remain in place). The current remedy for managing the site (now that all other active measures have been discontinued) is monitored natural attenuation.

4.1.2 Geology and Hydrogeology

Information on the site geology and hydrogeology at PCA 15 FFTF were not available as part of the initial site selection process. However, the stratigraphy was generally considered to be similar to that encountered at nearby OU3, which has been extensively characterized and reported. Consequently, the following description is based primarily on known conditions at OU3, with site-specific information on PCA 15 FFTF included when available.

The soils underlying the site are part of Coastal Plain marine sediments, although surface soils have been extensively modified and there are extensive areas where fill was used, especially in previously low-lying areas. As a result, surface topography is relatively flat. Below the surface fill, interbedded layers of sand, clayey sand, sandy clay, and clay are encountered to depths of approximately 150 ft bgs. Each of these layers is somewhat discontinuous and not encountered at all locations, but the upper soil intervals are generally dominated by sands. Laterally extensive clays have been encountered at depths of 10 to 20 ft bgs and range in thickness between 2 and 10 ft. In some portions of the site, the clay is often present as two smaller lenses, separated by thin sublayers of sandier soils. When present, the clayey sands are either interbedded in the clay or present in transitional zones between the upper sands and clay.

The deposits form a surficial aquifer unit that consists of two different layers: 1) unconfined upper sand layer that extends from the surface to the depth of the clay (approximately 10 to 20 ft bgs); and 2) an intermediate sand layer that is confined by the clay. The total thickness of the surficial aquifer (upper plus intermediate layers) is generally considered to be 30 to 100 ft (USGS, 2000). At PCA 15 FFTF, most wells are screened in the upper layer (typically between 4 and 14 ft) but two are screened in the intermediate layer (between 30 and 35 ft) below the typical depth of where clay is encountered at nearby OU3.

The most recent water level survey at PCA 15 FFTF shows that groundwater in the surficial aquifer generally flows in an E/SE direction. However, there is also evidence that the groundwater flow direction is highly variable at the site, in part due to relatively mild gradients (see below). The 2014 groundwater monitoring report for PCA 15 FFTF states that flow has been to the E/SE for the past several annual monitoring events, but that "sampling events at the site prior to that time have indicated that groundwater flow in the shallow zone was to the northeast". Regionally, flow is oriented towards the St Johns River located NE/E of the site at a distance of approximately 2500 ft. Therefore, the dominant flow direction within the areas of interest may also shade towards the NE. Groundwater is first encountered at depths of approximately 5 ft bgs but historically vary to as much as 10 ft bgs. Based on the 2014 water level data, hydraulic gradients in the surficial aquifer are relatively small, in the range of about 0.001 to 0.005.

At nearby OU-3, the reported horizontal hydraulic conductivity for the upper sands based on pumping tests is approximately 20 ft/day. Horizontal hydraulic conductivities in the clay layer have not been established, but it is described in site reports as having "a very low hydraulic conductivity" and USGS modeling efforts (1998, 2000) used a hydraulic conductivity of 0.001 ft/day for this layer. These solute fate and transport models also assumed a vertical leakage rate between the upper and intermediate layers of 1 to 2 x 10^{-6} ft/day per ft (USGS, 1998; USGS, 2000). Reported groundwater velocities within the surficial aquifer sands vary between 2 ft/yr (USGS, 1998) and 70 ft/yr (USGS, 2000). The latter value is based on an effective porosity of 0.125 (total porosity of 0.25) that was used during solute fate and transport modeling (USGS, 2000). Because the BTEX plume at PCA 15 FFTF has not been fully delineated (i.e., there is no clean plume boundary on the downgradient edge) and the releases likely occurred over a large area, it is difficult to use the plume length to improve the groundwater velocity estimate.

The majority of the chemical data available at PCA 15 FFTF is related to the on-going management of the petroleum hydrocarbon plume (primarily BTEX). The plume boundaries are not firmly established, but the current hydrocarbon plume extends at least 150 ft in an area immediately south of the remnants of the firefighter training pit (no wells are installed in the former pit area).

4.1.3 PFAS Distribution

The majority of chemical data available at PCA 15 FFTF is related to the on-going management of the petroleum hydrocarbon plume (primarily BTEX). The latest data available were from a 2015 monitoring report that summarized data collected in 2014 (Solution IES, 2015). Total recoverable petroleum hydrocarbons in four wells located within the firefighter training area were between 1,000 ug/L and 15,000 ug/L during this period; these levels are generally above the applicable state-level screening level (5,000 ug/L). The plume boundaries are not firmly established, but the current hydrocarbon plume extends at least 150 ft in an area immediately south of the remnants of the firefighter training pit (no wells are installed in the former pit area).

In 2014, seven of the existing monitoring wells were sampled and the groundwater was analyzed for a large suite of individual PFASs at Oregon State University. This supplemental investigation was conducted to support a SERDP project and was not part of the site management or regulatory programs. PFASs were detected in all sampled wells, meaning that the PFAS plume occupied—at a minimum—at least as large of a footprint as the TPH plume. However, since PFASs were detected at the well located farthest downgradient, there is an assumption that the PFAS plume extends farther than currently recognized. Concentrations of up to 1.9 mg/L of PFAS were measured, and only a gradual

decrease in concentration is noted moving from west to east (in the apparent direction of groundwater flow). In addition, concentrations were generally higher in the deeper wells than in the shallow wells. This includes the deeper well FFF-PMW-06D, which (anecdotally) had the highest known recorded PFOS concentration (approximately 1.1 mg/L) measured at any site at the time of sampling, as well as the greatest number of individual PFASs measured for any site (unpublished data).

4.2 SITE 2: NAVAL BASE VENTURA COUNTY (NBVC) POINT MUGU, CA; IRP SITE 9

4.2.1 Site History and Location

IRP Site 9 is located at the Naval Base Ventura County (NBVC) Point Mugu which is located in Ventura County, California, approximately 50 miles northwest of Los Angeles (Figure 4-2). The Navy has conducted operations at Point Mugu since 1945, and it is a major center for naval weapons systems testing and evaluation (Tetra Tech, 2003). The Site is approximately 1.5 acres and includes two firefighter training (or burn pits); one closed and one active. The closed burn pit was used for firefighter training from the late 1950s to 1984. The active burn pit is still available for use as a firefighter training area; however, the Navy indicated that the exercises involving the use of AFFF ceased in the mid-2000s (CH2M, 2018). This firefighter training area was the focus for the ESTCP field demonstration.

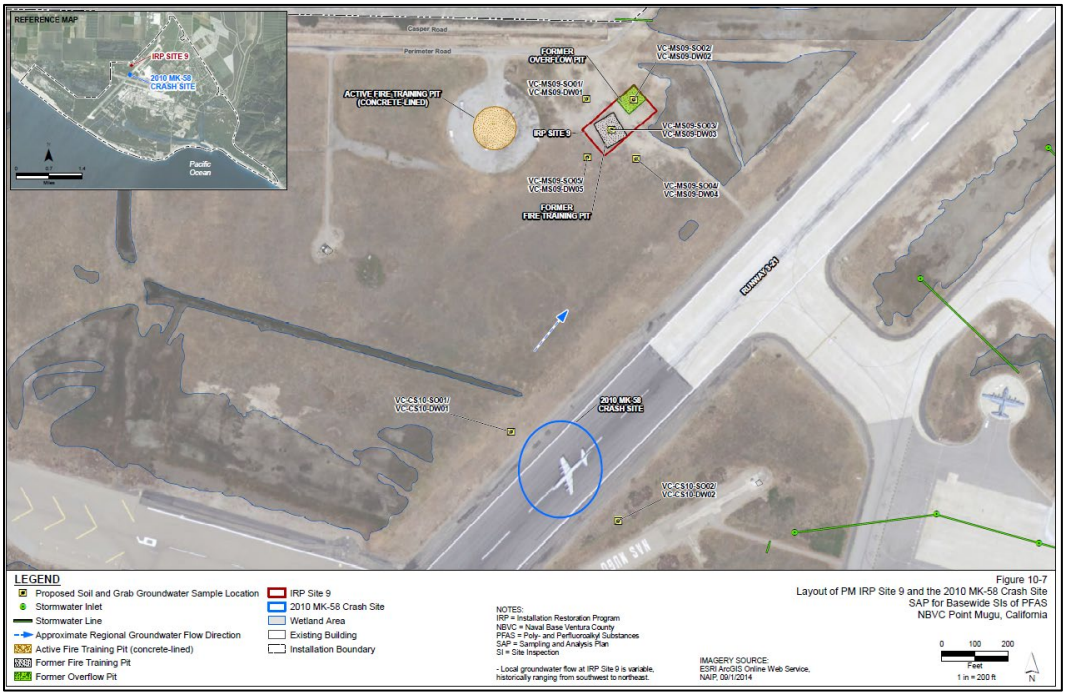

Figure 4-2. IRP Site 9 Map (Source: CH2M, 2018)

No information on historic remedial efforts in this area was available at the time of the site selection process.

4.2.2 Geology and Hydrogeology

Six aquifers have been identified in this region in the following order of depth: i) Semi-Perched; ii) Oxnard; iii) Mugu; iv) Hueneme; v) Fox Canyon; and vi) Grimes Canyon. The Upper Aquifer System (consisting of Oxnard and Mugu Aquifers) is separated from the Lower Aquifer System (consisting of Hueneme, Fox Canyon, and Grimes Canyon) by aquitards that are leaky and discontinuous (Tetra Tech, 2003).

The Semi-Perched Aquifer is the focus of this demonstration and extends from the water table (i.e., 2-10 ft bgs) to approximately 85 to 135 ft bgs (Tetra Tech, 2003). It is comprised of interbedded sands, silts and clays. Generally, groundwater flows to the north-northwest in the northwestern half of the base, and to the southeast-east in the remainder of the base (Tetra Tech, 2003). At IRP Site 9, the groundwater flow is to the northeast during the dry season, and to the southwest during the rainy season.

Due to pumping of the Upper and Lower Aquifer Systems, the historical groundwater gradient was reversed, with groundwater flowing inland from the Pacific Ocean. As such, this inland flow produced seawater intrusion into the aquifers regionally. At the NBVC Point Mugu Site specifically, high concentrations of total dissolved solids (TDS) exist, along with anion and cation chemistry that is similar to seawater (Tetra Tech, 2003). Finally, the average hydraulic conductivity of 47 ft/day was calculated using a rising head test. As such, the groundwater at IRP Site 9 was determined to flow at an average velocity of 318 ft/yr (Tetra Tech, 2003).

4.2.3 PFAS Distribution in Groundwater

Groundwater samples were collected in 2018 from IRP Site 9 in the following locations: i) the former firefighter training pit; ii) former overflow pit; and iii) the active firefighter training pit. PFAS were analyzed at a commercial lab using a modified EPA 537 method, and results indicated significant levels of PFAS are present in the former firefighter training pit and former overflow pit. For instance, PFOS and PFOA concentrations were >100,000 ng/L in both sampling points in the former firefighter training pit area. As such, this area was considered a promising site for a focused, more detailed characterization effort as part of this project.

4.3 SITE 3: NAVAL AUXILIARY LANDING FIELD (NALF) FENTRESS, VA, AFFF STORAGE AND TRANSFER AREA; NEAR BUILDING 106

4.3.1 Site History and Location

NALF Fentress is located in Chesapeake, Virginia and was established in 1940 for field carrier landing practice operations. It is under the command of NAS Oceana and is primarily used by squadrons stationed at NAS Oceana or Naval Station Norfolk Chambers Field for field carrier landing practice operations. Storage and maintenance of aircraft does not occur at this site. The base is located several miles inland of the Chesapeake Bay (Figure 4-3).

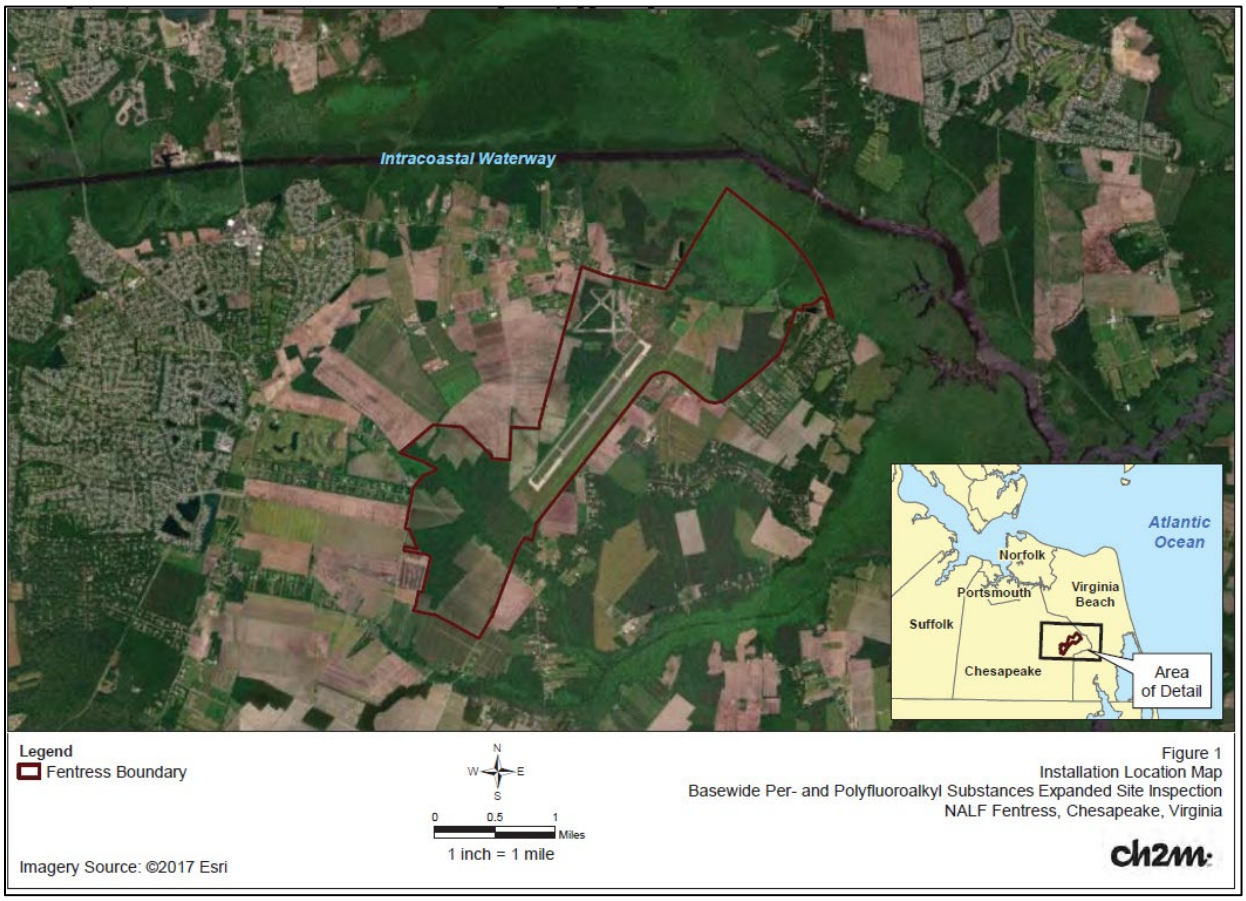

Figure 4-3. Installation Location Map (Source: CH2M, 2017)

Aqueous film-forming foam (AFFF) was used historically during firefighting activities, and several potential PFAS release areas have been established at this site based on historical records. This includes what are known as Site 14 (a former landfill), Site 17 (a former firefighting training area), and Building 106 (an AFFF storage and transfer area) that were identified for further evaluation of PFAS. Preliminary investigations were completed in these areas (including field sampling), and the results were summarized in an April 2018 Basewide PFAS Site Inspection Report that was available for review by our project team (CH2M, 2018).

The AFFF Storage and Transfer Area near Building 106 was selected for the focused characterization effort as part of this ESTCP project. This area contains of a series of tanks and cans that provide approximately 1100 gallons of on-site AFFF storage capacity. Previously, Building 20 was used for AFFF storage until the location was switched to Building 106 at an unknown date; both buildings are located in close proximity. Based on interviews with site personnel conducted in 2015 (CH2M, 2018), only 3% AFFF is used, with previous or current use of 3M, Ansul, and Chemguard brands. Reportedly, AFFF has not been used at NALF Fentress for emergencies in the recent past. Interviewed personnel said that they did not think that AFFF has been sprayed at NALF Fentress in the past two decades for any emergency, including fuel releases, historical crashes or fires, or emergency runway landings. Spray tests have been conducted in the current crash truck equipment test area since about 2010, which is located more than a half mile southwest of Building 106. The spray test consists of testing the individual turrets and line, as well

as tests of the distance and width of the spray pattern. AFFF was also used at Site 17 (the training area), which is located approximately 1500 ft southwest of Building 106.

4.3.2 Geology and Hydrogeology

The main hydrogeologic unit at NALF Fentress is the Columbia aquifer, which extends to a depth of approximately 17-30 ft bgs. Below this aquifer is the Yorktown confining unit, which is approximately 15 feet thick and is underlain by the Yorktown-Eastover aquifer (approx. thickness of 100 ft) (CH2M, 2017). In the AFFF Storage and Transfer Area (Building 106), the groundwater flow is generally to the northeast in both the Columbia and Yorktown aquifers (CH2M, 2017).

4.3.3 PFAS Distribution

Based on previous investigations, total PFOS + PFOA concentrations in groundwater ranged from 10,000 to 53,000 ng/L in samples collected in the vicinity of the AFFF Storage and Transfer Area (Building 106). These data were reported in the 2018 site inspection report that was focused on identifying areas for further evaluation, and the concentrations in this area exceeded those in the firefighter training area (Site 17) or the landfill (Site 14). As such, the AFFF Storage and Transfer Area was expected to be promising for a focused, more detailed characterization effort as part of this project.

5.0 TEST DESIGN

The following sections describe the analytical and site-characterization methodology employed at all three sites.

5.1 CONCEPTUAL EXPERIMENTAL DESIGN

The field program was designed to collect high-resolution groundwater and soil data from multiple sites. Specific sampling methodology used during this project included:

1) High-resolution vertical stratigraphic profiling;

2) Depth-discrete collection of groundwater samples; and

3) Depth-discrete collection of soil samples.

Specifically, multiple sampling locations were characterized at each site with the focus on source areas, several downgradient locations and a minimum of one upgradient (background) location. A tiered approach was used to distinguish the intensity of data collection at different locations, with a high intensity used at Tier 1 locations and a slightly lower intensity used at Tier 2 locations. Tier 1 locations followed the groundwater flow direction, while Tier 2 locations generally were in cross-gradient transects. An overview of the high-resolution characterization methods is included in Figure 5-1. Additional criteria used in selecting sampling locations and depths are summarized below for the various types of analyses:

- ***Stratigraphic Profiling:*** The Hydraulic Profiling Tool (HPT) was used to provide stratigraphic information. Typically, three to five locations were chosen along the presumed direction of groundwater flow to establish the distinct permeability zones, with the specific aim of identifying low-permeability sublayers (e.g., clays) that might impact PFAS fate and transport.

- ***Groundwater Sampling Locations:*** Groundwater samples were collected from at least four depths at all temporary investigation points using direct-push technology (DPT). This ensured that there was data from both above and below any low-permeability units. In addition to the temporary investigation points, a number of existing monitoring wells were sampled. These data help validate results from earlier rounds of testing and provide a comprehensive snapshot of the distribution of individual PFAS within longer-screened wells. At existing monitoring wells from one site (NAS Jacksonville), samples were collected from: 1) the midpoint of the screened interval; and 2) from just below the air-water interface.

- ***Soil Sampling Locations:*** Soil sampling locations were chosen to coincide with groundwater sampling locations. Surface soil samples were collected at each of these locations, along with multiple samples from both high-permeability and low-permeability zones. Surface soil samples were also collected at several additional locations where groundwater and subsurface soil sampling were not completed.

- ***Background Sampling Location:*** A location upgradient of the source area was selected on the regional groundwater flow direction.

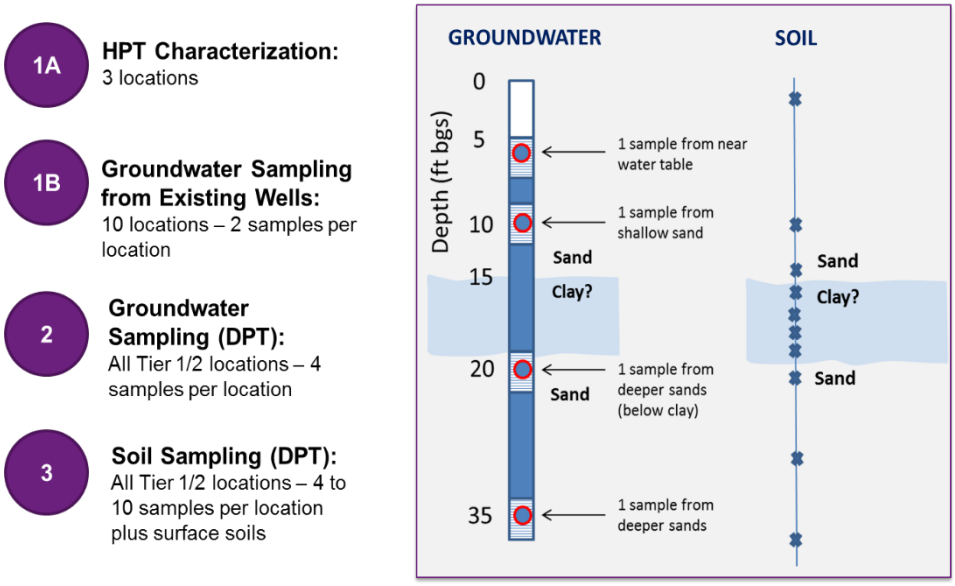

Figure 5-1. Conceptual Design for High-Resolution Characterization – Transect Locations. *Multiple methods were used at each location. Generalized sampling depths are designated by red circles (groundwater) or blue crosses (soil); actual sampling depths varied based on site conditions. The presumed depths of the sand and clay layers were based on information available prior to mobilization.*

All groundwater samples were analyzed for the following:

- ***Total Fluorine.*** A state-of-the-art analytical method for Total Fluorine was employed by the University of Notre Dame (laboratory of Graham Peasele, located at Hope College at the start of this project). The PIGE (Particle Induced Gamma-ray Emission) spectroscopy method has the potential to be a cost-effective method to rapidly determine total fluorine to guide characterization locations for the more costly analysis of individual PFASs by LC-MS/MS. The method yields total fluorine (TF) measurements by bombarding samples with a beam of protons and measuring the resulting gamma rays. Two gamma rays which are characteristic of the decay of the fluorine nucleus indicate the proportion of fluorine present in the sample (Ritter et al., 2017). The novel assay is quick (180 s per analysis) and was used to both screen for the presence or absence of PFASs in groundwater during drilling and to quantify total PFASs for the purpose of delineating the footprint of PFAS impacted sites.

- ***PFAS***. Aqueous-phase samples were primarily analyzed for PFAS at Oregon State University using a combination of LC-MS-MS and LC-QTOF-MS in both ESI- and ESI+ modes. This detailed PFAS analysis of groundwater can determine the distribution and concentrations of hundreds of individual PFASs. The analyte list for this project includes all the analytes listed in US EPA Method 537 but expands beyond this list by including a wider range of hundreds of PFAS known to be present in AFFF formulations and at

impacted sites. The method also quantifies all required analytes in the latest DoD QSM list (40 as of the date of this report) and follows the QA/QC protocols in that guidance. In addition, non-target analysis was performed on all samples to determine if a larger set of compounds (identified through suspect screening) were present, along with an estimated concentration for each. This was based on the protocol described in Appendix A.2.

- ***Volatile Organic Compounds (VOCs) + methane***. VOCs via EPA Method 8260B and methane via EPA Method RSK-175 were analyzed in a subset of groundwater samples by a commercial lab.

- ***Field Parameters***. Field parameters such as pH, redox, temperature, electrical conductivity, and dissolved oxygen were obtained using a YSI probe (or similar) in the field and recorded on designated field forms.

Soil samples were analyzed for the following:

- ***PFAS***. All analyses of solid-phase samples for PFAS were completed at Colorado School of Mines using LC-QTOF-MS in both ESI- and ESI+ modes with appropriate dilutions. The PFAS analyte list was designed to be as similar as possible to that performed for groundwater at OSU, though the absence of appropriate stable isotope surrogate and internal standards may preclude quantitative analyses of some PFASs due to significant matrix effects in these more problematic matrices. For soil and sediment, a previously established protocol[46] employing stable-isotope surrogate standards will be used for all soil and sediment soil analyses. The method quantifies all analytes in the latest DoD QSM list (40 as of the date of this report). In addition, non-target analysis was performed on all samples to determine if a larger set of compounds (identified through suspect screening) were present, along with an estimated concentration for each. This was based on the protocol described in Appendix A.1.

- ***Volatile Organic Compounds (VOCs)***. VOCs via EPA Method 8260B were analyzed in subset of the obtained soil samples by a commercial lab.

- ***Fraction of Organic Carbon***. Total organic carbon via EPA Method 9060A were analyzed in a subset obtained soil samples by a commercial lab.

- ***Cation Exchange Capacity***. Cation exchange capacity via EPA Method 9081 were analyzed in a subset of soil samples by a commercial lab.

Finally, for analytical quality control, field sample duplicates, and field blanks were obtained. Specific quantities and frequency of QA/QC samples will be determined by the research team (GSI, Navy, Notre Dame, Oregon State, and Colorado School of Mines).

5.2 BASELINE CHARACTERIZATION ACTIVITIES

The field work involved a single mobilization to each site (3 mobilizations were required at NAS Jacksonville) to collect samples. There were no baseline characterization activities required beyond reviewing existing characterization data to support well selection.

5.3 TREATABILITY STUDY RESULTS

No laboratory or treatability testing was performed for this project.

5.4 DESIGN AND LAYOUT OF TECHNOLOGY COMPONENTS

The following sections describe the primary components of the proposed field demonstration and the preliminary locations at each source area where these procedures were utilized (Figure 5-2).

- **Tier 1 Locations:** These locations are within transects placed perpendicular to the groundwater flow direction. Characterization generally consisted of two transects with 3 investigation points per transect. At each point, it was envisioned that 4 groundwater samples and 10 soil samples were to be collected from the interval of interest. Data from these points were designed to provide resolution on how concentrations vary with depth and relative permeability of the formation, as well as the mass discharge. At Tier 1 locations, groundwater samples were sent for immediate PIGE analysis and used to help define Tier 2 locations.

- **Tier 2 Locations:** These locations were along a single transect placed in the direction of groundwater flow (longitudinal). At least 3 investigation points were envisioned along this transect (in addition to the two Tier 1 locations that are also along this same transect). At each Tier 2 point, it was envisioned that 4 groundwater samples and 4 soil samples will be collected from the interval of interest. Thus, the data resolution from these Tier 2 locations was somewhat less than the Tier 1 locations.

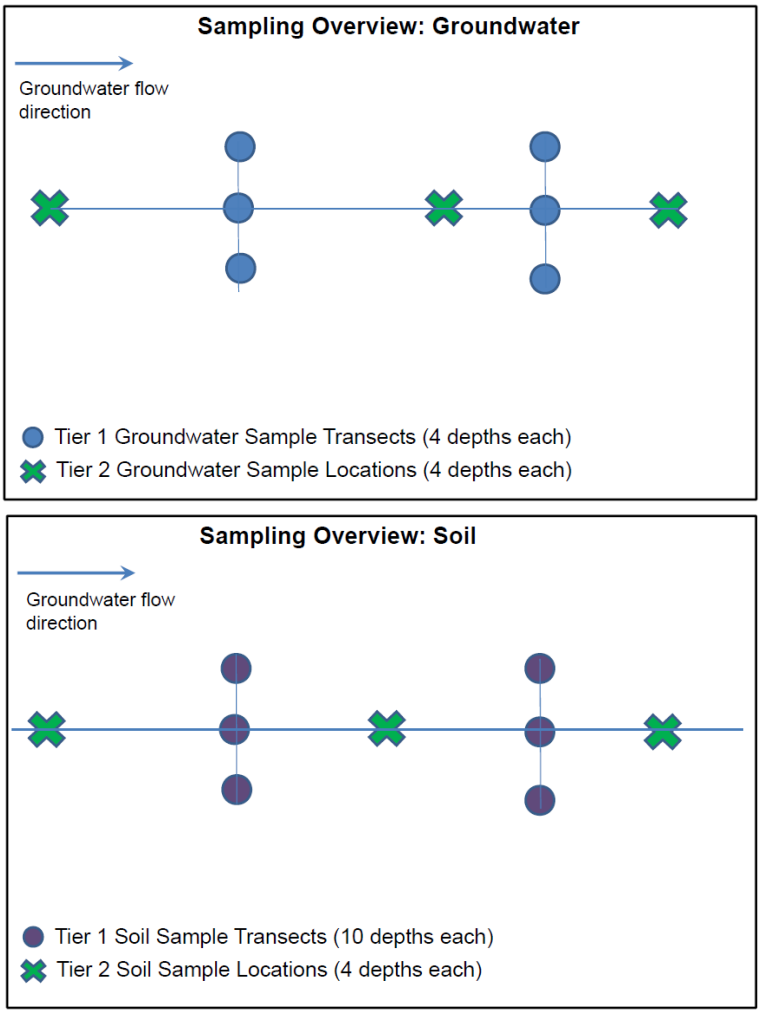

Figure 5-2. Tier 1 and Tier 2 Groundwater (top panel) and Soil (bottom panel) Sampling Plan.

5.4.1 High Resolution Characterization

A detailed vertical characterization of 2 to 4 locations per site was completed using the Hydraulic Profiling Tool. The goal of this characterization step is to rapidly provide screening level data on hydrostratigraphy at multiple locations to inform conceptual site models and to select depths for subsequent soil and groundwater sampling. Data are displayed real-time for on-site interpretation of results and thus well-suited for determining sampling intervals.

The Geoprobe Hydraulic Profiling Tool (Geoprobe HPT®) is a direct-push tool described by McCall (2011). HPT provides a real-time indication of hydraulic conductivity via logging water injection rates and pressures during tool advancement. Software tools are available for evaluating the data including use of empirical correlations for direct estimation of hydraulic conductivity. The tool also includes an EC sensor array providing another means of assessing presence of lower hydraulic conductivity (i.e., silt and clay-rich) zones. Because the goal of this step is rapid stratigraphic characterization, no samples were collected during advancement of the HPT. Instead,

samples were collected during separate advancements at these same locations after the stratigraphic data had been processed and interpreted.

5.4.2 Depth-Discrete Groundwater Sampling

Groundwater samples were collected by advancing a direct push technology (DPT) groundwater sampling probe on the DPT rods at a location adjacent to the original HPT survey location. The sampling probe was advanced to the desired depth interval and the operator then pulled up the DPT rods, allowing for the sampling screen to be exposed. Polyethylene tubing was lowered into the rods and a Waterra valve was used to extract water for sampling purposes. A grab groundwater sample was collected in method-specified containers (see Table 5.2) and immediately placed on ice. New polyethylene tubing and Waterra valve was used to collect each sample.

A summary of the number of samples and analysis plan is provided in Table 5.1 and Table 5.2.

5.4.3 Depth-Discrete Soil Sampling

Soil cores will be obtained using a direct push rig and location-specific samplers at specified depths. Each soil sampling location was within several feet of the location where the HPT characterization and depth-discrete groundwater sampling was completed to ensure that highly similar subsurface conditions are encountered. Soil samples were collected from both the same depths where groundwater samples were collected as well as additional depths to provide higher resolution vertical data.

A summary of the number of samples and analysis plan is provided in Table 5.1 and Table 5.2.

Table 5-1. Summary of Sampling Plan per Site

Project Component	Matrix	Collection Method	Analyte(s)	Location
High-Resolution Groundwater Sampling	Groundwater	DPT Unit for depth-discrete GW sampling using tubing and Waterra pump	Total Fluorine, PFASs, VOCs, methane, field parameters	Tier 1 and Tier 2 sampling points
Groundwater Sampling of Existing Monitoring Wells	Groundwater	Low-flow groundwater sampling from existing wells	Total Fluorine, PFASs, VOCs, methane, field parameters	Existing Monitoring Wells at Site
High-Resolution Soil Sampling	Soil	DPT Unit for depth-discrete soil sampling at same depths as GW samples	PFASs, VOCs; fraction organic carbon, cation exchange capacity	Tier 1 and Tier 2 sampling points

Table 5-2. Summary of Analytical Methods for Samples Collected per Site

Matrix	Analyte	Method(s)	Container and Preservative	Laboratory
Groundwater	Total Fluorine	PIGE Analysis	(Qty: 1) 500 mL; Standard HDPE containers without lid liner. No preservative necessary; Ship in cooler with ice.	University of Notre Dame
	PFASs	LC-MS/MS	(Qty: 4) 6 mL samples in 15 mL centrifuge tubes	Oregon State Univ. (OSU)
	VOCs and methane	Method 8260B (VOCs) RSK-175 (methane, ethane, ethene)	(Qty: 3) 40-mL VOA vials (VOCs) (Qty: 3) 40-mL VOA vials (methane) Ship in cooler with ice.	Commercial Lab
	Field Parameters: Geochemistry (Dissolved oxygen, pH, redox, temperature, electrical conductivity, iron)	YSI Probe	> 100 mL; no preservative	Not applicable (field measurement)
Surface Water	Total Fluorine	PIGE Analysis	(Qty: 1) 500 mL; Standard HDPE containers without lid liner. No preservative necessary; Ship in cooler with ice.	University of Notre Dame
	PFASs	LC-MS/MS	(Qty: 4) 6 mL samples in 15 mL centrifuge tubes	Oregon State Univ. (OSU)
	Field Parameters: Geochemistry (Dissolved oxygen, pH, redox, temperature, electrical conductivity, iron)	YSI Probe	> 100 mL; no preservative	Not applicable (field measurement)
Soil	PFASs	LC-MS/MS	(Qty: 1) 100-250 mL HDPE jar Ship in cooler with ice	Colorado School of Mines (CSM)
	VOCs; fraction organic carbon, cation exchange capacity	Method 8260B (VOCs) Method 9060A (Total Organic Carbon) Method 9081 (Cation Exchange Capacity)	(Qty: 1) Terra Core (VOCs) (Qty: 1) 8 oz glass jar (geochemical, fraction organic carbon, cation exchange capacity)	Commercial Lab

5.5 FIELD TESTING

Data from the project was analyzed to better understand key factors that control the migration of PFAS in both groundwater and soil. Key issues that were evaluated include: (1) identifying the location and magnitude of the source area and the PFAS sources that were contributing; (2)

documenting the concentration trends both vertically and laterally from the source area to understand the extent of transport; (3) evaluating the relevance of different possible fate and transport processes, including retardation due to partitioning, matrix diffusion effects, and biotransformation; (4) establishing site-specific factors that contributed to these processes; (5) determining if PFAS is present at background locations and if it is unrelated to usage of AFFF in the primary source area.

As noted in Section 5.3, data was collected at each site in a phased approach, starting with a screening-level hydrostratigraphic characterization, followed by groundwater and soil sampling. Sampling programs for each site are described in the following subsections.

5.5.1 Site 1: NAS Jacksonville, FL

Figure 5-3 below depicts all investigation points completed at the site and are described in the following subsections. The investigation focused on two primary areas: (1) the former firefighter training pit; and (2) the downgradient plume.

Hydraulic Profiling Tool (HPT) Characterization

HPT was conducted in the former firefighter training pit at locations 2 and 3, and at one far downgradient point, location 14. Vertical profiling was obtained from ground surface to 40 – 50 ft bgs. All HPT logs are provided in Appendix B.

Soil and Groundwater Locations

The former firefighter training pit served as the presumed source of PFASs in the area, and one cross-gradient transect was placed immediately northeast of the pit boundary (locations 9, 10, 11). A second cross-gradient transect was placed far downgradient plume (locations 13, 15).

As noted previously, groundwater flow is variable but generally moves in an easterly or northeasterly direction. For the purposes of this investigation, we assumed that the primary historic flow was in the northeasterly direction. Therefore, additional Tier 2 locations were selected to provide data along a longitudinal transect. Several surface soil samples were also collected at multiple locations in and around the perimeter of the former pit to help delineate the source (locations 4, 5, 6, 7).

In addition, one upgradient location was initially selected to provide background information (location 1). Analyses at this location indicated PFAS impacts from the source area. Subsequently, two additional background locations were sampled (locations 16 and 17).

All soil and groundwater samples were collected to a depth of approximately 35 ft bgs, with the exception of selected locations where samples were collected as deep as 50 ft bgs (locations 3 and 17).

Miscellaneous

A total of three temporary well clusters (locations 24, 25, and 26) were installed, with each cluster containing 4 separate wells. These were installed to provide vertical data but also to confirm that groundwater samples collected directly from the DPT rig (grab samples) did not overly bias the vertical concentration distribution (i.e., by pushing PFAS from shallow intervals to deeper

intervals). Cluster location 24 had wells installed at total depths of 5 ft bgs, 10 ft bgs, 35 ft bgs and 60 ft bgs. Locations 25 and 26 had wells installed at total depths of 5 ft bgs, 10 ft bgs, 35 ft bgs and 50 ft bgs. Each well was constructed of 2" PVC casing and was developed using standard well development protocols prior to sampling.

Finally, groundwater was collected from all 10 existing monitoring wells in the area through grab sampling at both the air-water interface (top of water table) and the middle of each screen interval. Screen intervals at these wells typically ranged from 4 -14 ft bgs (8 wells) and from 30-35 ft bgs (2 wells).

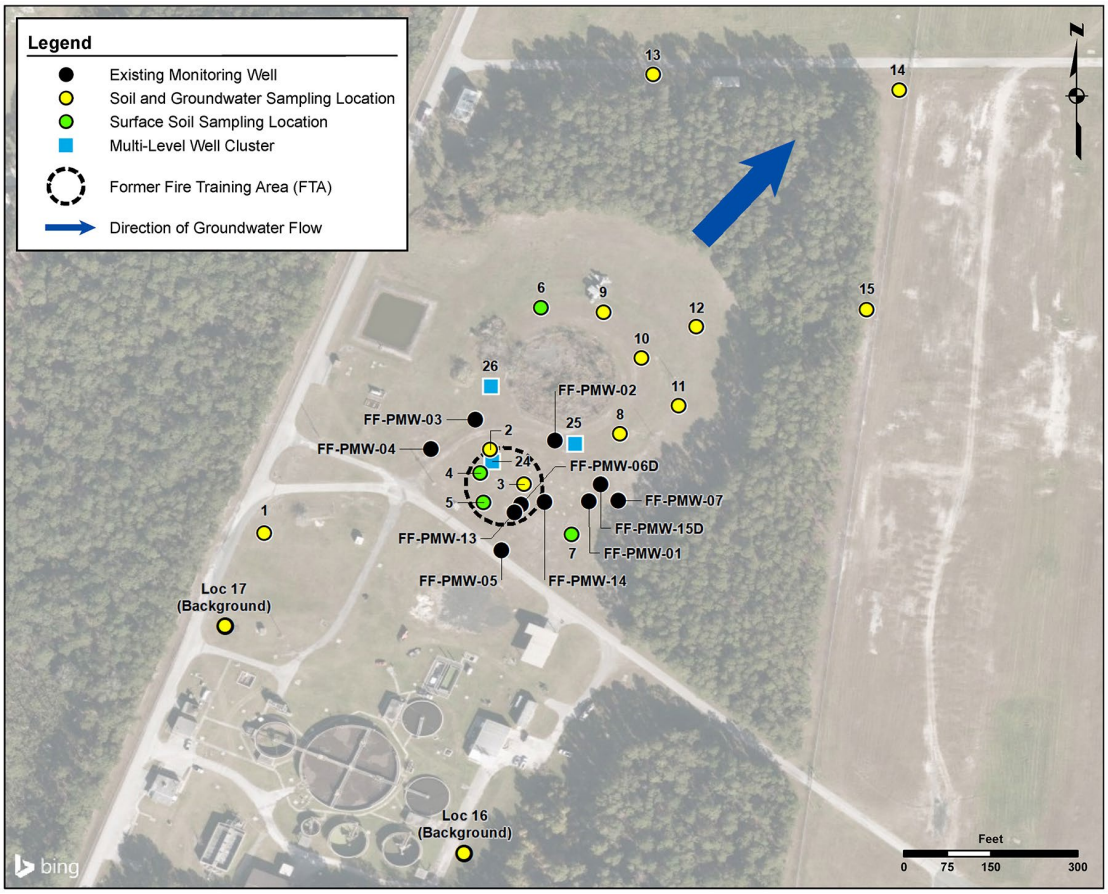

Figure 5-3. Site Map of Firefighting Training Area at NAS Jacksonville.

5.5.2 Site 2: NBVC Pt. Mugu, CA

Figure 5-4 below depicts all sampling points conducted at the site and are described in the following subsections. Investigation efforts focused on the former burn pit (location L5), and downgradient locations. The wet season is generally November through March. From this source area, groundwater flow direction is to the northeast (toward L9) for drier parts of the year, and to the southwest (toward L1) for wetter parts of the year.

Hydraulic Profiling Tool (HPT) Characterization

HPT characterization was conducted three locations, H-1, H-4, and H-9 (Figure 5-4) from ground surface to 40 ft bgs. All HPT logs are included in Appendix C.

Soil and Groundwater Sampling Locations

The investigation focused on the former burn pit and downgradient points (Figure 5-4). All Tier 1 and Tier 2 locations were placed along the direction of groundwater flow, as opposed to perpendicular. This is because flow is known to show seasonal variability, with both NE and SW flow observed depending on the season. As a result, a decision was made to focus resources along the longitudinal transect in both directions of groundwater flow.

Several surface soil samples were also collected at SS1, SS2, and SS3. Finally, two upgradient locations were selected (B1 and B2) to provide background information.

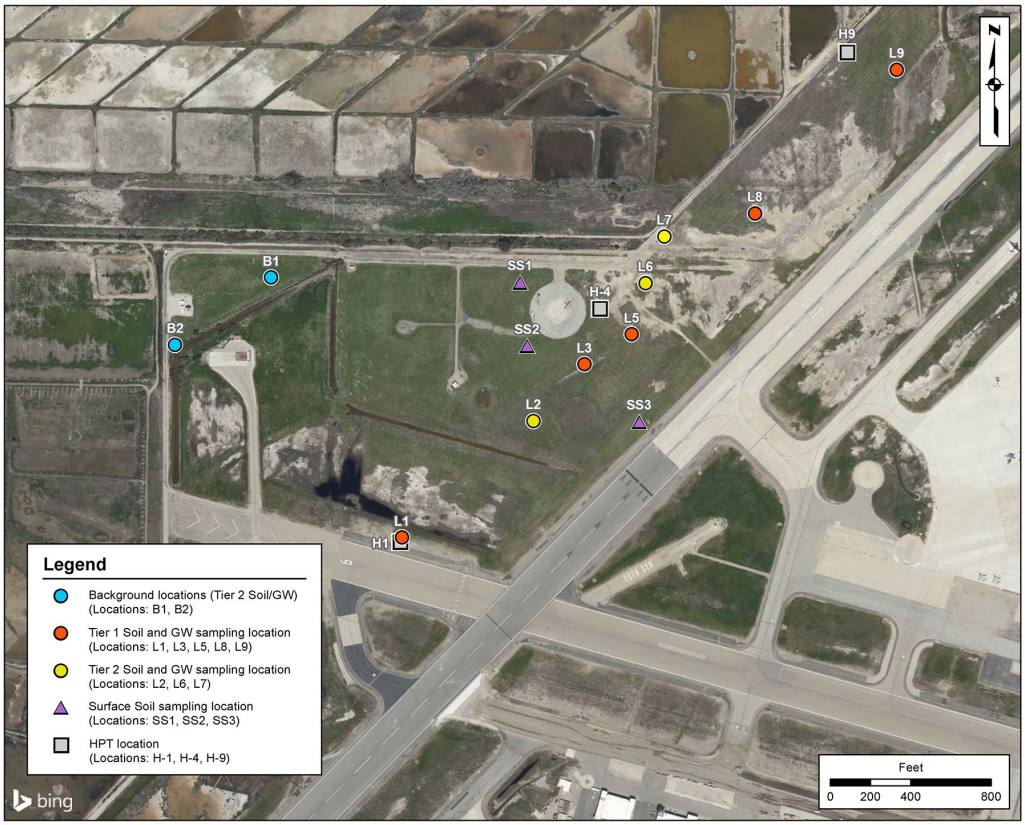

Figure 5-4. Site Map of Firefighting Training Area at Pt. Mugu. *The former firefighter training area is adjacent to location L5 and is considered the source area with peak concentrations. The ponds on the northern part of the image are flooded from July through March for migratory waterfowl. The wet season is generally November through March. From this source area, groundwater flow direction is to the northeast (toward L9) for drier parts of the year, and to the southwest (toward L1) for wetter parts of the year (depicted in blue arrows).*

Groundwater samples were collected to a depth of approximately 40 ft bgs from the Semi-Perched Aquifer. However, due to the high permeability sands at this site, drilling conditions proved

challenging when obtaining soil samples. As such, soil samples were collected to a depth of approximately 25 ft bgs at most locations, except at L5 (depth of 47 ft bgs) and L9 (depth of 38 ft bgs).

5.4.3 Site 3: NALF Fentress, VA

Figure 5-5 below depicts all sampling points conducted at the site and are described in the following subsections. Investigation efforts focused on the AFFF storage and transfer area (location L2 and L3), and downgradient locations towards the east.

Hydraulic Profiling Tool (HPT) Characterization

HPT characterization was conducted at locations B1, B2, L1, L5, and L7 to depths of 30 to 50 ft bgs. All HPT logs are provided in Appendix D.

Soil, Groundwater, and Surface Water Sampling Locations

The investigation focused on the AFFF storage and Transfer Area as well as downgradient points (Figure 5-5). One cross-gradient transect was placed in the source area (Tier 1 locations L1, L2, L3), while the second cross-gradient transect was placed further downgradient (Tier 1 locations L6, L7, L8) at the boundary of the site. Three Tier 2 locations were placed along the direction of groundwater flow to provide data along the longitudinal transect (locations L4, L5, and L9). The approximate total depth of investigation was 30 ft bgs which spanned the Columbia aquifer, Yorktown confining unit, and the upper portion of the Yorktown aquifer.

Several surface soil samples were also obtained for multiple locations in and around the perimeter (SS1, SS2, SS3). Two water samples from an existing lagoon to the east of the source area were collected (S1 and S2). Finally, two background locations (B1 and B2) were placed upgradient of the source area (Figure 5-6).

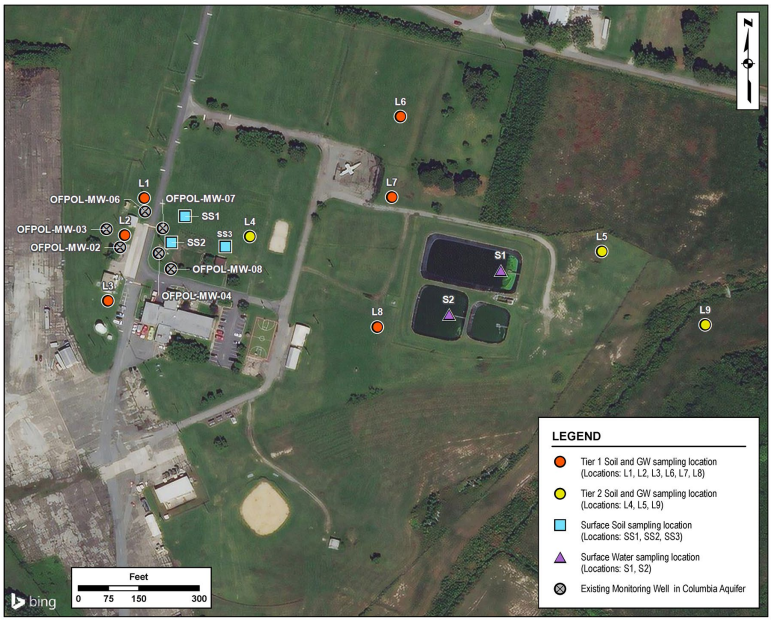

Figure 5-5. Site Map of NALF Fentress VA, Key Source and Downgradient Areas

Miscellaneous

As seen in Figure 5-6, there are several existing shallow monitoring wells in the vicinity, screened from approximately 2–12 ft bgs in the Surficial Aquifer. These were sampled by the existing subcontractor at the site and analyzed as part of this project.

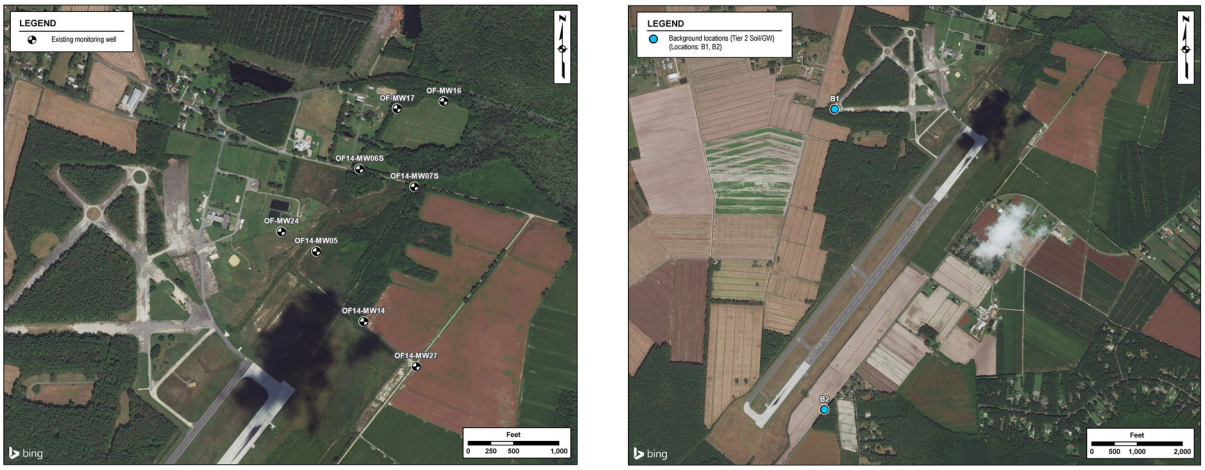

Figure 5-6. Site Map of NALF Fentress VA, Downgradient Monitoring Wells (Left Panel) and Background Locations (Right Panel)

5.6 SAMPLING METHODS

5.6.1 Overview

A summary of the sampling plan is provided in Table 5.1, and the analytical program for these samples is summarized in Table 5.2. Collectively, the sampling and analysis plan generate data provided sufficient understanding of PFAS distribution at each site.

5.6.2 Quality Assurance Sampling Program

Laboratory analyses were completed using the methods and protocols outlined in Table 5.1 and Table 5.2. In all cases, method-specific containers were obtained from the respective laboratories prior to sampling. Labs were consulted on the necessary lab QA/QC samples to ensure that appropriate sample containers for these samples are provided to field personnel as well. A summary of the QA/QC sampling program is provided in Table 5.3 below.

Table 5-3. Summary of QA/QC Sampling Program

QA/QC Sample Category	Sampling Frequency	Analytes
Equipment Rinsate Sample	1 sample/site	PFASs
Rinsing Water Sample	1 sample/site	PFASs
Field Duplicates	Approximately one for every ten samples (soils and groundwater); additional duplicate soil samples collected to evaluate several performance criteria	All requested analytes for each lab
Field Blank	1 sample/site	PFASs
Matrix Spike/ Matrix Spike Duplicates	Approximately one for every twenty samples (soils and groundwater)	Lab and method-specific
Laboratory Control Samples	One per method, batch, and matrix	Lab and method-specific
Laboratory Method Blank	One per method, batch, and matrix	Lab and method-specific

5.6.2.1 PFAS-Specific Sampling Procedures

Due to ubiquitous nature of products containing PFAS compounds (sampling equipment, field supplies, clothing, etc.), special procedures and alternative equipment were used to avoid cross-contamination as specified in Appendix B.

5.6.2.2 Field Quality Assurance Procedures

Field QA/QC samples were collected and analyzed to i) evaluate field precision and accuracy, and ii) facilitate validation of sample results. Field sampling precision and accuracy was assessed through the collection and laboratory analysis of field replicates and field blanks.

Data from field QC samples were examined to determine if any problems are evident for specific media or with laboratory procedures. The individual laboratories (Oregon State University, University of Notre Dame, and Colorado School of Mines (CSM) were responsible for reviewing the QA/QC data and to develop appropriate corrective actions should any problems be encountered.

- ***Rinsing Water Sample:*** Determine if the water used to clean the sampling equipment between wells/surface water locations contains background levels of PFASs, a sample of the cleaning water was collected and analyzed for each site.

- ***Equipment Rinsate Sample:*** After each sampling event, when moving to the next well/location, any sampling equipment that was reused was fully cleaned. A sample was collected of the sampling system rinse water.

- ***Field Duplicate Samples:*** The precision of field sample collection techniques was evaluated by collecting and analyzing field duplicates. Duplicate samples were defined as those samples collected simultaneously from the same source under identical conditions into separate but identical containers, and preserved, stored, transported and analyzed in

the same manner. Thus, to prepare a duplicate, an aliquot was collected from a sample source and divided equally into two separate but identical sample containers. Each duplicate was identically preserved, stored, transported and analyzed. Field duplicates were given a different identification number to disguise the source of the sample from the laboratory. Field replicates were analyzed by the same laboratory analyzing investigative samples.

5.6.2.3 Laboratory Quality Assurance Procedures

The off-site laboratories (Oregon State University, University of Notre Dame, and Colorado School of Mines) implemented a QA/QC program to ensure the reliability and validity of analyses performed in the laboratory. Internal quality control checks differ slightly for individual procedures, but in general QC requirements included the following:

- Method blanks
- Instrument blanks
- Matrix spikes/matrix spike duplicates
- Surrogate spikes
- Laboratory duplicates
- Laboratory control standards
- Surrogate spikes
- Internal standard spikes
- Mass spectral tuning

Laboratories used extra sample volume for preparation and analysis of matrix spike and matrix spike duplicates. QC sample results were properly recorded and included in the analytical data package.

5.6.3 Decontamination Procedures

Standard decontamination measures were employed during sampling activities and all other investigations associated with the project. This included the one-time use of sample and method-appropriate containers, decontamination of all sampling equipment (pump tubing, trowels) prior to sampling and between collecting each sample. During soil sampling, drill rods and all other downhole equipment was decontaminated (using pressure washing) prior to the start of drilling activities, and only decontaminated drilling equipment was used when moving to a new drilling location. All investigation-derived waste was collected and disposed of per site regulations.

5.6.4 Sample Documentation

Sample containers provided by the laboratories for this project were shipped by common carrier in sealed coolers to individual laboratories. The containers and sample coolers were maintained in the custody of GSI until received by the individual laboratories.

5.7 SAMPLING RESULTS

The follow sections describe data analyses and key results of characterization efforts at each site.

5.7.1 Data Analysis

Identification of Source Zones(s)

The fingerprint of PFASs in soil and groundwater obtained from downgradient transects were compared to those in the presumed source areas. Source zones were identified when i) total PFAS concentrations were highest at most depths in both soil and groundwater; and i) were characterized by a relative abundance of the more hydrophobic PFAS (e.g., long-chain, zwitterionic/cationic).

PFAS Transport Processes

Estimates of field retardation factors were calculated using co-located soil and groundwater samples. First, apparent soil adsorption coefficients (K_d values) were calculated for every sampling depth and location where both soil and groundwater were collected and had resulting detections. The apparent K_d values were calculated by dividing the total soil concentration in ng/g (which includes both sorbed and aqueous phase mass) divided by the groundwater concentration in ng/L. This apparent K_d approach was used because some of the soil/groundwater pairs using K_d = (total mass – aqueous mass) ÷ (aqueous mass) resulted in negative K_d's. These discrepancies were attributable to scatter in the groundwater and soil data (i.e., direct measurements of soil porewater mass were not available, so groundwater data were used as a surrogate). Therefore, this simpler apparent K_d was as employed here because of the discrepancies with estimating the porewater concentration as described above.

As such, these were calculated as follows:

$$K_d \text{ (L/kg)} = \text{Soil concentration (ng/g)} / \text{Groundwater concentration (ng/L)} \times 1000 \quad (1)$$

Retardation factors were then calculated per the following equation:

$$R = 1 + K_d \rho_b / \theta \quad (2)$$

where:

R is the retardation factor for a certain PFAS compound (unitless)
Kd is the soil adsorption coefficient (L/kg)
ρb is the soil bulk-density (kg/L). For sands = 1.75 kg/L, silts = 1.65 kg/L, and clays = 1.35 kg/L.
θ is the porosity (unitless). For sands and silts = 0.38, and clays = 0.55.

Subsequently, at sites with sufficient data, Spearman's correlation coefficients were determined between soil adsorption coefficients and site-specific characteristics such as fraction organic carbon, cationic exchange capacity, etc.

Additionally, aerial maps depicting the distribution of classes in both soil and groundwater were created, specifically: i) anionic vs. cationic and zwitterionic PFAS; and ii) PFAAs vs. precursors.

Finally, for each groundwater sample and specific PFAS compound, the weighted average chain length was calculated as follows:

Weighted Average Chain Length for $PFAS_i$ = C_i (ng/L) / Total PFAS C (ng/L) x CL_i (3)

where:

i is the specific PFAS compound
C_i = groundwater concentration of i (ng/L)
Total PFAS C = sum of all PFAS in groundwater (ng/L).
CL_i = chain length of specific PFAS compound.
For the sample as a whole, the sum of all weighted averaged chain lengths from each PFAS compound were determined as a representative chain length at that location/depth.

Natural Attenuation Evidence

Evidence for natural attenuation was assumed to fall into one or more different categories:

1) ***Attenuation in total PFAS concentrations with distance from the source.*** This was evaluated by comparing PFAS groundwater data collected from locations within the source and those collected along a downgradient transect. Total PFAS concentrations that decrease significantly within a short distance of the source are indicative of an attenuating source and/or attenuation in the plume due to non-destructive processes. This is because PFAS sources resulting from AFFF releases (which are episodic and include compounds that do not completely mineralize) would be otherwise assumed to have high concentrations extending far beyond the source.

2) ***Changes in the total PFAS represented by precursors with distance from the source.*** This percentage would be expected to decrease due to natural attenuation processes. This is also supported by the assumption that many types of zwitterionic/cationic precursors would be expected to be retarded relative to anionic endproducts.

3) ***Presence of specific compounds (or classes of compounds) that are expected to be transformation intermediates.*** This can include various fluorotelomer sulfonates and carboxylates, polyfluorinated fluorotelomers with an odd number of fluorinated alkyl carbons, and

4) ***Changes in the spatial patterns of specific sets of compounds that are known and/or expected based on presumed biotransformation pathways.*** This is primarily based on shifts along groundwater flow directions where the detection/enrichment of degradation products is observed due to biotransformation.

Differentiate AFFF and non-AFFF Sources

The evaluation of possible sources of PFAS at these sites included the following:

1) ***Detection of Compounds Known to be Associated with AFFF.*** This involved identification of compounds and compositions that would suggest the presence of one or more types of AFFF.

2) ***Site History and Known Proximate Sources.*** This type of information was limited for this set of sites. However, the firefighter training area for NAS Jacksonville is located

immediately northeast of a wastewater treatment plant, and biosolids were known to have been applied in the area.

3) ***Relationships Between Compounds Detected in Source Areas vs. Background Locations.*** If background locations contained a preponderance of unique compound relative to those detected in the suspected primary source area (which were all related to AFFF usage), then this is evidence of unrelated PFAS sources in the background sources.

4) ***Statistical Analysis of PFAS Composition.*** PCA and/or hierarchical analysis show differences between source area composition and concentrations vs. background locations.

For the statistical analyses, comparisons were generally performed separately on groundwater data and soil data after transforming analyte concentrations into a percentage of total PFAS detected within a sample. Evaluations were performed on unfiltered data as well as datasets where only specific analytes (e.g., target analytes) or specific locations (e.g., surficial soils) were included. Transformed data were entered into ClustVis (http://biit.cs.ut.ee/clustvis/), and pareto scaling was used as an initial data processing step to minimize the effects of large concentration ranges. Clustering was performed using Euclidean distances, and Ward's Method was selected for linking clusters. Detailed methods associated with this tool for cluster analysis are described elsewhere (Metsalu and Vilo 2015).

PIGE as Cost-Effective Guidance Tools for Drilling and Plume Footprint

Results of the PIGE analyses were compared to those obtained by LC-MS/MS. A linear regression analysis and other statistical measures were used to compare Total Fluorine from PIGE vs. Total PFASs from LC-MS/MS data.

5.7.2 Results: NAS Jacksonville, FL

Site Characterization Overview

Field work was completed in several phases between 2017 and 2018. An overview of the high-resolution characterization methods was described previously, and sampling points are depicted in Figure 5-7 below.

As part of this program, a total of 58 depth-discrete groundwater samples were collected, and a total of 105 depth-discrete soil samples were collected. From the existing monitoring wells, 22 groundwater grab samples were collected from both the top and middle of the screen interval.

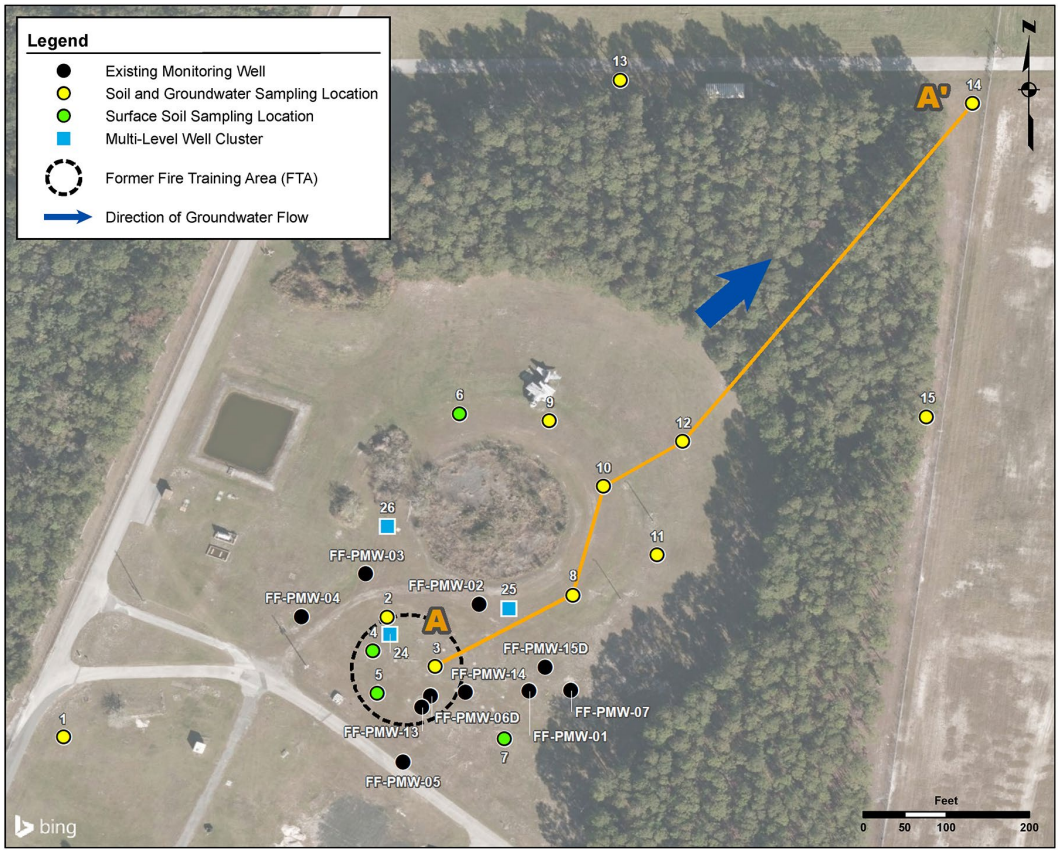

Figure 5-7. Sampling Points at NAS Jacksonville, and Cross-Section A-A'

Site Hydrogeology

Data are available from 3 locations where HPT was completed and 11 locations where soil cores were collected and logged. The total depth for each boring was generally between 35 and 50 ft bgs. Figure 5-8 below depicts the geologic cross-section at the site from the source area (location 3) to the far downgradient point (location 14). These data largely corroborated existing site information. The following are key features that influence PFAS fate and transport at this site:

- The surficial aquifer is largely permeable sands but contains significant lower permeability sublayers in the form of silts and clay. The depths that these silt and clay-rich layers were encountered (based on visual inspection of cores) were largely consistent with the depths where the HPT data indicated low hydraulic conductivity. Based on the HPT logs, the permeability for the low-k layers vs. higher-k layers differs by several orders of magnitude.

- The first low-permeability layer is generally encountered at a depth of approximately 12 ft bgs. The thickness of this first low-k layer varies significantly across the site. Near the former pit, it is typically 1 to 2 ft. Moving northeast away from the pit, the thickness generally increases, with a maximum thickness of approximately 20 ft at Location 14.

- A second, deeper low-k layer is generally encountered starting at a depth of approximately 30 to 35 ft bgs. This layer at least 4 ft thick at most locations and extended beyond the depth of the borings at several locations northeast of the pit.

- Collectively, these data indicate that there is a relatively thick transmissive layer underlying the former pit area, with a thin and potentially discontinuous low-k layer between shallow and deeper portions of the aquifer. The former pit area is closer to the mound reported in earlier investigations by the USGS, and the hydrostratigraphic profiles are consistent with high potential for recharge with vertical transport and radial flow. Based on historic water elevation data collected during routine groundwater monitoring events, the shallow monitoring wells (e.g., FFF-PMW-13) and deep monitoring wells (e.g., FFF-PMW-6D) show a strong hydraulic connection with downward gradients. This pattern has the potential to contribute to downward migration of PFAS released at the surface (discussed in more detail below).

- Outside of the pit area, the data indicate that the transmissive portions are generally much thinner and that lower-k soils constitute a relatively high percentage of the surficial aquifer (typically > 50%). The area to the northeast of the pit was most extensively investigated because this represents the direction of regional groundwater flow (with the understanding that localized flow directions may differ in proximity to the mound). These thicker low-k zones are likely more effective at preventing vertical migration of PFAS and reduce downgradient mass discharge rates (relative to conditions observed closer to the pit). However, their lack of transmissivity may also promote diffusion-based storage of PFAS.

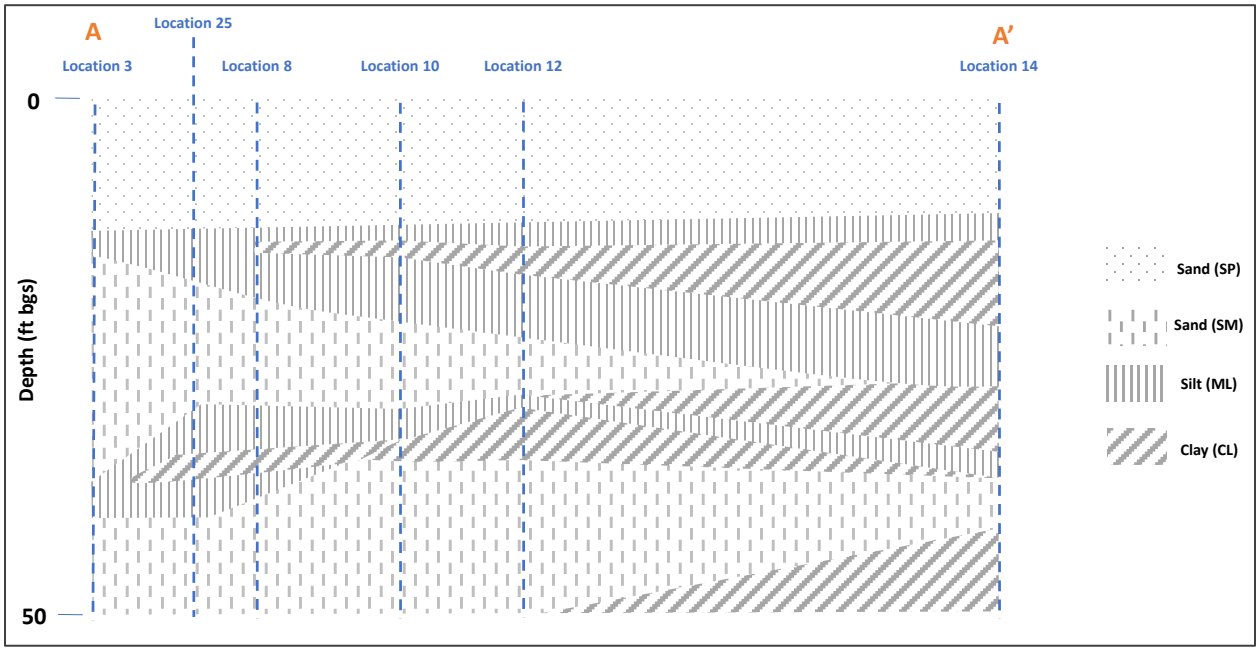

Figure 5-8. Geologic Cross-Section A–A'. *Horizontal distance is approximatley 920 ft. Groundwater flow direction is from left to right (northeasterly).*

Identification of Source Zone

The highest total PFAS concentrations in both soil samples (30,000 ug/kg, location 3) and groundwater samples (5,140 ug/L; location 25) were found in the immediate vicinity of the former firefighter training area (FFTA). A similar pattern was observed for most individual PFAS. In addition, the highest PFAS concentrations in surficial soils were observed within the same general

area (Figure 5-9). This distribution supported the assumption that AFFF used in the vicinity of the former pit is the primary source of PFAS (Figure 5-9).

ECF-based AFFF was known to have been used at the site and is confirmed based on the high concentration of PFOS as well as the widespread occurrence of PFOS at expected branching percentage (i.e., percent of branched PFOS isomer) (22-25%) (Figure 5-9, 5-10, 5-13). Telomer-based AFFF was also presumably used at the site, as evidenced by the presence of elevated levels of multiple fluorotelomers within the source area (e.g., 4:2 FTS, 6:2 FTS, 8:2 FTS) and several PFOA samples where the branching percentage was too low to be plausibly attributed to PFOA in ECF-based foams.

The relative contribution of PFOS and PFOS precursors is high, particularly in the FFTA. However, PFOA mass is significant at some depths and locations, particularly at depths ≥ 35 ft bgs (Figure 5-11, Figure 5-12).

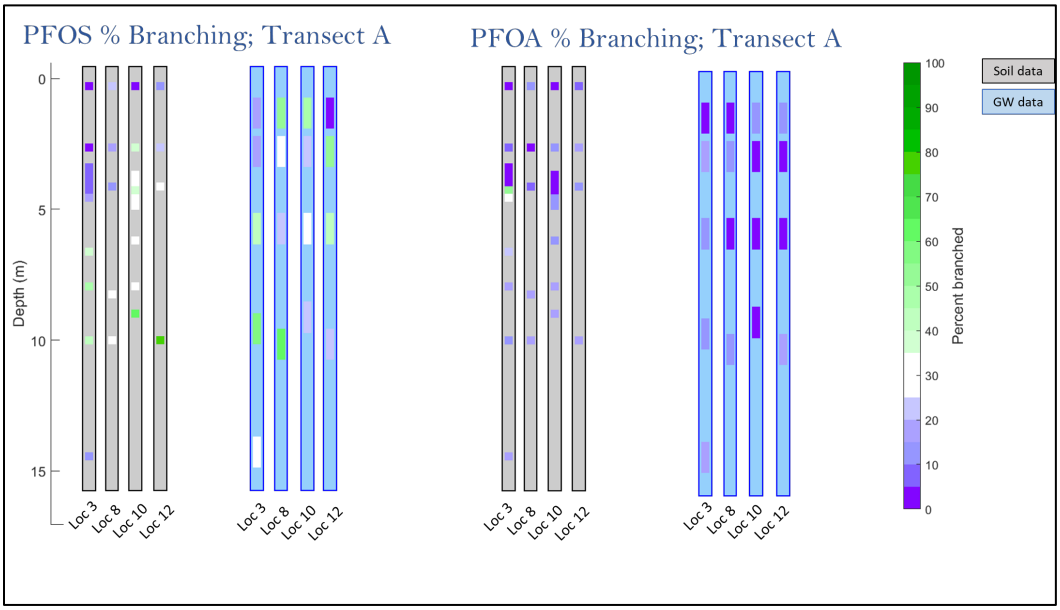

Figure 5-13. Percentage of Branched Isomers in PFOS (left) and PFOA (right) in Soil and Groundwater for Transect A.

Transport Processes: Downgradient Transport

Hydraulic gradients and PFAS data suggest groundwater flows to northeast/east in shallow sands (< 10 ft) but more easterly in deeper sands (> 20 ft). These flows have resulted in formation of a PFAS plume within the surficial aquifer, but concentrations decrease significantly with distance downgradient (see representative contours in Figures 5-14 and 5-15). A contributing factor to this attenuation is likely the decreasing thickness of the shallowest permeable sand layer with distance and diffusion into the lower-k layers, which serve to restrict migration.

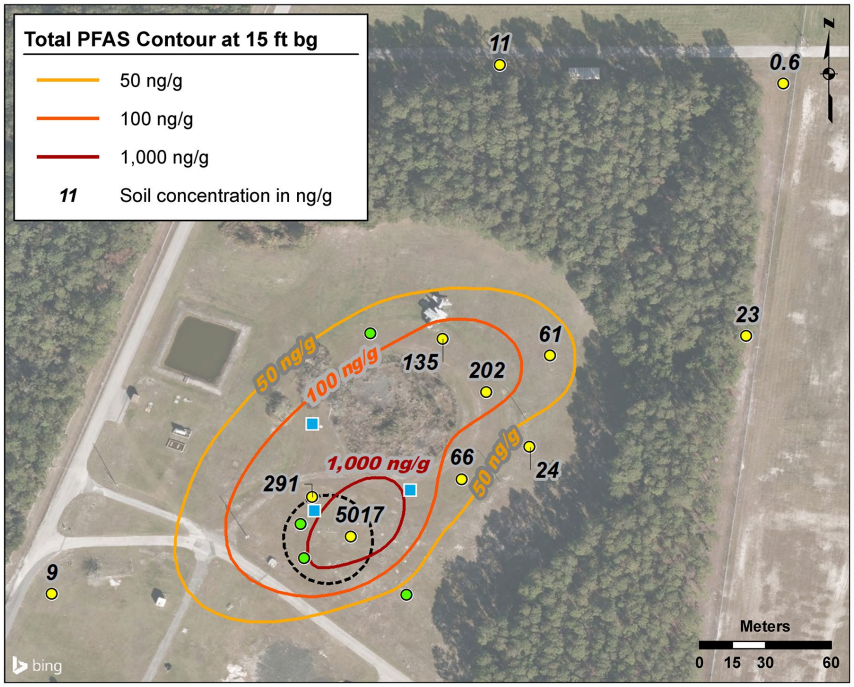

Figure 5-14. Total PFAS in Saturated Soil (15 ft bgs)

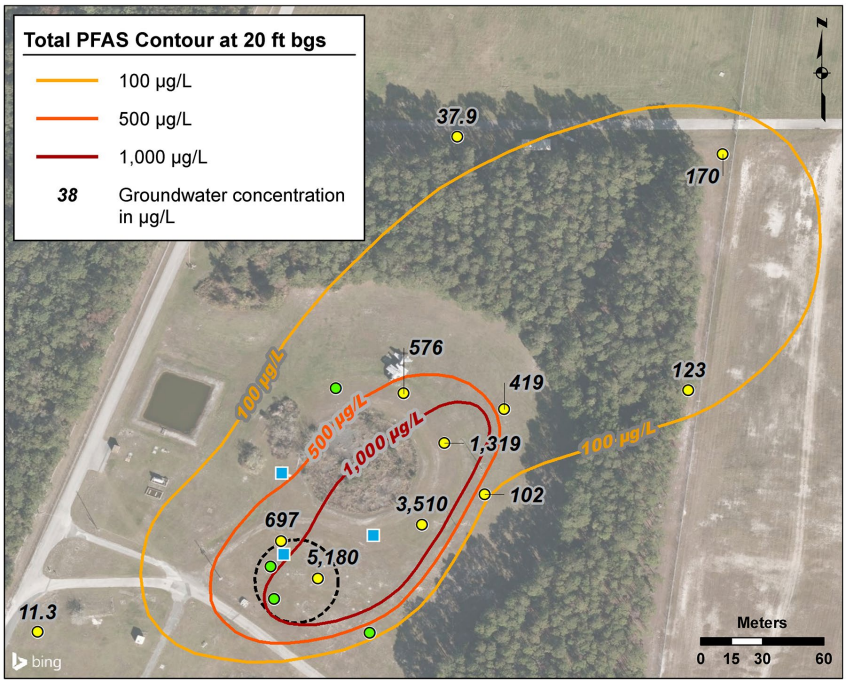

Figure 5-15. Total PFAS in Groundwater (20 ft bgs)

Precursors generally represented a lower percentage of the total PFAS concentration with distance downgradient of the source (Figure 5-13). A similar pattern was observed with depth. This confirms: 1) the likely biotransformation of the more degradable polyfluorinated precursors during

downgradient transport; and 2) the higher contribution of less mobile cationic/zwitterionic species to the total PFAS measured in the source area relative to downgradient areas.

Cationic and zwitterionic PFAS are located primarily within the source area, confirming that these precursor compounds are migrating slower than anionic PFAS as expected (Figure 5-16, Figure 5-17).

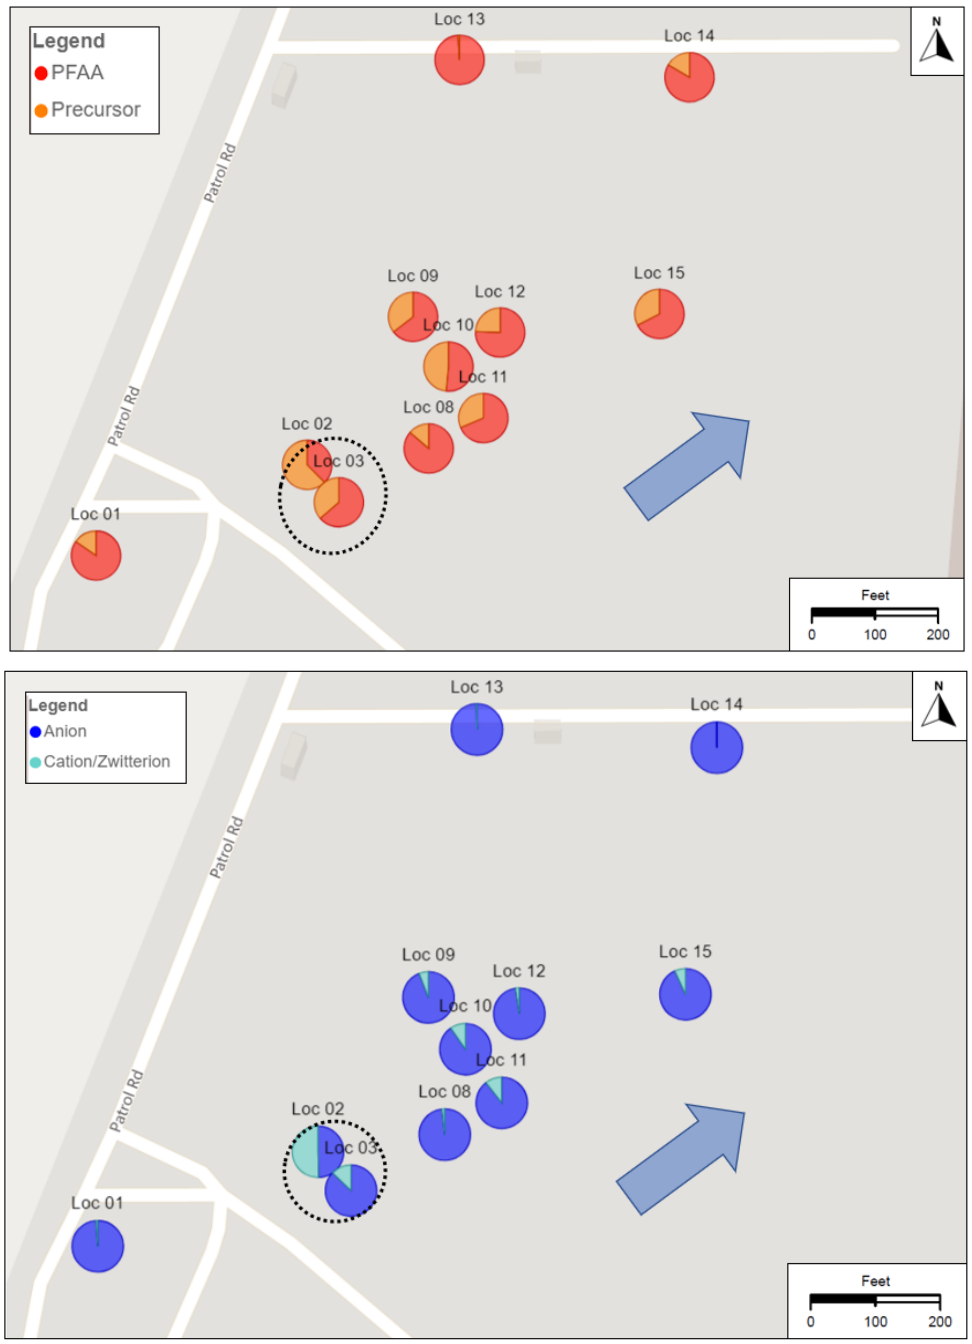

Figure 5-16: Distribution of PFAAs/Precursors (top panel) and Anions and Cations/Zwitterions in Groundwater (bottom panel).

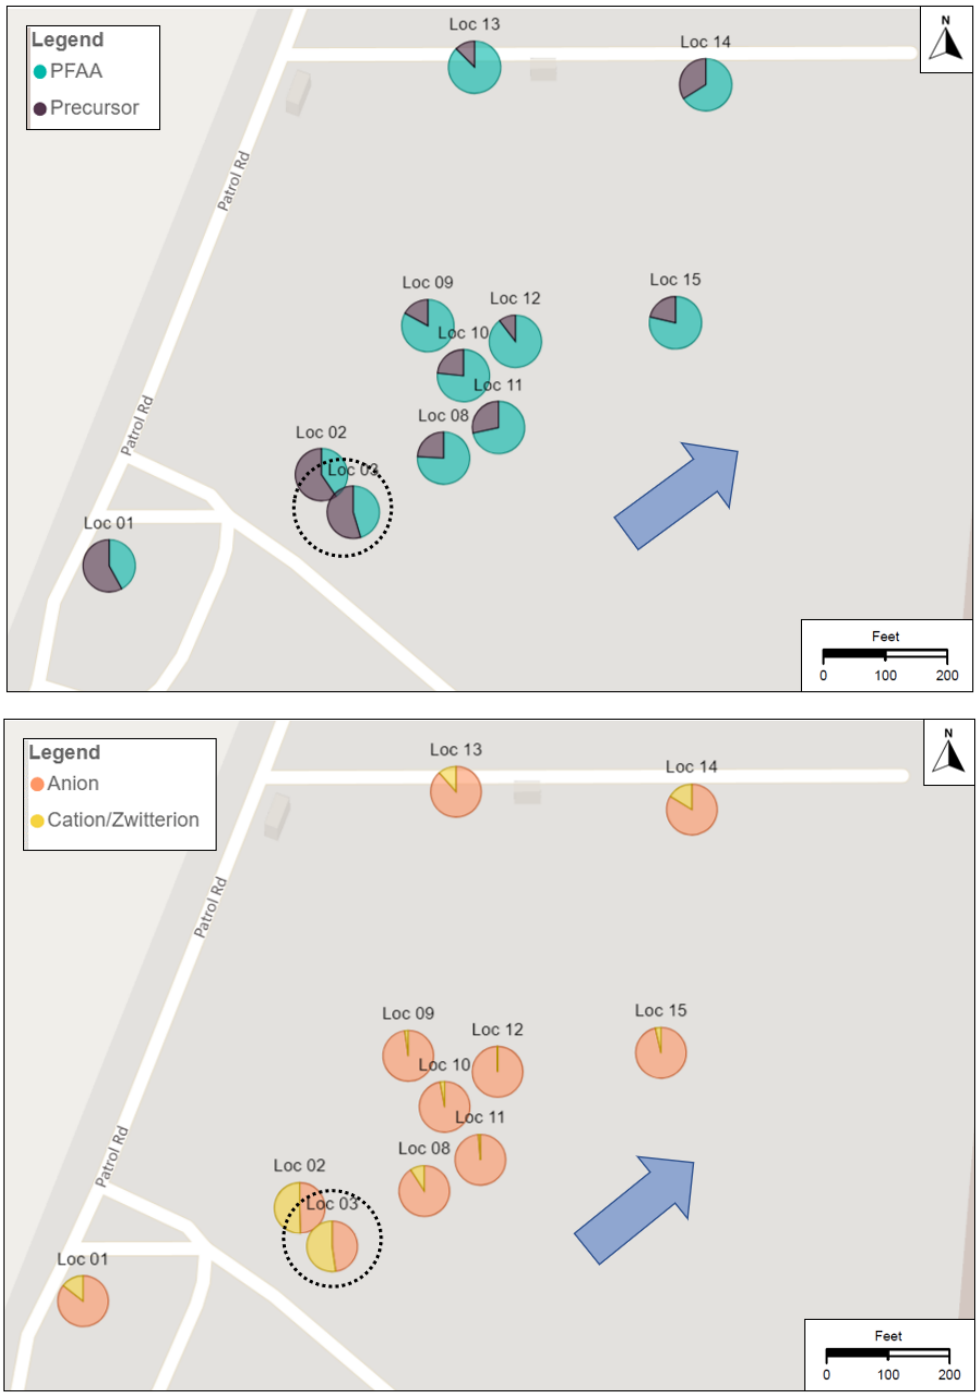

Figure 5-17: Distribution of PFAAs/Precursors (top panel) and Anions Cations/Zwitterions in Soil (bottom panel).

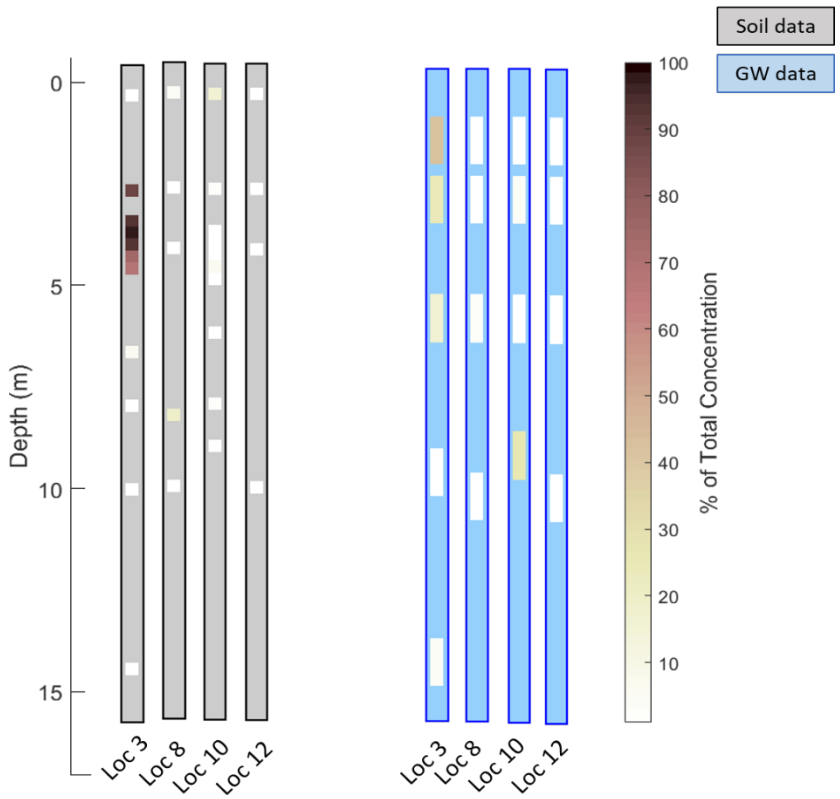

Figure 5-18. Contribution (%) of the cationic and zwitterionic PFAS to the total PFAS concentrations downgradient from the source zone along transect A.

The carbon chain length of PFASs in groundwater samples from the source area and nearby vicinity (6.05–6.74) is generally higher than in groundwater samples located near downgradient (5.82–6.75) and far downgradient (5.83–6.43) (Figure 5-19). Wilcoxon Rank Sum tests conducted on the weighted average chain lengths in the source vs. near downgradient ($p=0.69$) and source vs. far downgradient locations ($p=0.55$) were not statistically significant. Despite the lack of statistical significance, the general spatial trend is consistent with less retardation of shorter-chain compounds during groundwater transport.

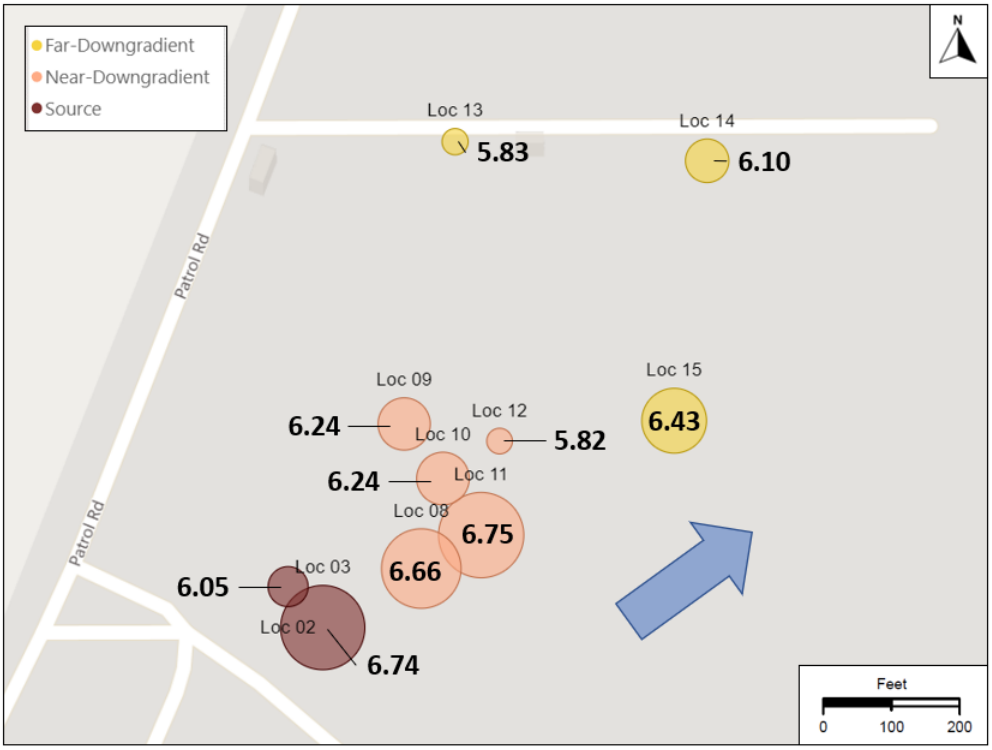

Figure 5-19: Weighted-Average Chain Lengths per Location

Finally, PFAS has been observed at several—but not all—locations along the shoreline for the St. John's River (data not shown, sampled by others). PFAS detected in the shoreline samples were solely anionic and included no precursors. Compounds with the highest concentrations were PFOS, PFHxS, PFOA, PFHxA, and PFBS.

Transport Processes: Retardation

Soil adsorption coefficients (apparent K_d values) were calculated for every sampling depth where a paired soil and groundwater sample were collected (total of 32 pairs). The apparent K_d values were calculated by dividing the total soil concentration in ng/kg (which includes both sorbed and aqueous phase mass) divided by the groundwater concentration in ng/L. This apparent K_d approach was used because some of the soil/groundwater pairs using K_d = (total mass – aqueous mass) ÷ (aqueous mass) resulted in negative K_d's. These discrepancies were attributable to scatter in the groundwater and soil data (i.e., direct measurements of soil porewater mass were not available, so groundwater data were used as a surrogate). Therefore, this simpler apparent K_d, which is sometimes used in the groundwater field as an approximate K_d, was employed here. Because it does not correct for porewater concentrations in the denominator, it is likely a slight overestimation of the actual K_d. Additionally, soil and groundwater characteristics were analyzed at those locations/depths in order to evaluate site-specific factors that may affect retardation.

Table 5-4 below summarizes results of key PFAAs (PFBA, PFHxA, PFOA, PFHxS, and PFOS), as well as the geomean values per soil type. Appendix B includes both K_d and retardation factors for all locations and compounds at NAS Jacksonville.

Notes: i) Each row represents a soil-groundwater sample pair at different locations and depths.

For individual PFAS, the locations where the maximum groundwater concentration were encountered were often different than the depths/locations where the maximum soil concentrations were observed. These patterns highlight the challenges associated with fate and transport modeling that uses equilibrium assumptions for partitioning.

Overall, values of K_d varied significantly with distance, both with depth and distance downgradient. Collectively, the K_d values were generally low compared to literature values, typically below 1 before correcting based on organic carbon content. Additionally, K_d values generally increased with increasing PFAS chain length and were higher for PFSAs than PFCAs, as expected (Figure 5-20).

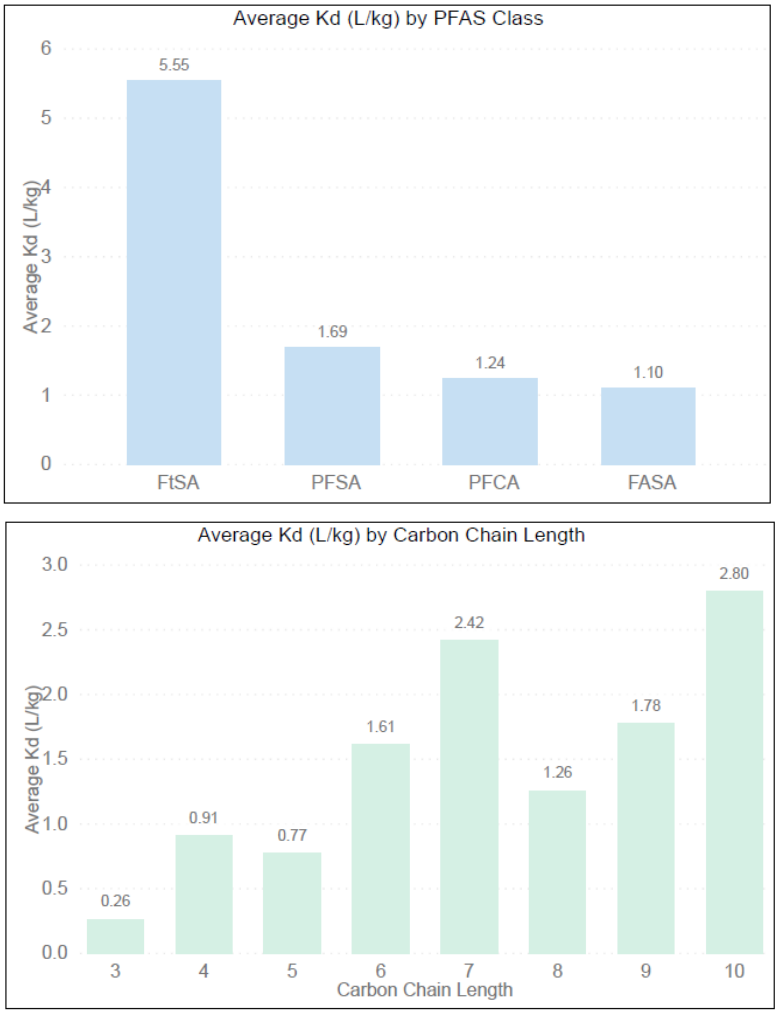

Figure 5-20. Soil to Water Partitioning Coefficient (K_d) for PFAS Based on PFAS Class (Top Panel) and Fluorinated Carbon Chain Length (Bottom Panel) at NAS Jacksonville. ***Values represent average observed in all samples collected from all locations.***

Pearson's correlation factors were evaluated for a range of PFAS (carbon chain length and PFAS class) (Figure 5-21). For most PFAS, a positive correlation with organic carbon could be established, indicating the importance of hydrophobic sorption as a mechanism for retardation (Figure 5-21). Little effect was observed for pH or EC, suggesting that partitioning due to electrostatic interactions may have been limited relative to hydrophobic sorption. In contrast to the expected inverse relationship, cation exchange capacity (CEC) was positively correlated with K_d, but this is likely due to the increased organic carbon associated with soils with higher CEC. Finally, the adsorption of some PFAS compounds can be used to predict the adsorption of other PFAS compounds, as seen in the positive correlations between specific compounds.

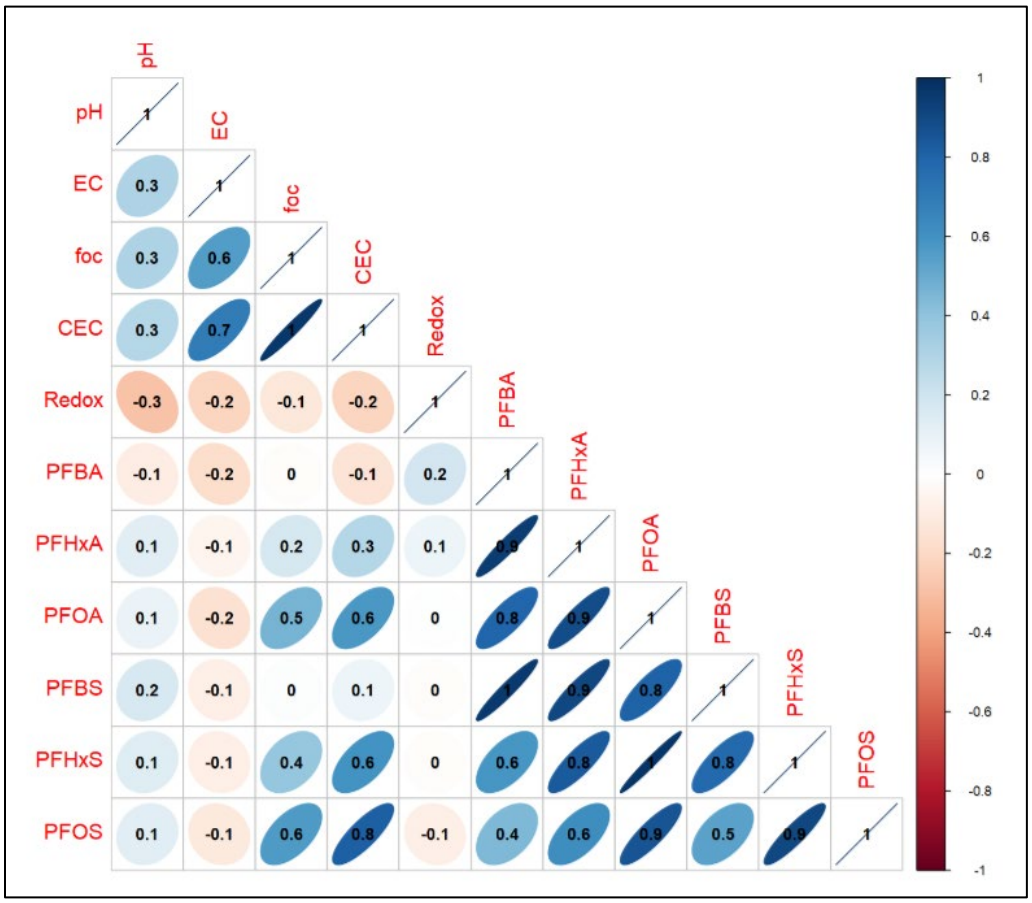

Figure 5-21. Pearson's Correlation Matrix for K_d Values for Individual PFAS vs. Various Soil/Groundwater Parameters at NAS Jacksonville. *Stronger correlations are indicated by numbers closer to 1 or -1, with positive numbers representing a positive correlation and negative numbers representing a negative correlation.*

Transport Processes: Vertical Transport

The vadose zone is thin at this site (often < 5 ft bgs), such that the retention of PFAS within unsaturated soils due to accumulation at the air-water interface or sorption to soils is likely to be limited when compared to sites with a thicker vadose zone. PFAS concentrations in surficial soils were generally lower than those observed in the shallow saturated intervals (Figure 5-9). In part, this may reflect historic remedial efforts within the FFTA, which involved excavation and treatment of surficial soils using low-temperature thermal desorption. In addition, fluctuations in the water table may have promoted periodic flushing that reduced the retention capacity of the shallow vadose zone.

Within the saturated zone, site data confirmed that there is a downward vertical gradient that would promote natural transport between shallow sands and deeper sands. Stratigraphic and geologic data confirmed that the shallow clay layer is relatively thin (a few ft) within FFTA and may not serve as a barrier for vertical transport. Historic data confirm that a groundwater mound with high recharge is present to the immediate west of the FFTA, which can promote radial flow and enhance vertical transport. PFAS data confirm that concentration of most PFAS increase with depth to

about 35 ft bgs. This pattern was observed regardless of whether the samples were collected using DPT (grab samples) or from multi-level temporary piezometers (i.e., the trend was not the result of drawdown of PFAS from shallow depths during drilling). PFAS data also confirm that branching percentages of certain ECF-associated compounds increases with depth to 35 ft bgs, confirming that differential transport of more mobile isomers (i.e., branched) is occurring.

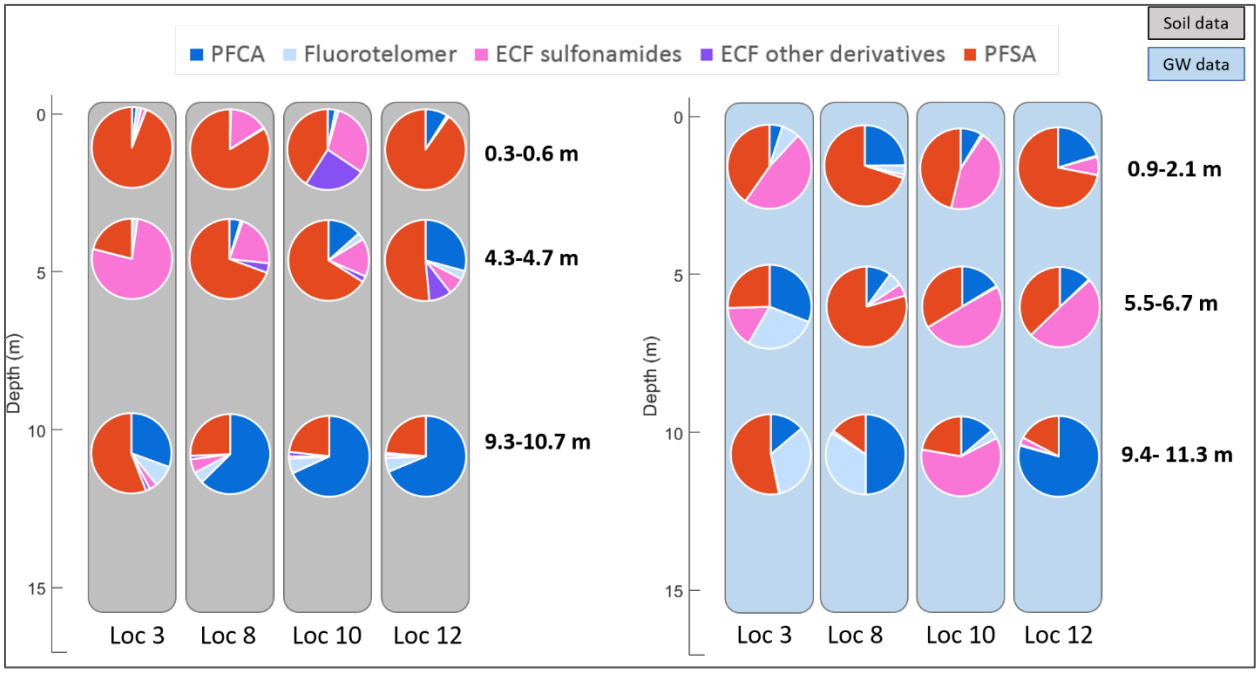

Figure 5-22. PFAS composition changes with depth and distance from the source zone (Location 3) for soil and groundwater along Transect A. *For this graphic, total PFAS concentrations have been split into five superclasses: 1) perfluorinated carboxylates (PFCAs), 2) perfluorinated sulfonates (PFSAs), 3) fluorotelomer-derived compounds, 4) electrochemical fluorination (ECF)-derived sulfonamides, and 5) ECF other derivatives.*

For both soil and groundwater, PFAS composition changes were observed with depth and distance from the source zone (Figure 5-22). PFCAs represented a greater contribution to the total PFAS mass with depth at all locations in soil samples and two of four locations in groundwater samples. Differences between the matrices are potentially due to transformation of fluorotelomer precursors in groundwater. The contribution of ECF sulfonamides, which were primarily of zwitterionic and cationic PFASs, was highest at mid-range depths, coinciding with layers of silt and clay with higher measured values of cation exchange capacity. Only a small percentage of the total PFAS concentration was represented by fluorotelomer compounds, presumably because the AFFF formulations were primarily ECF-derived and/or fluorotelomer compounds had already been transformed to PFAA end products. For the latter case, this would imply that fluorotelomer precursors transform more rapidly than ECF-derived precursors.

Linear and branched isomeric compositional data were also collected for selected PFAS, and the magnitude and spatial distribution of these ratios also provide insight into site history, AFFF formulations used (ECF vs fluorotelomer), transport, and precursor transformation. In both soil and groundwater, enrichment of branched PFOS was observed with downgradient distance from

the source and with depth (Figure 5-13). Enrichment of branched PFASs is consistent with previous studies that have shown that branched isomers are less retarded than their linear counterparts. In soil, only the shallowest samples contained <30% branched PFOS isomers (3-21%), consistent with less retention of branched isomers. The percentage of branched PFOS isomers was more sporadic in groundwater (0-75%), likely as a result of transformation, sorption to soil, and transport across the plume. In addition to differential transport, isomer-specific transformation of precursors is also possible.

The % branching profile for PFOA was different from PFOS, with most soil and groundwater samples containing <20% branched PFOA isomers regardless of location and depth of sampling. The low proportion of branched isomers suggests that at least some PFOA presently in the subsurface was derived from transformation of linear fluorotelomer precursors, as discussed in more detail later in this section.

Transport Processes: Evidence for Matrix Diffusion

The depth-discrete PFAS data, as reflected in the cross-sections, indicated that total PFAS concentrations were generally higher in shallow clay/silt sublayers relative to adjacent sandier sublayers. This suggested that PFAS mass storage due to diffusion and/or sorption.

Compartmental modeling of this dataset was performed as part of a companion study and was published in Adamson et al. (2020). In this case, it was important to distinguish soil intervals contain PFAS primarily due to advection vs. primarily due to diffusion. Hydraulic conductivity of the four main soil types at the site were estimated and showed clean sand (SP) is dominated by advection while the remaining soil types can be considered low-permeability and likely dominated by diffusion. Based on this evaluation, 82% of the total PFAS mass was found to be associated with soils classified as lower permeability. This percentage was even higher for precursors (91%). The PFAS distribution confirmed that that there has been sufficient time to cause retention of most of the remaining PFAS mass within lower-permeability (lower-k) zones. This is particularly notable within the source area, given that 93% of the total PFAS mass (and 99% of the precursor mass) was found to be associated with lower-permeability soils. Radial flow and vertical gradients observed within the source area likely contributed to migration of PFAS to interfaces between high and low permeability zones. PFAS mass that is now located in these lower-permeability zones is subject to enhanced, long-term retention due to the lack of flushing and the relatively slow back diffusion rates that would be expected. Back diffusion from low-permeability matrices has been shown to be a major contributor to plume persistence for other compounds, and these results suggest that it is likely to be a relevant fate and transport processes at some PFAS sites as well.

The mass balance evaluation reported in Adamson et al. (2020) also confirmed that significant retention of zwitterionic and cationic PFAS within low-permeability zones was observed at this site. Only 6% of the estimated total mass of zwitterionic/cationic PFAS was present in the most permeable sands. This was likely attributable to the higher cation exchange capacity (CEC) and higher organic carbon that were measured in the silt and clay-rich portion of the groundwater-bearing unit. These precursors may be persistent due to limited bioavailability within lower-k soils where mass transfer limitations would be an issue. These mechanisms likely contribute to the observed persistence of precursors within the source area and limit the rate of conversion to PFAA end products.

Evidence for Biotransformation of Precursors

Several presumed biotransformation products have peak concentrations at intermediate locations from the source. This includes the fluorotelomer sulfonates (4:2 FTS, 6:2 FTS, and 8:2 FTS), which are at the highest concentrations of all fluorotelomer compounds in both soil and groundwater. These compounds are suspected intermediates the transformation of other precursors because they are generally not a major component of AFFF or other PFAS sources. The fluorotelomer sulfonates are present in both soil and groundwater, but while the highest soil concentrations are found near the source, the highest aqueous-phase concentrations are found a considerable distance from the source at Location 11. This suggests transformation is occurring along the downgradient flow path from the source.

Production of PFOS from perfluoroalkyl and polyfluoroalkyl sulfonamide derivatives is expected based on existing aerobic soil biotransformation studies. Several C8 ECF-sulfonamides were detected at the site, including TAmPr-FOSA, AmPr-FOSA, TAmPr-FOSAPrA, and these may be PFOS precursors.

The low proportion of branched isomers indicates that some portion of PFOA presently in the subsurface was derived from transformation of linear fluorotelomer precursors. In addition, sulfonamide-based ECF PFASs can be precursors to PFSAs, but amide-based ECF PFASs may also be precursors to PFCAs. For example, N-dimethyl ammonio propyl-perfluorooctane amide (AmPr-FOAd, a C8 amide) is a potential precursor to PFOA and was detected at 399 ng/g at Loc 3-12 ft bgs soil. Other soil samples from this same location (e.g., Loc 3-15 ft) contained higher percentages of branched PFOA than the rest of the site, which could be related to transformation of branched AmPr-FOAd or other amide-based ECF precursors.

Given the relatively high concentrations of ECF-derived precursors observed at this site, the data suggest that these compounds may transform more slowly than fluorotelomer-derived precursors. Increases in the PFHxS:PFOS ratio with distance have also been used in other studies as an indicator of biotransformation along the groundwater flow path, and this pattern was observed at this site.

Evidence was also observed of specific transformation pathways, specifically patterns where compounds that were found at higher concentrations in downgradient soil and, in some cases, groundwater (relative to the source zone) that were suspected to be a result of transformation. Although transport can also result in higher concentrations downgradient, the source zone soil typically acts as a long-term source to the groundwater due to retention processes (e.g., partitioning, diffusion). Evidence of specific transformation pathways included identification of precursors that would result in the formation of perfluorohexane sulfonamide (FHxSA), including N-dihydroxy propyldimethyl ammoniohydroxymethyl propyl-perfluorohexane sulfonamido propyl sulfonate (DiOHPrAm-MeOHPr-FHxSAPrS), N-sulfopropyl dimethylammoniopropyl perfluorohexane sulfonamido propyl sulfonate (SPrAmPr-FHxSAPrS), N-hydroxyethyl dimethylammoniopropyl perfluorohexane sulfonamido propylsulfonate (EtOH-AmPr-FHxSAPrS), and other ECF sulfonamide-based zwitterions that potentially undergo transformation to form. These zwitterionic precursors were detected in AFFFs in Barzen-Hanson et al. (2017). The perfluoroalkyl sulfonamides are of particular interest because they can be precursors to PFSAs under certain conditions and have been detected at high environmental

concentrations. Although transformation of these particular zwitterions has not been previously reported, Mejia-Avendaño et al. (2017) did report the transformation of a structurally-similar perfluorooctane sulfonamide quaternary ammonium compound to FOSA. Figure 5-23 shows one possible transformation pathway where FHxSA is formed via sequential cleavage of the alkyl group at the tertiary and then secondary sulfonamide. This is similar to the perfluorooctane sulfonamidoethanol transformation pathway proposed in Rhoads et al (2008).

All of the zwitterionic PFASs in Figure 5-18 were primarily encountered in soil and groundwater samples from the source area, while their potential transformation products were detected at higher concentrations in groundwater and soil downgradient of the source. The intermediate SPr-FHxSA was not detected in soil samples from the source area Location 3, but it was in sporadic downgradient soil samples as well as most groundwater locations. This compound is likely more mobile due to its two negative charges at environmental pH, which increases its tendency to partition to the aqueous phase.

FHxSA was prevalent in both soil and groundwater. In many samples, its concentration was among the highest anionic PFASs. While the samples with the highest concentrations of zwitterionic and cationic precursors were encountered in the source area, the soil sample with the highest concentration of anioic FHxSA was farther downgradient at Location 8 in the near surface sample (448,000 ng/kg). In addition, the farthest downgradient wells still contained FHxSA. This suggests that FHxSA is an in situ transformation product. Groundwater concentrations of FHxSA were also higher downgradient, suggesting that transformation of this compound has occurred during groundwater transport. These results illustrate that FHxSA and other FASAs are important analytes for site characterization because they can provide insight on in situ transformation. Previous studies have reported perfluoroalkane sulfonamides in an AFFF-impacted drinking water supply, AFFF-impacted groundwater, and surface water (D'Agostino and Mabury, 2017, Xiao et al., 2017; Rodowa et al., 2020). The findings herein support previous hypotheses that these compounds are associated with in situ biotransformation processes.

Note that while the zwitterions listed above all contain a propyl sulfonate group, there are many other zwitterionic and cationic compounds which contain the perfluoroalkyl sulfonamide chain and could therefore be precursors to FHxSA and eventually lead to the formation of PFHxS. For example, compounds in the classes TAmPr-N-MeFASA and TAmPr-FASA were among the highest concentrations at source area Location 3. Specifically, the C6 homologs TAmPr-N-MeFHxSA and TAmPr-FHxSA were present at concentrations of 2800 ng/g and 2200 ng/g, respectively, in soil, and at 170 ug/L and 58 ug/L, respectively, in groundwater at 13 ft bgs.

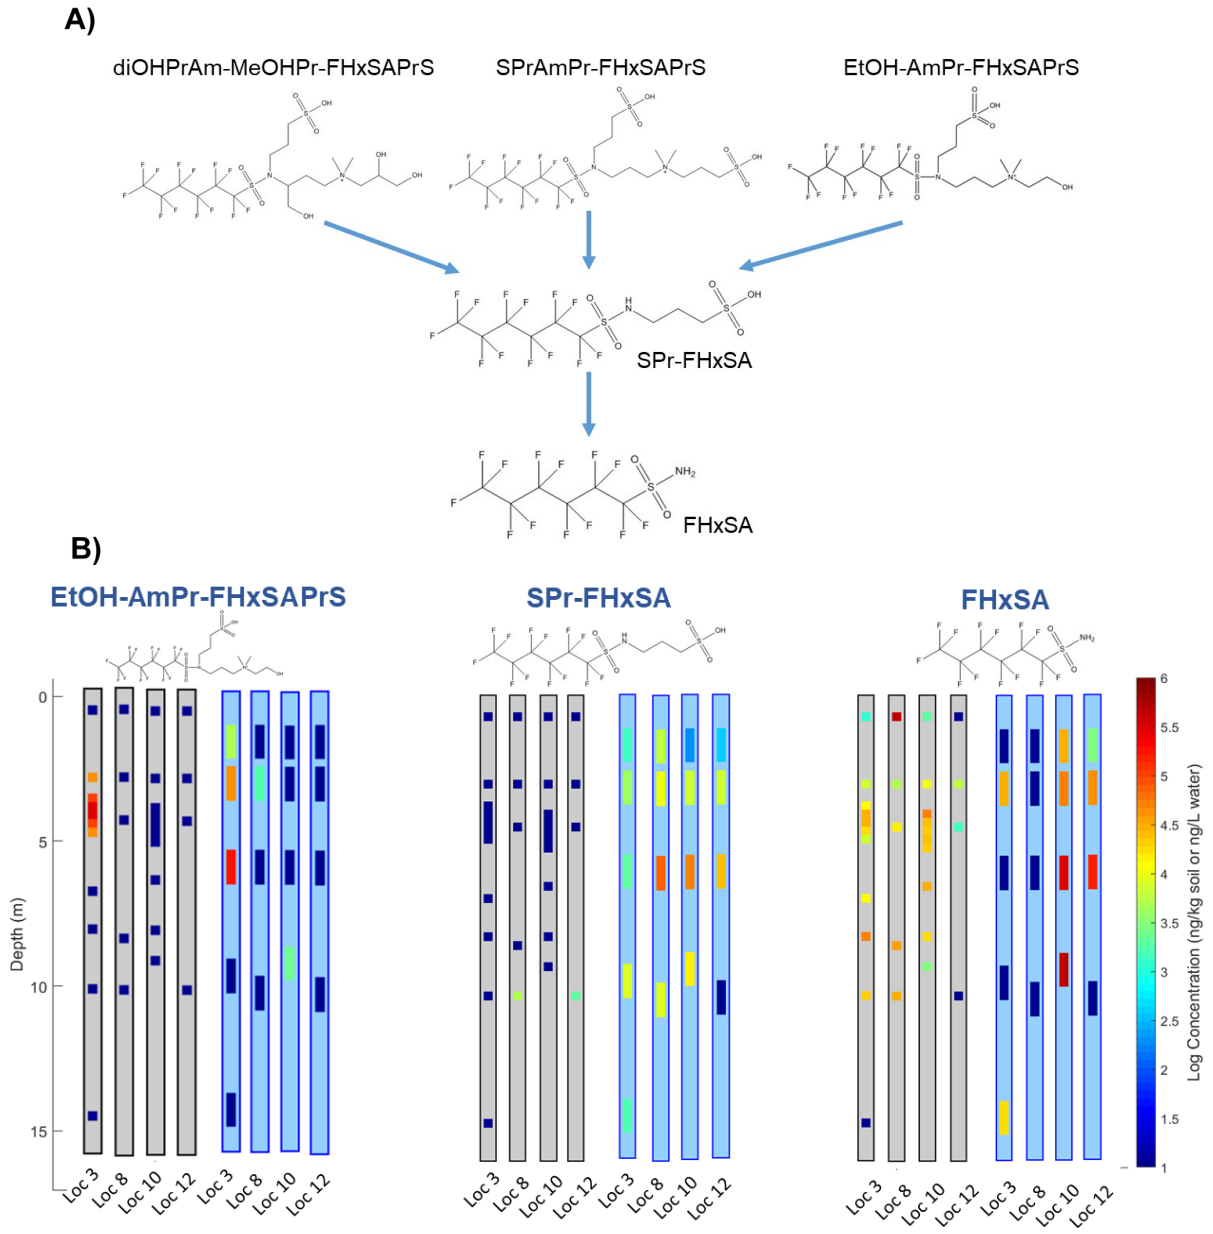

Figure 5-23. The proposed transformation pathway is EtOH-AmPr-FHxSAPrS→ SPr-FHxSA→ FHxSA, along with other potential precursors detected in soil samples (Panel A). *Concentration profiles of possible transformation products in soil and groundwater are shown along transect A (Panel B: soil data in gray bars, groundwater data in blue bars).*

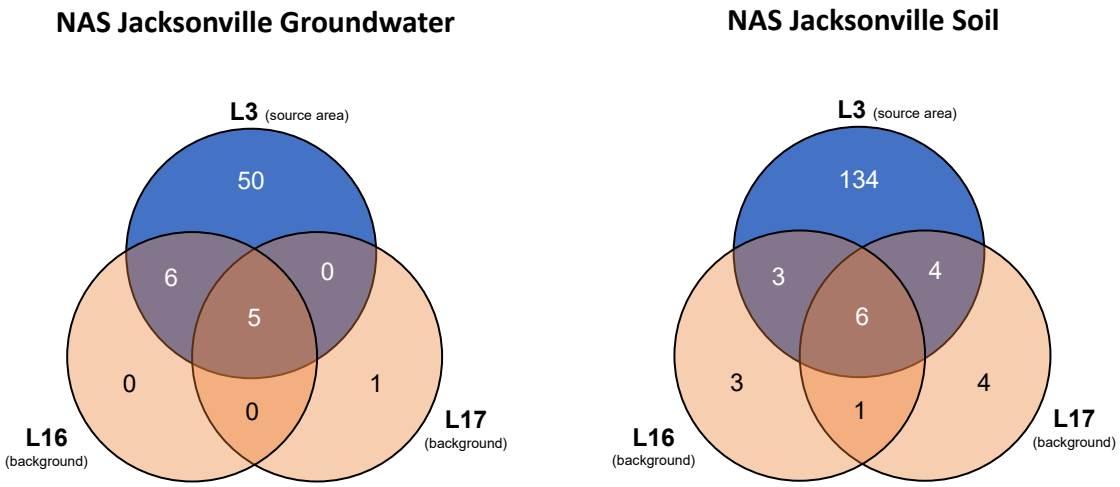
Differentiate AFFF and non-AFFF Sources

PFAS compositional data confirm that multiple types of AFFF have been used within the investigation area. Signature compounds of ECF-based AFFF have been identified, and PFOS is present at or above the expected branching pattern (particularly at the surface). Signature compounds of fluorotelomer foams and other fluorotelomer-based products are also present, and

PFOA branching patterns (< 20% in many samples) confirm that some PFOA is likely originating from a non-3M AFFF source (especially at the deepest intervals). Within the source area, PFOS and PFHxS were typically the highest concentration PFAAs in soil, along with PFOA and PFHxA. PFCAs and PFSAs of multiple chain lengths were both well represented in most samples, with the latter generally at higher concentrations. However, ECF-based sulfonamides (predominantly C6 compounds) and other ECF-based derivatives were frequently present at higher concentrations than PFAAs, as well as fluorotelomers in soil and (to a lesser extent) in groundwater, The primary fluorotelomer sulfonates present were 6:2 FTS and 8:2 FTS.

PFAS was present at all locations, but the background locations (L16 and L17) contained relatively low levels in both soil and groundwater. The number of different precursor compounds detected in some samples are consistent with not only multiple types of AFFF but also raise the possibility of other PFAS sources. For example, in the soil and groundwater samples from location L3 (the presumed source area), a total of 147 different compounds were detected in soil and 61 different compounds were detected in groundwater. Background locations were dominated by anionic compounds, which were largely similar to those detected in the source area (see Figure 5-24 Venn diagram). The compounds that were unique to the background locations included several longer-chain fluorotelomers in soil (10:2 FTSi, 11:2 FTCA, 12:2 FTCA). The presence of these compounds suggests that alternative PFAS sources may have contributed to the observed PFAS, although a source cannot be readily identified. For example, shorter chain fluorotelomer intermediates that have been proposed to be diagnostic of landfill leachate (e.g., 5:3 FTCA) could not be detected at any location. Sulfonamides that are generally not expected to be associated with AFFF (e.g., MeFOSA, EtFOSA, corresponding sulfonamidoacetic acids) were detected sporadically and only at trace levels, although FOSA (a potential degradation product) was detected more consistently at multiple locations, albeit at relatively low levels. Given that many of the unique compounds to the background (as well as source area) locations were identified through suspect screening, care should be taken when using these data for forensic purposes.

Location L1 was slightly upgradient of the firefighter training area and relatively proximate to the wastewater treatment plant. However, due to the radial flow directions in this portion of the site, contributions from the firefighter training area releases were expected at location L1. The data generally support this assumption, especially given the relatively higher concentrations observed in groundwater (maximum total PFAS concentration = 190,000 ng/L). However, soil concentrations were generally lower in magnitude, and the maximum total PFAS concentration (37,800 ng/kg) was encountered at a depth of 34.5 ft bgs. The total concentration of precursors, as well as the relative contribution to the total PFAS concentration, increased with depth at this location. Because many of the precursors were zwitterionic/cationic and expected to be less mobile, a portion of these may have originated from releases that are relatively close to location L1, with an assumption that anionic PFAAs or other more mobile species had already been transported away from this location due to high recharge. Detections that were unique to location L1 included PFCPeCA (perfluoro cyclopentane carboxylic acid) and PFOSi (perfluorooctane sulfinate).



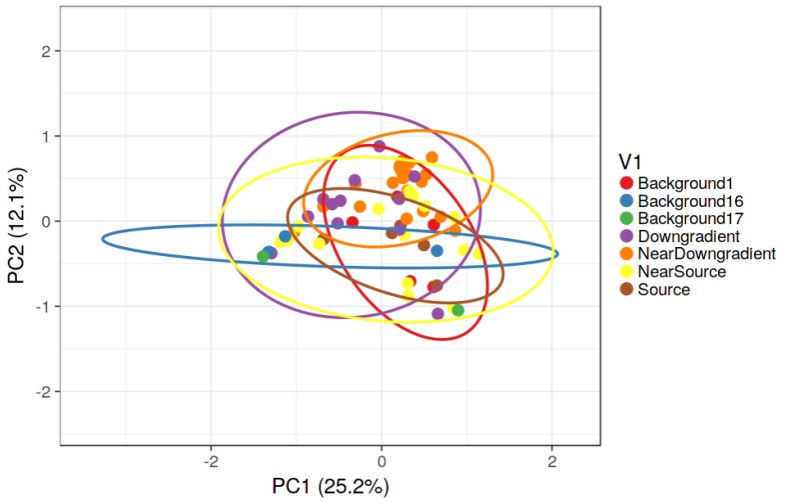


Figure 5-24. Comparison of Detected Compounds at Selected Locations in Groundwater (Left Panel) and Soil (Right Panel) from NAS Jacksonville.

At the other, more distant background locations (Locations L16 and L17), the presence of zwitterionic/cationic PFAS in the source area and relative absence of zwitterionic/cationic PFAS in background locations serves as a secondary line of evidence for differentiating between the AFFF source and other diffuse sources. Specifically, the absence of zwitterionic/cationic species in background locations provides further evidence that the PFAS present in these locations derives from a non-AFFF source, potentially through a different application or transport route.

Cluster analysis provided mixed evidence that different PFAS sources were contributing to the observed patterns. PCA results for unfiltered soil and groundwater data are shown in Figure 5-25 highlight that there is substantial overlap in the confidence intervals for source area locations vs. those from background locations. In part, this reflects the variability in the PFAS composition at different individual locations that are within the same groupings. The soil data show more distinct separate clustering of the source area data relative to the two primary background locations (L16, L17). However, PCA1 and PCA2, which are primarily associated with PFAAs for these datasets, only explain 22.9% and 37.3% of the variance for soil and groundwater data, respectively. This reflects the large number of variable (analytes) that are included in the unfiltered analysis and confirms that further processing of the data is warranted.

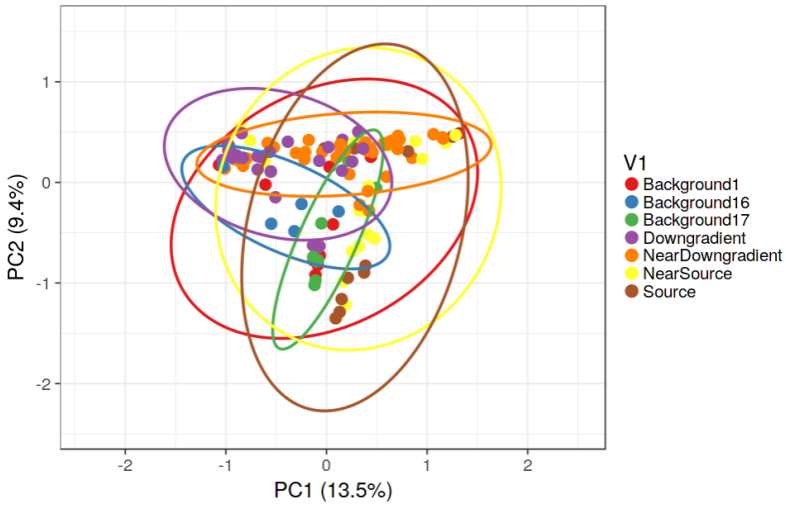

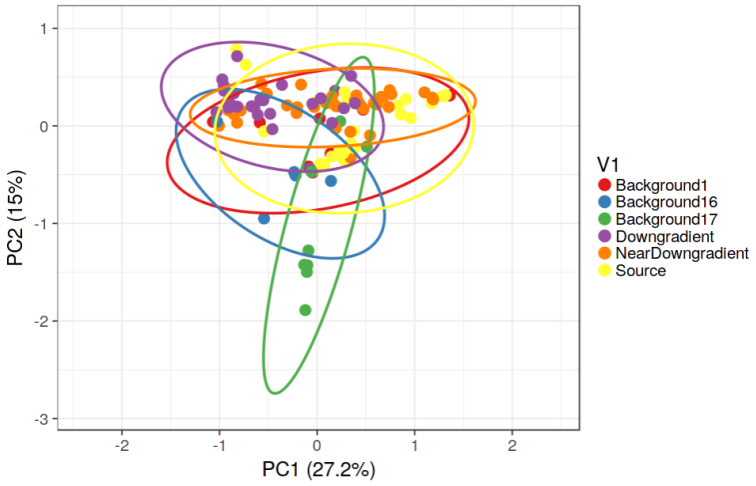

Figure 5-25. Principal Component Analysis for Groundwater Data (Top Panel) and Soil Data (Bottom Panel) from NAS Jacksonville. *Analyses performed on transformed data from all locations and included all reported analytes (unfiltered).*

Filtering the soil data to include only target analytes (Figure 5-26, top panel) and to include only select locations (Figure 5-26, bottom panel) provided further resolution and insight. By reducing the number of variables to only target analytes, the source area data clusters similarly with the near downgradient and downgradient location data, suggesting that these are represent similar PFAS sources even accounting for transport-related compositional shifts. Location L1 also falls within this group, which is consistent with the assumption that PFAS at this location is likely partially associated with the firefighter training area due to radial flow within this area. Data from the primary background locations (L16 and L17) largely fall into clusters that are different than those associated with the AFFF source area, with the exception of a few samples. This clustering pattern becomes even more apparent when only the data from source area location L3 and background location L16 and L17 were included (Figure 5-26, bottom panel). The confidence intervals for the background locations are similar and overlap with only a small portion of the confidence interval

for the source area locations. The variability explained by PCA1 and PCA2 is slightly higher for these two evaluations (42.2% and 34.7%), but these results help illustrate the complexity of these datasets given the degree of spatial variability of PFAS concentrations.

A similar pattern is noted in the HCA results, where the background samples group similarly and are relatively distinct from those from the source area. Collectively, these data support that the PFAS detected at the background locations at this site are unrelated to the releases associated with the firefighter training area, and that the PFAS may have come from non-AFFF sources.

PIGE vs. Total PFAS Concentrations

PIGE results for 43 samples were compared to the Total PFAS concentrations in groundwater. As seen in Figure 5-28 below, the relationship is moderately linear, with an r2 of 0.57. The Spearman's Correlation Coefficient indicated that the relationship is statistically significant ($p<0.05$). As such, results from this site indicate that PIGE could be used reasonably well to conduct site characterization for groundwater.

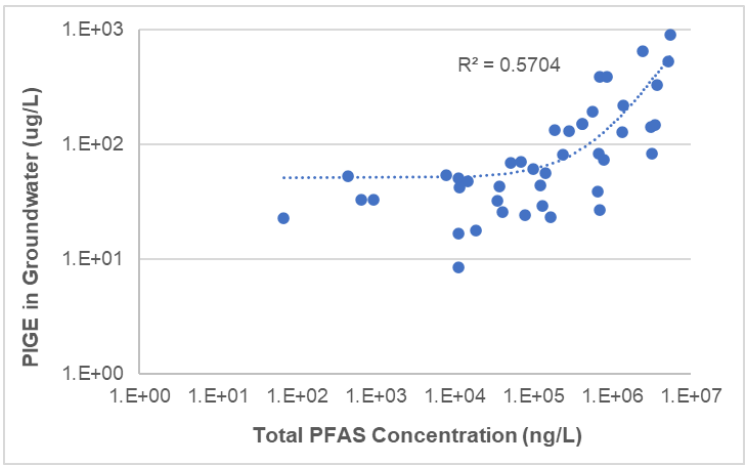

Figure 5-28. PIGE in Groundwater vs. Total PFAS. Log-scale axes with best fit line from linear regression.

Conceptual Site Model

The spatial patterns in PFAS data were used to develop a Conceptual Site Model that identifies the relevant transport processes, the potential for migration, and active natural attenuation mechanisms at the site (Figure 5-29). This can include retardation due to various mechanisms, as well as biodegradation of polyfluorinated compounds which may serve as precursors to PFAAs. As described above, PFAS concentrations were generally highest in shallow saturated soils, in part due to the presence of low-permeability soils that helped limit transport. PFAS was present at elevated levels in surface soils, but the contribution of vadose zone processes was limited by the shallow water table and previous soil excavation and treatment efforts. PFAS retention within the source area can be attributed to mechanisms such as retardation due to the partitioning of PFAS to solid-phase surfaces as a result of hydrophobic and electrostatic interactions, and slow advection and diffusion into shallow lower-permeability soils. These processes were particularly evident for zwitterionic/cationic precursors, which were strongly retained within source area soils with low permeability. The groundwater plume was largely comprised of PFAAs, and the presence of intermediates of suspected biotransformation pathways confirmed that this mechanism was active within the plume. Collectively, these processes contribute to attenuation of PFAS concentrations moving away from the source, with decreases in concentration of several orders of magnitude observed between the source area and the farthest downgradient locations.

5.7.3 Results: NBVC Pt. Mugu, CA

Site Characterization Overview

Site characterization was conducted at NBVC Point Mugu, in Ventura County, California from 11 - 27 March 2019. The investigation focused on the former firefighter training area and downgradient points (Figure 5-30). This burn pit (located near investigation point L5) served as the presumed source of PFAS in the area. Locations were selected along a transect that followed the presumed direction of groundwater flow. As noted above, the groundwater flow direction changes seasonally, so this necessitated collecting data in areas to the northeast of the burn pit as well as areas to the southwest of the burn pit. Additionally, two upgradient locations were selected (B1 and B2) to provide background information.

A total of 38 groundwater samples, 72 soil samples and 50 soil and groundwater QA/QC samples were collected as part of this field program.

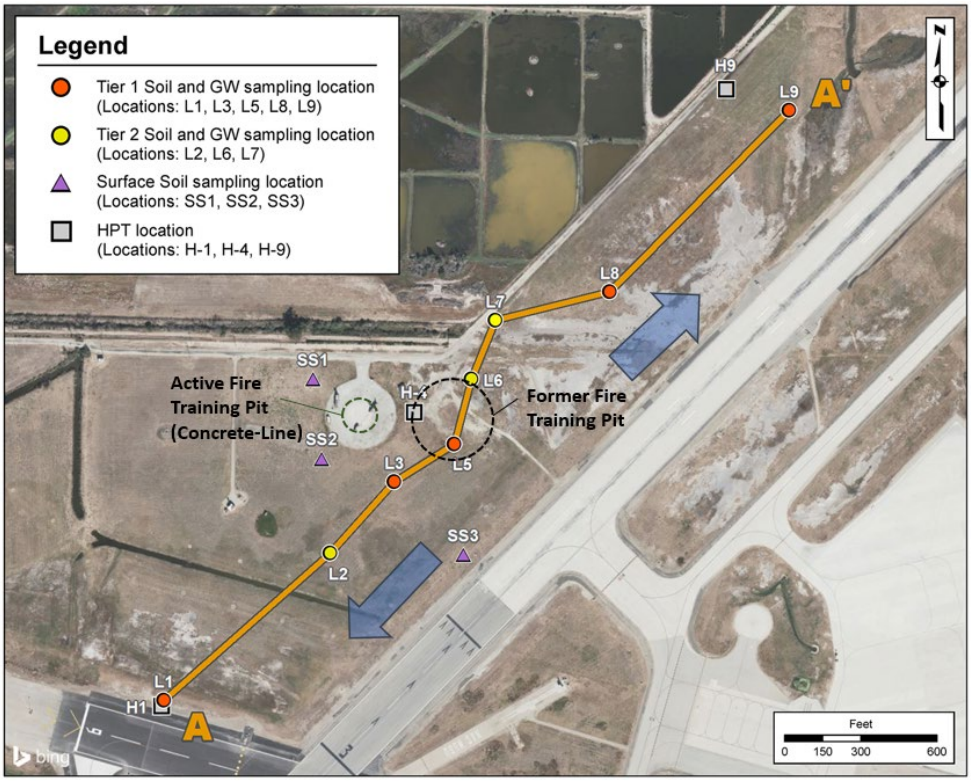

Figure 5-30. Site Map with Characterization Locations and Transect A-A'

Site Hydrogeology

Figure 5-31 below depicts the geologic cross section A-A'. Visual inspection and classification of soil cores indicated that lower-permeability clay and silt lenses were present at shallow depths, with increasing thickness toward the northeast portion of the site. The southwest portion consists predominantly of sands, with the overlying clay/silt layer extending to no more than 10 ft bgs. In the northeast portion, the low-permeability layer extended to approximately 35 ft bgs, although several interbedded higher-permeability sand-rich lenses (0.5 to 2 ft thick) were encountered within this layer.

The HPT logs confirmed that these interbedded layers are reasonably permeable (K>20 ft/d), but a relative lack of lateral connections between lenses may limit their contribution to downgradient transport. The static water levels measured in the field were between 2 and 6 ft bgs depending on location, indicating that the water-bearing unit (sands) is confined or semi-confined. The sampling was conducted during the wet season (March), such that groundwater was assumed to flow to the southwest.

Note that soil characterization efforts were restricted to a depth of ~25 ft bgs at the majority of locations due to difficult drilling conditions (including poor recovery of cores). As such, the geology deeper that 25 ft bgs is approximated in the figures below.

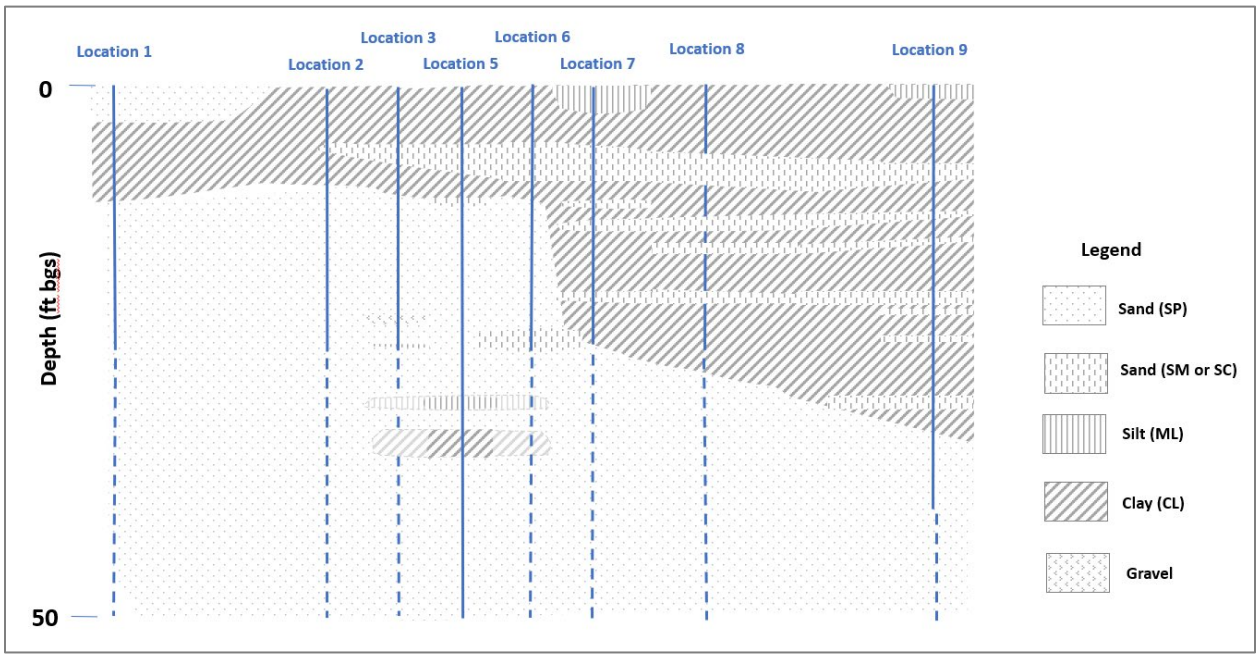

Figure 5-31. Geological Cross-Section A-A' . *Static water levels ranged from 2-6 ft bgs.*

Additionally, Figure 5-32 depicts specific conductivity in groundwater with depth at all characterization locations. Specific conductivity is typically high at this site (maximum specific conductivity of 74 mS/cm), particularly in shallower soils (<25 ft bgs) at locations northeast of the burn pit. In part, these high conductivities reflect regional surface water influences; the site is approximately 2 miles northeast of the Pacific Ocean. However, the patterns with depth are also presumably influenced by seasonal changes in the groundwater flow direction. Groundwater was generally reducing (particularly at deeper intervals) with pH values consistently near neutral.

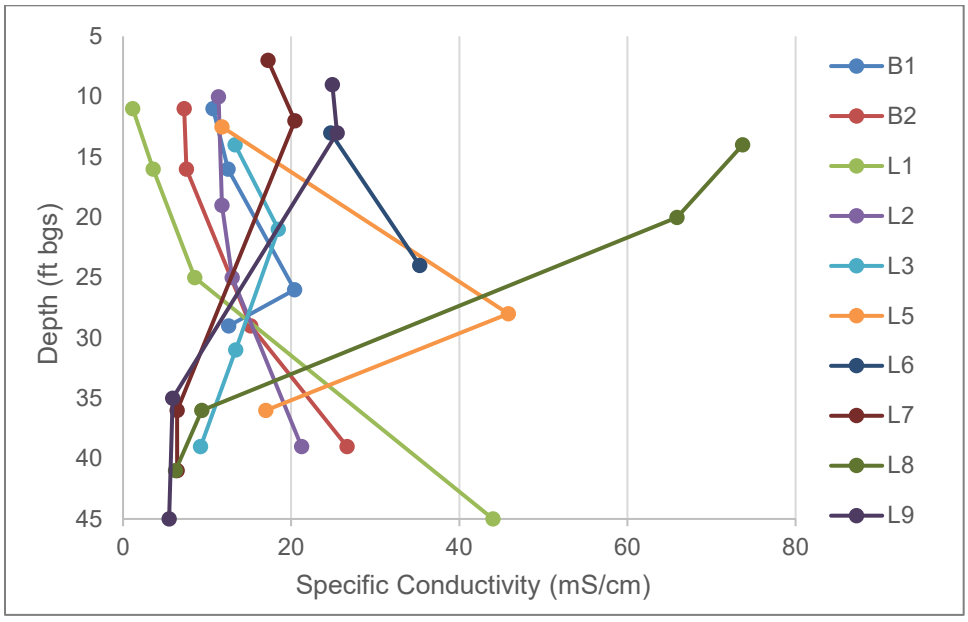

Figure 5-32. Specific Conductivity with Depth at Characterization Locations. *Static water levels ranged from 2-6 ft bgs.*

Identification of Source Zone

Soil and groundwater analytical data were collected for a large suite of PFAS using the high-resolution analytical methods (including target and non-target analyses). Results for PFOS, PFOA, and Total PFAS in both media across the site transect are shown in Figures 5-33, 5-34 and 5-35.

Overall, higher soil concentrations are present near the source zone. For example, the highest total PFAS concentrations in soil are observed at location L6 and L5 near the former burn pit (maximum total PFAS concentration = 13,000,000 ng/kg). Soil concentrations in samples from all other locations are more than an order of magnitude lower than those in the source area. Groundwater concentrations generally show a similar pattern (maximum total PFAS concentration > 6,000,000 ng/L).

This distribution supported the assumption that AFFF used in the vicinity of the former pit is the primary source of PFAS (Figure 5-33, 5-34, 5-35). Similarly, the highest PFAS concentrations in surficial soils were observed within the same general area (Figure 5-9). PFAS was detected in surficial soils through the entire investigated area, with a large percentage of this total represented by PFOS and very little represented by PFOA.

Transport Processes: Downgradient Transport

While total PFAS concentrations in groundwater remain elevated across the site, PFAS concentrations generally decrease significantly moving away from the source area. For example, the average total PFAS concentration in location L6 was approximately 3 orders of magnitude higher than at the far downgradient locations in both downgradient flow directions (locations L1 and L9) (Figure 5-36). This is evidence of that plume expansion is affected by attenuation processes, and suggests that retention within the source area that can be attributed to at least two mechanisms: (1) retardation due to the enhanced electrostatic interactions and decreased partitioning to the aqueous phase within an aquifer with high specific conductivity; and (2) slow advection and diffusion in lower-permeability soils.

This distribution of PFAS in soil and groundwater was evaluated laterally from the source zone and included: i) PFAAs and Precursors and ii) Anions and Cations + Zwitterions (Figures 5-38 and 5-39). Key preliminary findings suggest the following:

- Higher concentrations of precursors in soil and groundwater are encountered in the source area (locations L5 and L6) and immediately downgradient in the southwest direction, as compared to further downgradient locations. The southwest direction (towards the ocean) is typically the dominant flow direction during the season when sampling was performed, and this is reflected in the both the soil and groundwater contours in that direction. Samples from locations in the northeast seasonal flow direction (locations L7, L8 and L9) exhibited much lower concentrations.

- Even though the total PFAS concentration was relatively low in locations outside of the source area, the percentage of total PFAS concentration represented by precursors was high (> 50%) in several samples from these locations, as discussed below.

- Higher concentrations of zwitterionic/cationic PFAS were generally measured in the source area relative to those measured in downgradient locations, particularly in shallow soils. For example, the shallow unsaturated soil sample from location L5 exhibited the highest concentration of zwitterionic/cationic PFAS (1,013 ng/g), with CEtAmPr-N-EtFOSA and TAmPr-FOSA (both C8 compounds) as the highest individual detections. Collectively, these zwitterionic/cationic PFAS represented 52% of all PFAS in this sample. Relatively high concentrations of zwitterionic/cationic PFAS (> 100 ng/g) were also found in shallow soils from location 6 in the source area, but at much lower percentages (< 10%) of the total PFAS concentrations. These charged compounds were largely absent from groundwater samples, reflecting their tendency to partition strongly to soils.

- The majority of soil samples from the two background locations contained elevated PFAS (0–14,000 ng/kg), and groundwater samples from these locations also exhibited concentrations (7,500–136,000 ng/L) that were similar to those observed in the areas downgradient of the burn pit. However, most background samples, including both soil and groundwater samples, were dominated by PFAS precursors. These were largely long-chain (> C8) anionic compounds that were generally unique to these locations (i.e., not found in the source area). A similar pattern was observed in locations L7, L8, and L9 that are in the non-dominant seasonal flow direction (northeast) that were almost solely anionic. In

addition, soil concentrations were higher in unsaturated zone and decreased with depth. As a result, the presence of these precursors outside of the source area is unlikely related to subsurface transport.

- The primary lines of evidence for the influence of groundwater chemistry on limiting transport include: (1) the specific conductivity in all groundwater samples was greater than 5 mS/cm, with a maximum specific conductivity of 74 mS/cm (i.e, at or above the salinity of seawater ~ 50mS/cm). This confirms that there is an abundant supply of ions to neutralize negatively-charged particles, decrease dissolution in groundwater, and enhance sorption of anionic PFAS (both PFAAs and precursors) (also referred to as PFAS "salting out") (Newell et al., 2021); (2) PFAS concentrations decrease significantly in locations outside of the source area (in both of the seasonal directions of groundwater flow), indicating that PFAS transport is retarded relative to groundwater flow despite a strong consistent source term; and (3) Anionic precursors generally comprise a higher percentage of the total PFAS concentration in groundwater than cationic and zwitterionic precursors in all locations. This suggests that the tendency for enhanced mobility of anionic PFAS in groundwater is reduced at this site due to the natural ionic strength that enhances retention.

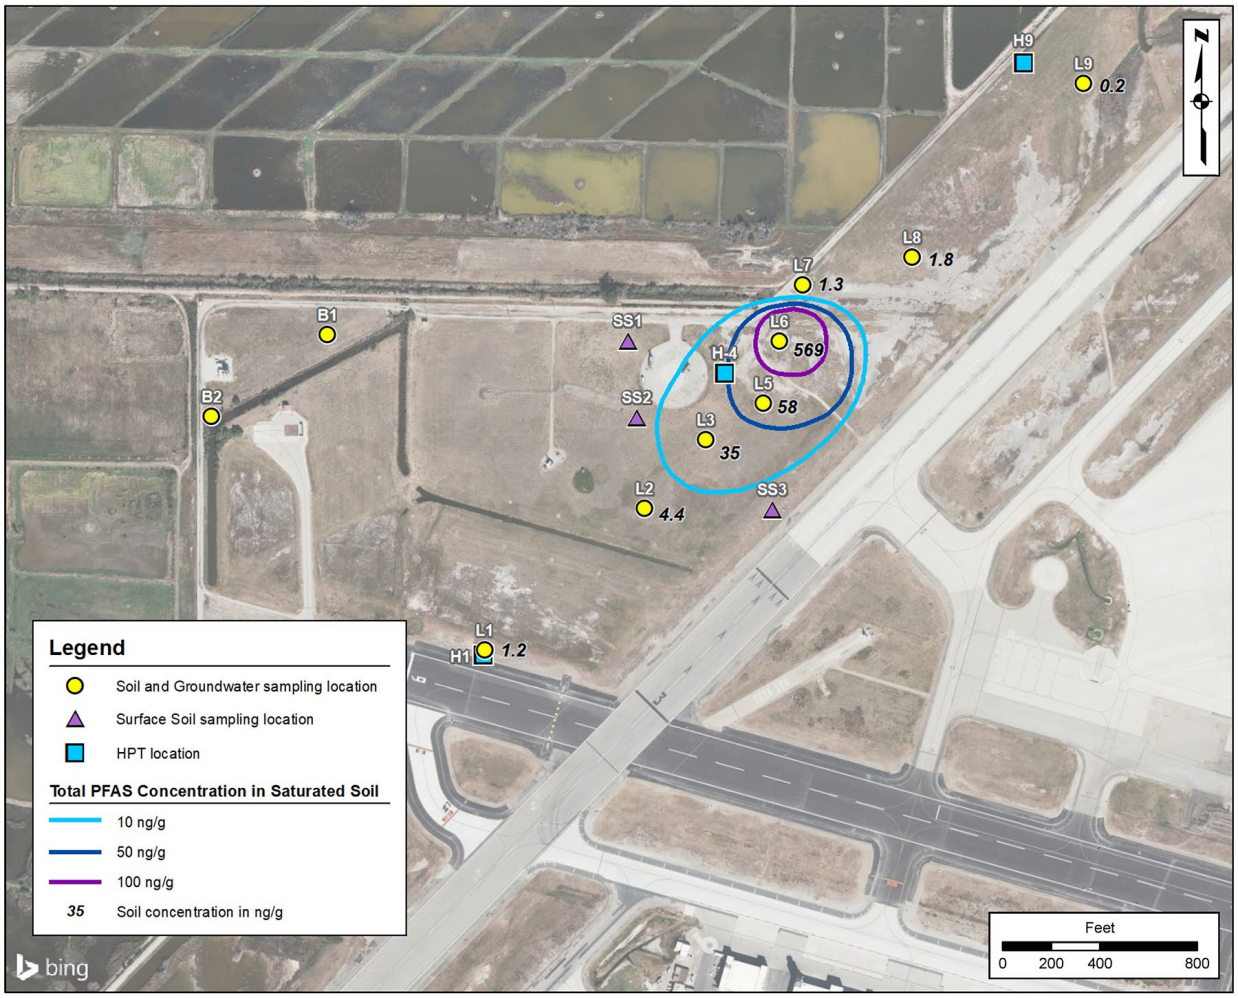

Figure 5-36. Average Total PFAS Concentration (ng/g) of Soil Samples from Saturated Zone

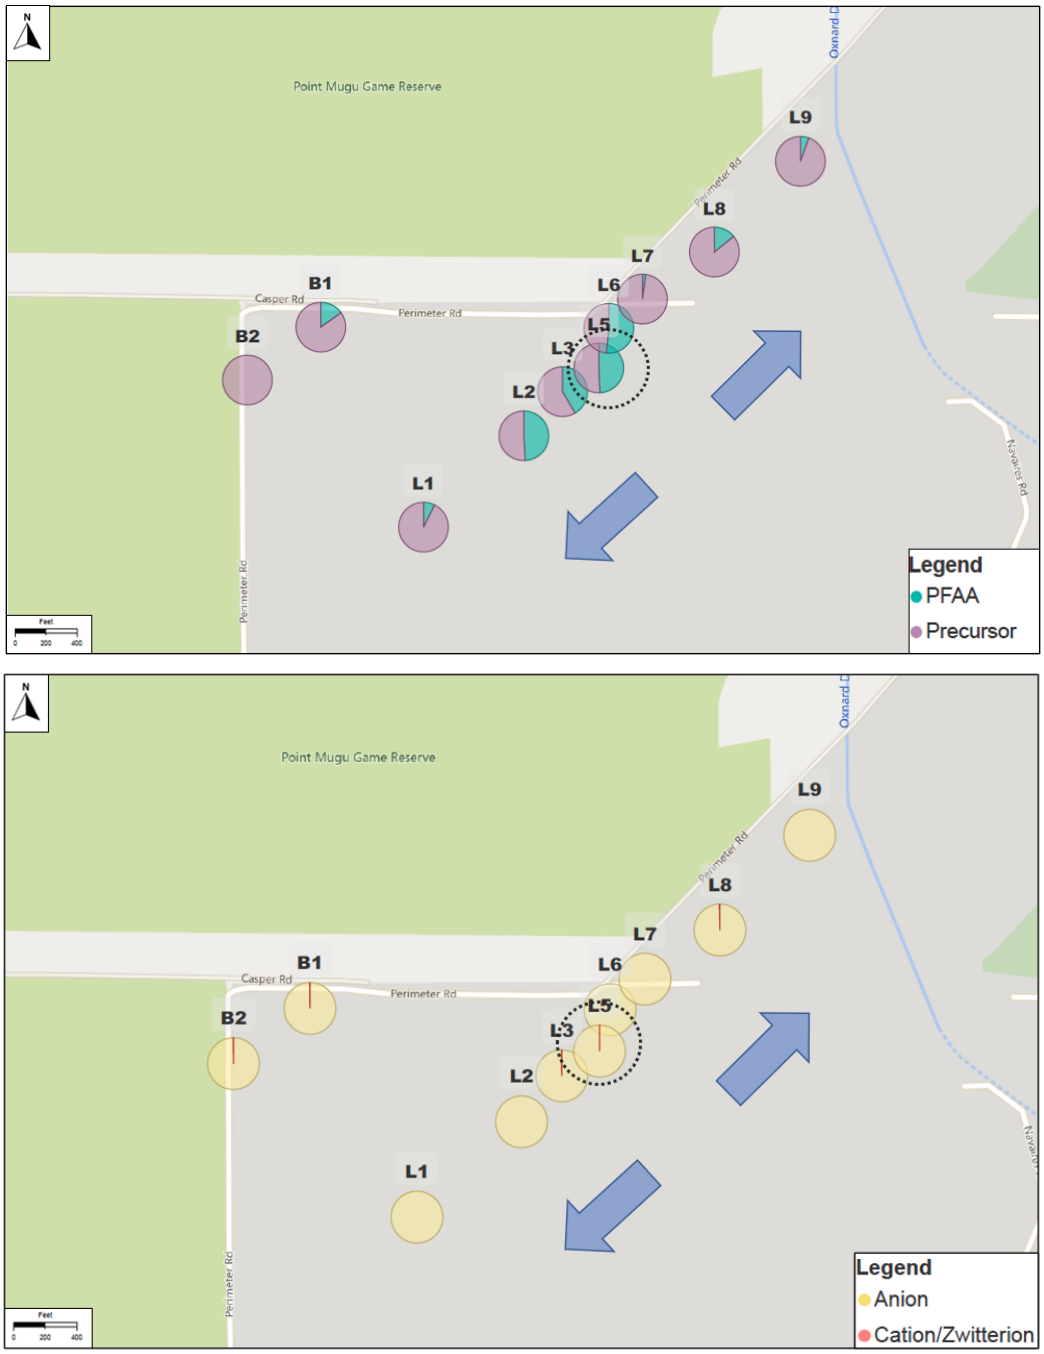

Figure 5-38. Distribution of PFAAs vs. Precursors (Top Panel) and Anions vs. Zwitterions/Cations (Bottom Panel) in Groundwater. *Distribution at each location is based on the average of all depths per location. Arrows show general direction of seasonal fluctuating groundwater flow direction.*

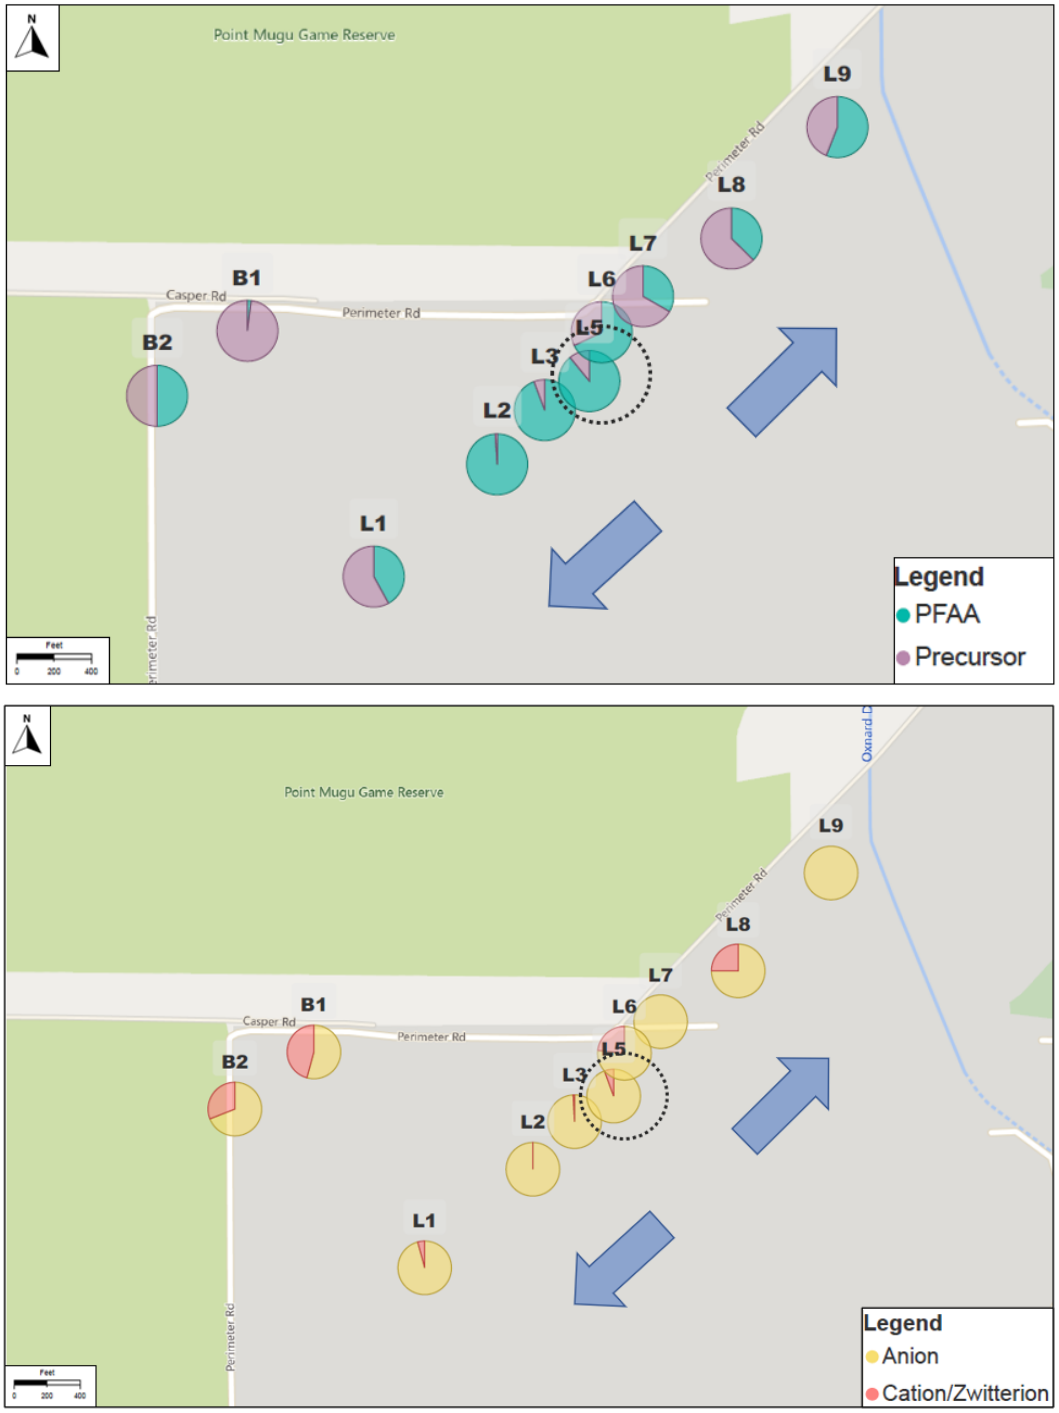

Figure 5-39. Distribution of PFAAs vs. Precursors (Top Panel) and Anions vs. Cations/ Zwitterions (Bottom Panel) in Soil. *Distribution at each location is based on the average of all depths per location. Arrows show general direction of seasonal fluctuating groundwater flow direction.*

Weighted average chain lengths in the source zone were generally higher in the source area (5.37-6.19) as compared to downgradient in the northeast direction (4.68-6.00) and the southwest direction (4.85-6.08) (Figure 5-40). Wilcoxon Rank Sum tests conducted on the chain lengths in the source area vs. near downgradient locations indicated that the there was no statistically significant difference in the datasets (p=0.22). However, tests conducted on the source vs. far downgradient did show statistically significant differences in the chain lengths (p=0.03).

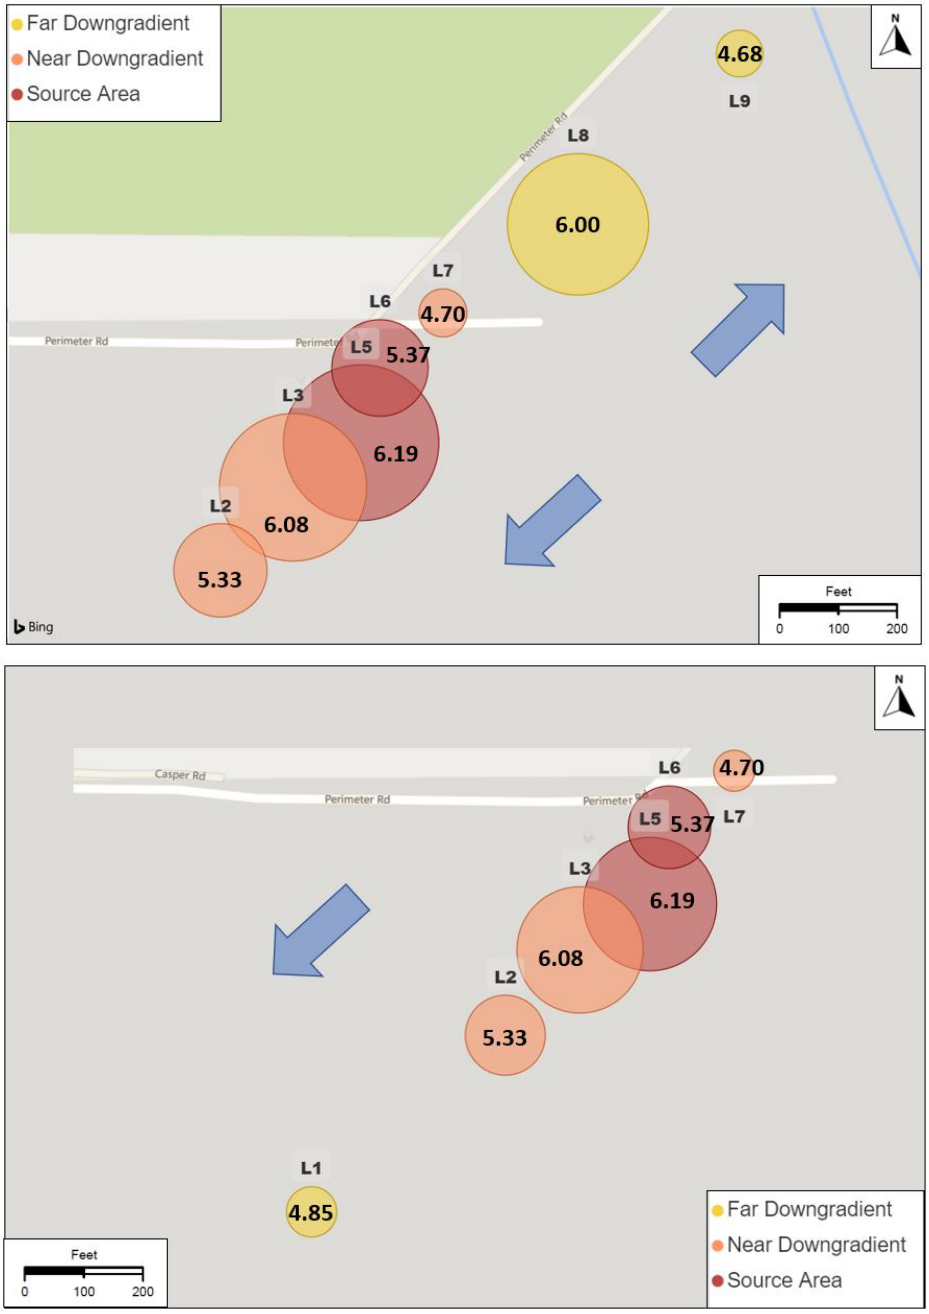

Figure 5-40. Weighted Average Chain Lengths in Groundwater in the Source Area, Near Downgradient and Far Downgradient Locations.

Transport Processes: Retardation

Soil adsorption coefficients (apparent K_d values) were calculated for every sampling depth where both soil and groundwater samples were collected and similar sets of PFAS were detected in both matrices (total of up to 8 pairs). Additionally, soil and groundwater characteristics were analyzed at those locations/depths to evaluate site-specific factors that may affect retardation. Due to the small dataset, statistical correlations with site characteristics could not be conducted, however, general trends were observed based on site data.

Table 5-5 below summarizes the soil adsorption coefficients and retardation factors for key PFAS per soil/groundwater sample pair and soil type at that depth interval. Appendix C includes K_d and retardation factors for all locations and compounds at NBVC Pt. Mugu.

Values of K_d varied significantly for sample pairs. However, K_d values generally increased with increasing PFAS chain length and were higher for PFSAs than PFCAs, as expected. Apparent soil adsorption was generally greater in sands (SP) as compared to clays (CL) for the key PFAAs listed in Table 5-5. However, there were only two groundwater samples collected from intervals that could be classified as clay, such that the representativeness of the data cannot be established.

Upon evaluating the cation exchange capacity (CEC), sands had significantly lower CEC (1.2 – 3.3 meq/100g), as compared to those of clays (8.1 – 30 meq/100g). Higher CEC values reflect a greater tendency to repulse anionic compounds than soils with a lower CEC. As such, this trend indicated that electrostatic forces were a significant factor contributing to the adsorption of anionic PFAS onto sands relative to clays, as compared to hydrophobic forces.

Similarly, trends of f_{oc} and other anions detected in soil (e.g., chloride, fluoride, sulfate), indicated that clays typically had significantly higher concentrations of other anions, despite also having greater f_{oc} values, as compared to sands. As such, the high salinity of this site significant influenced adsorption due to electrostatic forces.

Transport Processes: Vertical Transport

The highest PFAS concentrations are generally encountered in shallow depth intervals and concentrations decreased with depth (see transects above). This is particularly true in soil samples. Elevated PFAS concentrations at depths greater than 20 ft bgs were limited to a few locations with highly permeable soils within the investigated interval where groundwater could be collected. It should be noted that many locations were dominated by poorly draining, clay-rich soils within the shallow vadose zone. These soils would be expected to have less air-water interfacial retention (due to water logging) and thus less resistance to transfer of AFFF-applied PFAS to the water table. However, within the saturated intervals, these zones would less subject to advective flushing such that other processes (e.g., sorption, diffusion) may promote retention.

The isomeric data from the groundwater analyses also provide some insight on source zone transport mechanisms (Figure 5-41). At location L5 within the source area, the branched isomer percentage of both PFOS and PFOA increases with depth in the shallowest two samples, consistent with preferential vertical transport of the branched isomer from a surface-applied PFAS source (e.g., AFFF).

In addition, relatively high percentages of the branched isomers of PFOS (52%) and PFOA (31%) were observed in the shallowest groundwater sample (13 ft bgs) from location L3, which is approximately 275 ft downgradient of the source area. This is evidence of preferential lateral transport of the branched isomer from the source area to downgradient locations. However, the branched isomer percentage is slightly lower in samples from deeper intervals at many locations, including locations L5 (source area) and L3 (downgradient). While there is no clear explanation for this deviation from the expected pattern. It may be that PFAS is transported to these deeper intervals via multiple routes, with less "chromatographic separation" of PFAS isomers occurring in one or more of these routes.

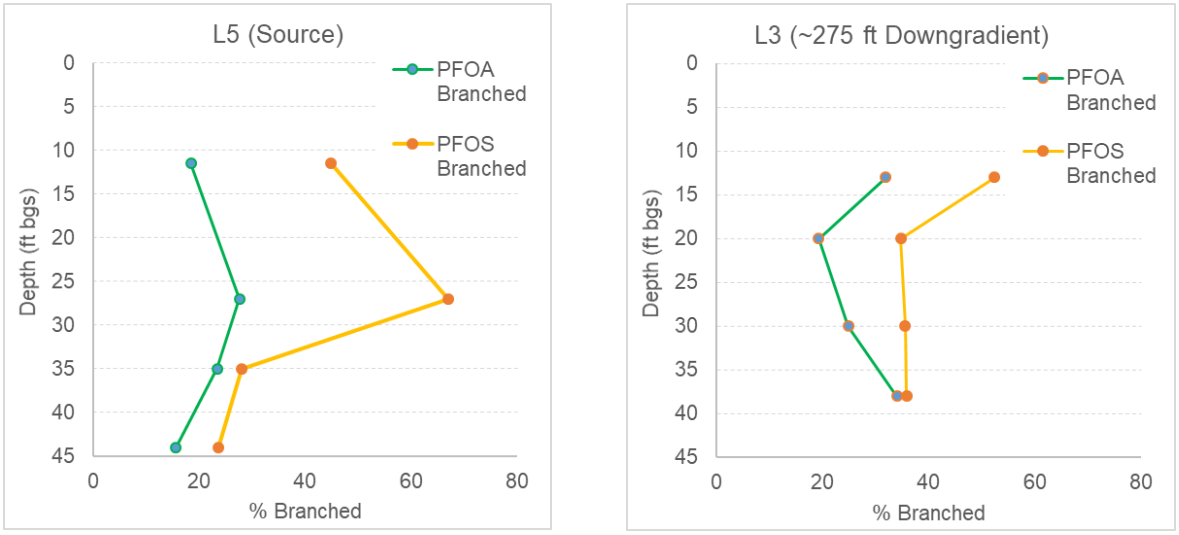

Figure 5-41. Percent Branched PFOA and PFOS at L5 (Left Panel) and L3 (Right Panel)

Transport Processes: Low Permeability/Matrix Diffusion

Elevated concentrations of PFAS were encountered in samples that consisted primarily of low-permeability soils such as clays and silts. As an example, three of the four soil samples with the highest total PFAS concentrations (all from locations L5 and L6) were clay samples. Mass transfer into these soils may have occurred by either infiltration, diffusion and/or slow advection. Despite the finding that these many of these soils have low apparent retardation factors, the overall concentration distribution at the site suggests that these soils helped limit PFAS transport, based on the following primary lines of evidence:

- PFAS concentrations are low in locations in the northeasterly direction from the source area (Locations L7, L8, and L9) where the thickness of the clay/silt layers increases significantly. The soils in this direction have limited transmissivity that apparently reduces PFAS mass discharge based on the availability data.

- PFAS is retained in shallow unsaturated soils throughout the site, and these shallow soils are dominated by low-permeability silts/clays. As noted above, these shallow soils in the unsaturated zone would not be expected to drain efficiently, which may reduce retention due to air-water interfacial partitioning, but the overall effect is to limit advection and presumably enhance matrix diffusion-related retention.

- The only locations where relatively elevated levels of PFOA and PFOS are encountered below 20 ft bgs are those where the surficial low-permeability layers are relatively thin and the deeper soil intervals are dominated by sand (L5 and L6). As a result, near-surface layers are providing less resistance to vertical transport of PFAS.

In addition, the locations that are dominated by lower-permeability soils (L7, L8, and L9) generally have high specific conductivity levels as well as a higher percentage of precursors. This suggests that PFAS that has migrated into these zones (either via diffusion or slow advection) is being retained and subject to slower transformation to PFAAs. Diffusion into lower-permeability soils contributes to longer-term retention because the potential for advective flushing is low within these zones. However, this process also limits PFAS migration, mass discharge, and the potential rate of plume expansion.

Evidence for Biotransformation of Precursors

Field measurements indicated the geochemical conditions were not particularly favorable for aerobic biotransformation (the presumed natural attenuation pathway for PFAS) at site at the time of the investigation. The median dissolved oxygen (0.3 mg/L) and ORP (-175 mV) levels in groundwater samples suggest that the aquifer is anoxic and that oxygen limitations may slow transformation rates. An additional limiting factor is the high electrical conductivity (median value of all samples = 12 mS/cm)

However, several lines of evidence for PFAS biotransformation were observed at this site, including the detection of several presumed biotransformation products at multiple locations. These include the fluorotelomer sulfonates (4:2 FTS, 6:2 FTS, and 8:2 FTS), which are at the highest concentrations of all fluorotelomer compounds in both soil and groundwater. These compounds are suspected intermediates the transformation of other precursors because they are

generally not a major component of AFFF or other PFAS sources. The fluorotelomer sulfonates are present in both soil and groundwater, with the highest concentrations in both matrices generally found near the source (locations L5 and L6) within relatively permeable soils.

Because PFOS was the highest-concentration PFAS in nearly all samples, the presence of PFOS precursors was also seen as a strong indicator of biotransformation at the site. Several C8 ECF-sulfonamides were routinely detected in soil samples and identified as possible PFOS precursors (e.g., AmPr-FOSA, TAmPr-FOSA, CEtAmPr-N-EtFOSA, TAmPr-FOSAPrA, FOSA).

The proportion of branched PFOA PFOA in many samples was < 20% (i.e., lower than the proportion expected from ECF-derived PFOA). This provides further evidence that some PFOA presently in the subsurface was derived from transformation of linear fluorotelomer precursors. Similarly, N-dimethyl ammonio propyl-perfluorooctane amide (AmPr-FOAd, a C8 amide) is a potential ECF-based precursor to PFOA and was detected in samples from both location L5 and L6.

FHxSA was also frequently detected in both soil and groundwater at relatively high concentration when compared to other detected precursors. This included FHxSA groundwater concentrations that were comparable or higher at downgradient locations L3 and L8 than at source area locations L5 and L6, suggesting transport and transformation of this compound in groundwater. The precursors to FHxSA described in the pathway presented in Section 5.7.2 were not detected at this site in groundwater (i.e., the-perfluorohexane sulfonamido propyl sulfonates), although they were present in several soil samples within the source area. However, several other compounds which contain the perfluoroalkyl sulfonamide chain and could therefore be precursors to FHxSA—and ultimately PFHxS. For example, zwitterionic TAmPr-N-MeFASA and TAmPr-FASA classes were among the highest concentration compounds detected in soil within the source area, although they were not detected in groundwater. In groundwater, anionic SPr-FHxSA was detected at 1,100,000 ng/L at one of the samples from location L6, and this compound was greater than 5% of the total PFAS detected in all four samples from downgradient location L1. The anionic C6 homolog EtFxSA was also detected at relatively low levels at downgradient locations L3 and L8 (20 ng/L and 13 ng/L, respectively).

Spatial trends in the contribution of precursors to the total PFAS concentration did not provide clear evidence of biotransformation. Biotransformation to PFAAs during transport would be expected to decrease the contribution of precursors to the total PFAS concentration. Instead, precursors were generally higher in soil and groundwater samples collected at locations moving away from the source area. This may reflect the fact that total PFAS concentrations are lower at locations outside of the source area which limits mass transfer into the deeper, more permeable intervals of the groundwater unit where the precursors may be more bioavailable.

Differentiate AFFF and non-AFFF Sources

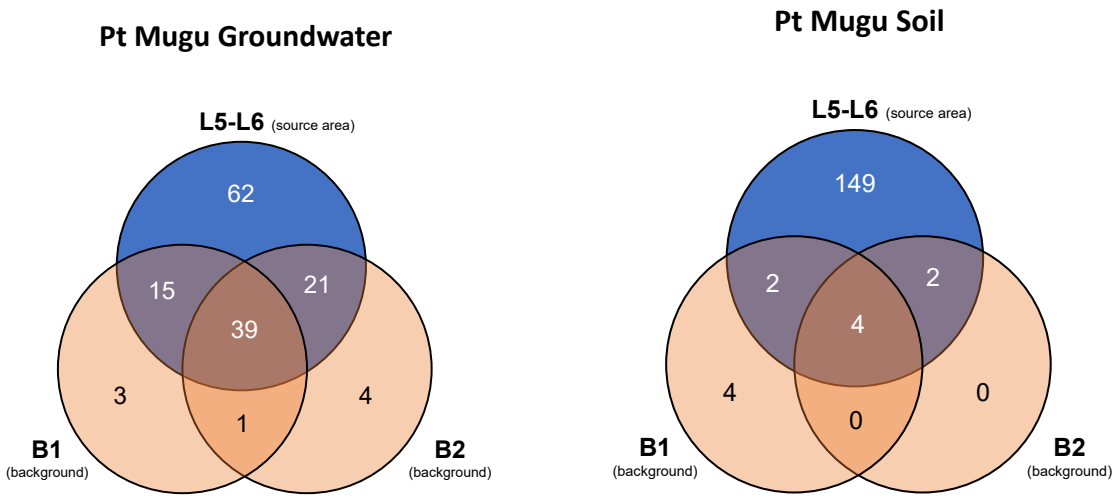
PFAS compositional data, including precursor data, confirm the use of multiple different types of AFFF products within the source area, including ECF-based foams as well as telomer-based foams. PFOA and PFOS are typically the highest concentration PFAS, along with PFHxS and PFHxA. PFCAs and PFSAs of multiple chain lengths are both well represented, with the latter generally at

higher concentrations. However, fluorotelomer sulfonates and alcohols are present at higher concentration that the various perfluoroalkyl sulfonamide derivatives in some samples.

The isomeric data from the groundwater analyses provide corroborating evidence on source types. Specifically, the percentage of the branched isomer of PFOS is typically at or above 20%, confirming that ECF-based AFFF is a primary PFOS source. The branched isomer percentage for PFOA is consistently between 14 and 34%, which suggests that both telomer and ECF-based AFFF are contributing sources of PFOA at this site.

PFAS was present at all locations, but the background locations (B1 and B2) contained relatively low levels in both soil and groundwater despite their relatively proximate location to the source area. Some locations had soil samples with no detectable PFAS. The number of different precursor compounds detected in some samples are consistent with not only multiple types of AFFF but also raise the possibility of other PFAS sources. For example, in the soil and groundwater samples from location L5 and L6 (the presumed source area), a total of 157 different compounds were detected in soil and 137 different compounds were detected in groundwater. The majority of these compounds are polyfluorinated precursors of varying chain lengths and functional groups. However, in samples where the total PFAS soil concentration is greater than 1,000,000 ng/kg (a total of six samples from L6 and L5), these precursors generally represent a modest portion of the total concentration (3 to 59%). Background locations were dominated by non-PFAAs compounds in both soil and groundwater, though they were largely similar to those detected in the source area groundwater.

The compounds that were unique to the background locations included several longer-chain hydrido-perfluorosulfonates in soil (e.g., H-PFPeDA, H-PFTeDA, H-PFTrDA). While the presence of these compounds suggests that other PFAS sources may have contributed to the observed PFAS, a source cannot be readily identified. It should also be recognized that many of the unique compounds to the background (as well as source area) locations were identified through suspect screening. Shorter chain fluorotelomer intermediates that have been proposed to be diagnostic of landfill leachate (e.g., 5:3 FTCA) could not be detected in soil and groundwater from any location. In addition, sulfonamides like MeFOSA and EtFOSA that are generally not expected to be associated with AFFF were detected in only a few samples and only at trace levels. Longer chain PFAAs (> C9) were detected primarily in soils (but not groundwater) in the source area locations, although PFDoA represented a substantial portion of the PFAS detected in several groundwater samples from one of the two background locations (B1).



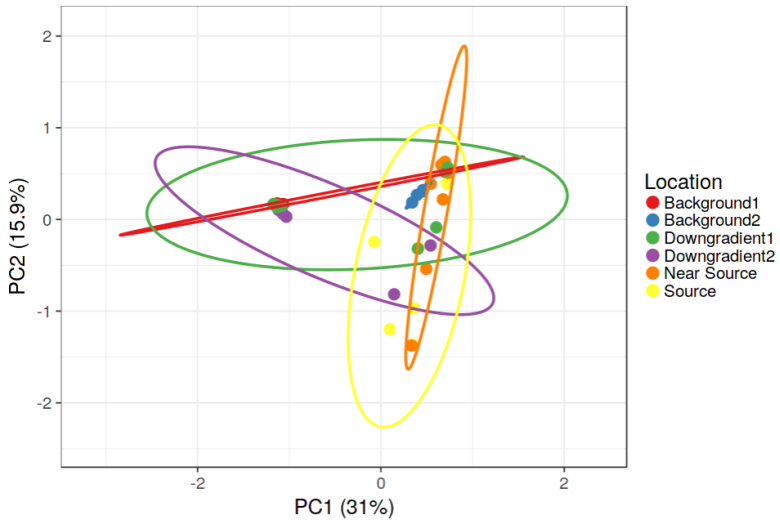


Figure 5-42. Comparison of Detected Compounds at Selected Locations in Groundwater (Left Panel) and Soil (Right Panel) from Pt Mugu.

The two background locations (B1 and B2) were located cross gradient to groundwater flow but are within approximately 800 ft of the farthest downgradient location (L1). As a result, PFAS resulting from AFFF releases in the firefighter training pits could have been the primary or sole contributor to the observed PFAS at B1 and B2. In this case, cluster analysis provided limited evidence that different PFAS sources were contributing to the observed patterns. PCA results for unfiltered soil and groundwater data are shown in Figure 5-43 confirm that there is moderate overlap in the confidence intervals for source area locations vs. those from background locations. This is indicative of substantial variability in the PFAS composition at different individual locations that are within the same groupings but also suggests a lack of ability to differentiate between potential source signatures with unfiltered data. The background location data cluster relatively similarly with the downgradient location data in both cases, especially when compared to the source area location data. However, PCA1 and PCA2, which are primarily associated with PFAAs for these datasets, only explain 25.5% and 46.9% of the variance for soil and groundwater data, respectively.

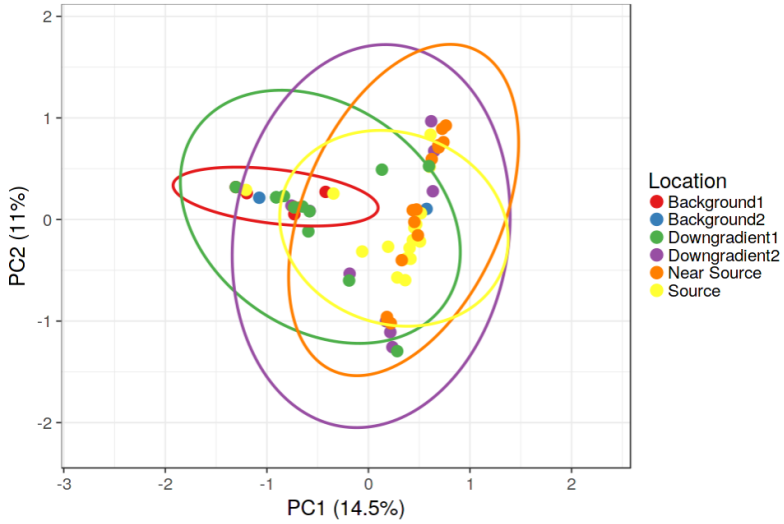

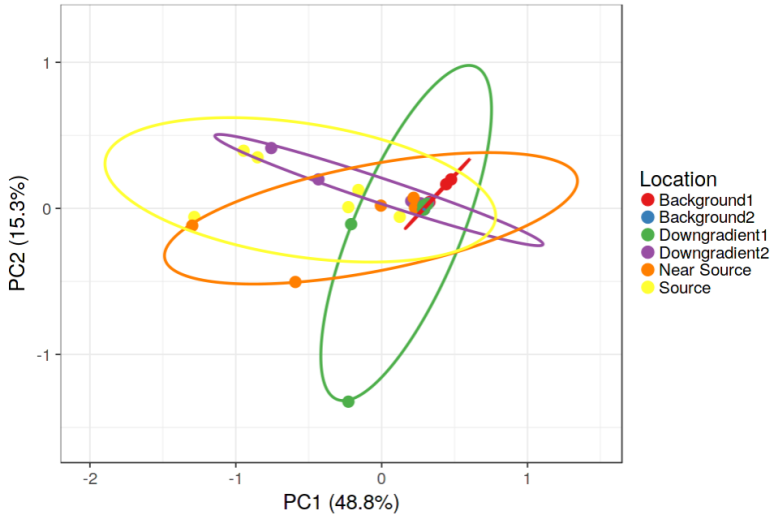

Figure 5-43. Principal Component Analysis for Groundwater Data (Top Panel) and Soil Data (Bottom Panel) from Pt Mugu. Analyses performed on transformed data from all locations and included all reported analytes (unfiltered).

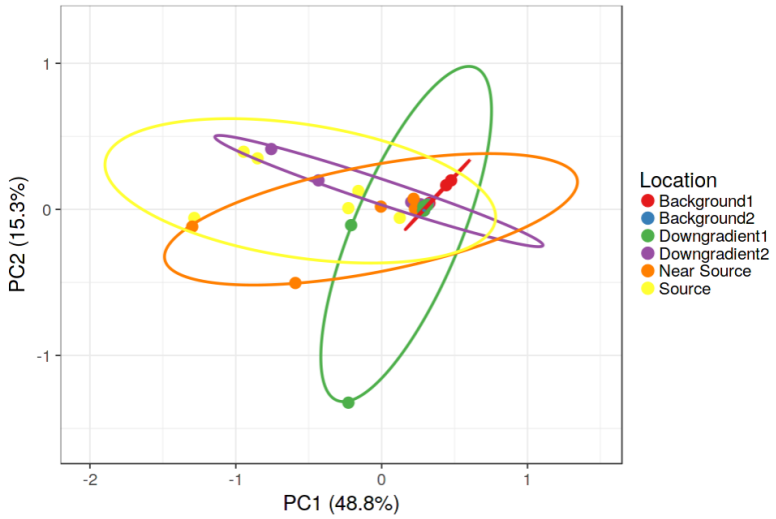
Based on statistical data exploration, filtering the soil analytical data into subgroups provided little additional insight due to the relative lack of detections in this matrix at many locations. However, filtering the groundwater to include only target analytes (Figure 5-44, top panel) and to include only select locations (Figure 5-44, bottom panel) improved the ability to distinguish samples from different locations. By reducing the number of variables to only target analytes, the background location data cluster within a small confidence interval, although the boundaries still overlap with the data from the source area. It should be noted that the overlap observed between the source area data and the data from near source and both downgradient directions supports that these areas represent similar PFAS sources even accounting for transport-related compositional shifts. When only the data from source area locations (L5, L6) and background locations (B1, B2) were included (Figure 5-44, bottom panel), the latter clustered differently than the source area data. These also captured a much higher percentage of the variability in PC1 and PC2. The HCA results



demonstrate a similar pattern, where the background samples group similarly and are relatively distinct from those from the source area.

Collectively, these data suggest that the PFAS signatures in samples from the background locations at this site are slightly different than those in the primary source area (the firefighter training area). However, the data do not provide strong evidence that the PFAS at these locations would have derived from non-AFFF sources.

PIGE vs. Total PFAS Concentration in Groundwater

Linear regression of the PIGE total fluoride results and the total PFAS concentrations measured in groundwater using LC-QTOF-MS yielded a strong linear correlation with an r^2 of 0.98 (Figure 5-46). These data were evaluated using the Spearman's Correlation test and resulted in p=0.002 (statistically significant: p<0.05). The relationship was much more consistent at higher PFAS concentrations. At lower PFAS concentrations, a number of PIGE results were non-detect; this was likely a function of the limit of quantification for PIGE in this set of analyses (5 ppb). PIGE data were also compared to total PFAS concentrations measured in co-located soil samples. Note that some deviation between PIGE data from aqueous samples and soil data are to be expected due to the influence of the matrix and partitioning characteristics. Despite this limitation, measurable fluorine was detected in 9 of the 14 samples where PFAS was detected in co-located soil samples.

Overall, a significant portion of the PIGE results (50%) from groundwater samples were non-detect, and these generally corresponded to samples with low PFAS concentrations. At this site, the total PFAS concentration was above 4 ppb in all samples. Collectively, these data suggest that the primary applications of PIGE as a characterization tool will be in source areas where PFAS concentrations are high enough to offset PIGE quantitation limits.

Linear regression of the PIGE total fluoride results and the total PFAS concentrations in soil yielded a weak linear correlation with an r^2 of 0.13. At this site, these results suggest that PIGE as a characterization tool is not applicable for soil analysis.

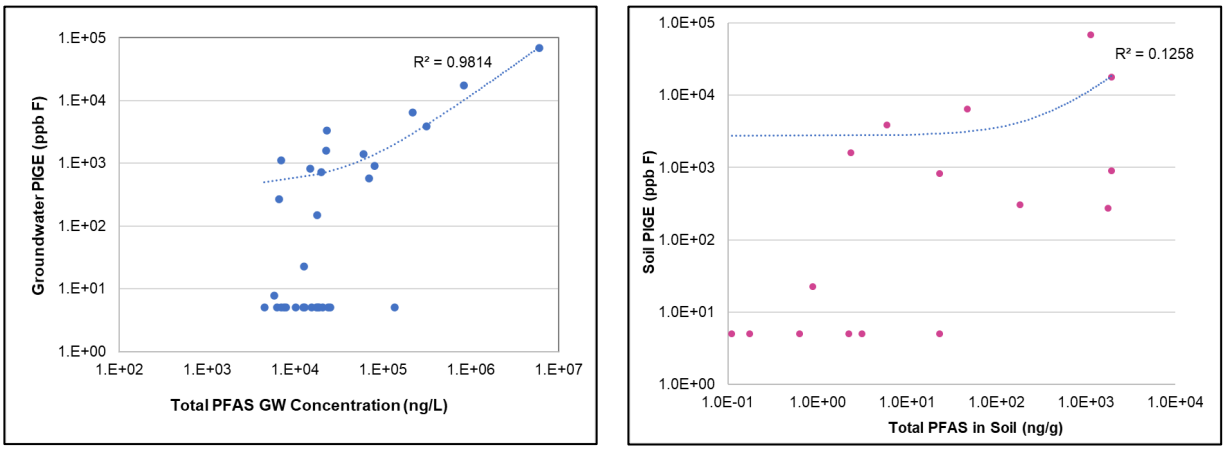

Figure 5-46. PIGE vs. Total PFAS in Groundwater (Left Panel) and Soil (Right Panel)

Conceptual Site Model

The spatial patterns in PFAS data were used to develop a Conceptual Site Model that identifies the relevant transport processes, the potential for migration, and active natural attenuation mechanisms at the site (Figure 5-47). This can include retardation due to various mechanisms, as well as biodegradation of polyfluorinated compounds which may serve as precursors to PFAAs.

As described above, PFAS concentrations were generally highest in shallow soils, in part due to the presence of low-permeability soils that helped limit transport, although the contribution of vadose zone retention processes was less pronounced at this site. Retention within the source area can be attributed to mechanisms such as retardation due to the enhanced electrostatic interactions due to the presence of brackish to saline groundwater (PFAS "salting out"), partitioning of PFAS to solid-phase surfaces as a result of hydrophobic interactions, and slow advection and diffusion into shallow lower-permeability soils.

The presence of intermediates of suspected biotransformation pathways confirmed that this mechanism was active, and differential transport rates caused a shift to shorter-chain compounds moving downgradient. Collectively, these processes contribute to attenuation of PFAS concentrations moving away from the source, with decreases in concentration of greater than 3 orders of magnitude observed between the source area and the farthest downgradient locations. However, due to the high source strength (maximum total PFAS concentration >6,000,000 ng/L in groundwater), plume development has resulted in elevated concentrations (>4,000 ng/L) throughout the investigated area.

5.7.4 Results: NALF Fentress, VA

Site Characterization Overview

Site characterization was conducted at NALF Fentress, in Chesapeake, Virginia from 19 September – 3 October 2019. The section summarizes analytical results from the high-resolution soil and groundwater sampling program at this site. The investigation focused on the AFFF Storage and Transfer Area as well as downgradient points (Figure 5-48).

A total of 49 groundwater samples, 87 soil samples, 2 surface water samples, and 74 soil and groundwater QA/QC samples were collected as part of this program.

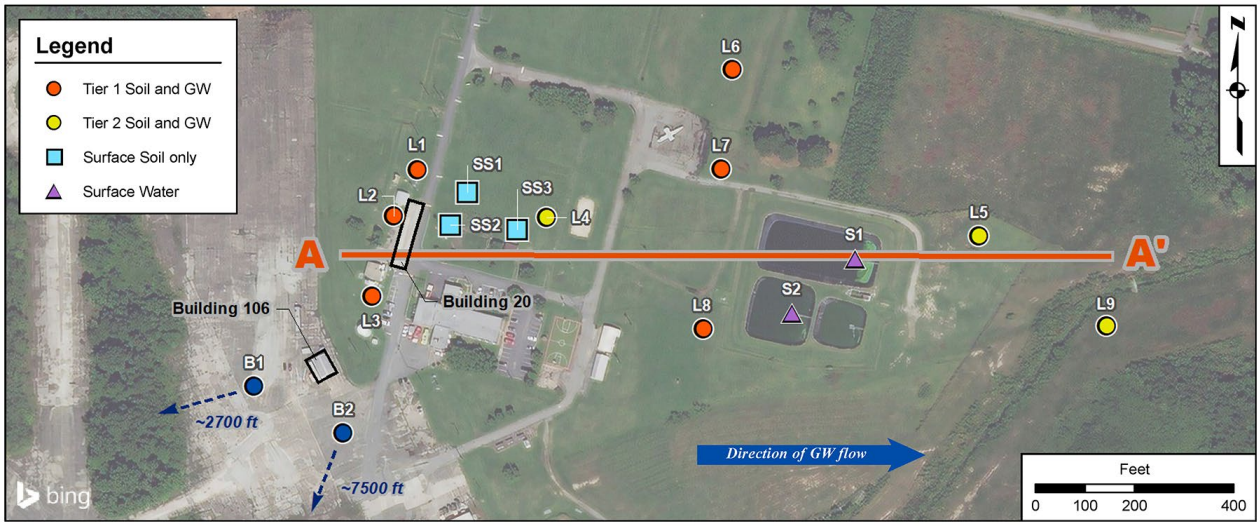

Figure 5-48. Site Map with Invesigation Locations and Transect A-A'

Site Hydrogeology

Figure 5-49 below depicts the geologic cross section A-A'. Visual inspection and classification of soil cores indicated that the first 1 to 5 ft of surficial, unsaturated soils were fine grained sands, but then consistently transitioned to a lower-permeability clay and silt layer that extended across the entire study area.

This clay-dominated layer was relatively thin (less than 5 ft) and was underlain by coarse permeable sands that were consistent with the Columbia aquifer. This water-bearing zone extended to a depth of approximately 30 ft bgs. A silt and clay confining layer approximately 5 to 10 ft separated the Columbia sands from a deeper coarse sand unit that was assumed to be the Yorktown aquifer. Two background locations upgradient of Building 106 were also characterized; one exhibited a similar geology (B1) while another that was farther upgradient had distinctly more fine-grained material within the Columbia sands (B2).

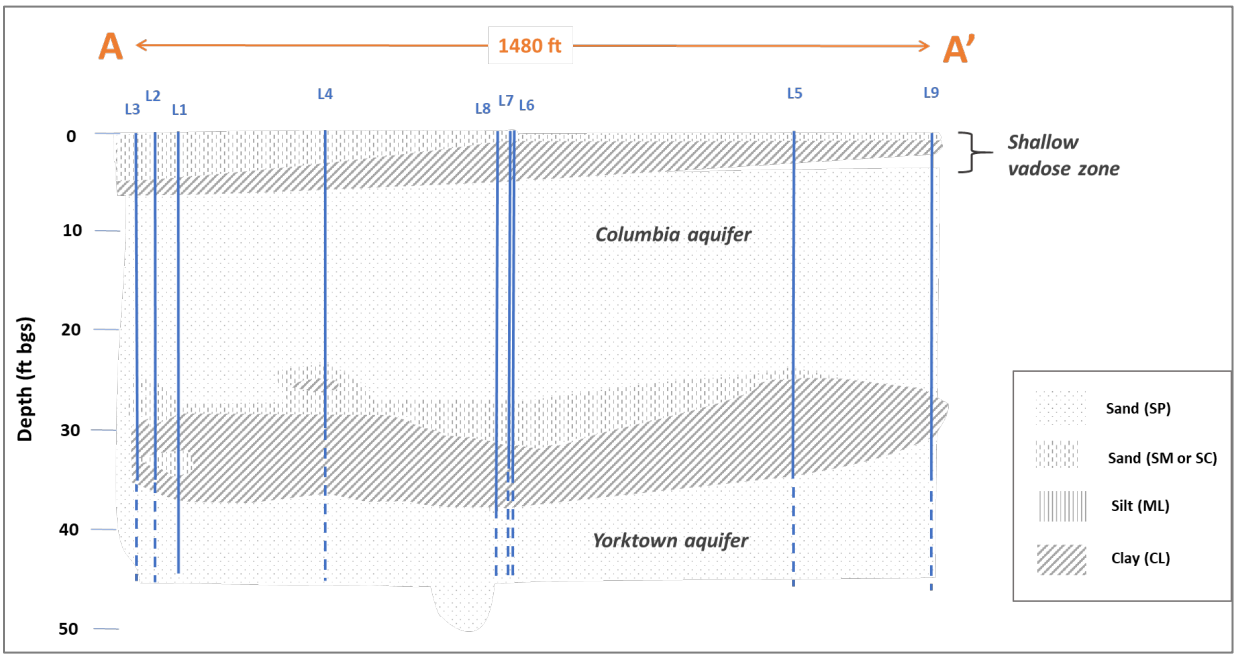

Figure 5-49. Geological Cross-Section A-A'. Direction of groundwater flow is from left to right (easterly direction). *Soil classification and depths are based on project-specific data (boring logs and HPT profiles). Static water levels ranged rom 4 to 7 ft bgs.*

The HPT logs confirmed that the shallow sands that extend to approximately 30 ft (i.e., the Columbia) and the deeper sands that start at approximately 40 ft bgs (i.e., the Yorktown) are reasonably permeable (estimated K values were generally between 50 - 100 ft/d). The clay-rich confining layer separating the Columbia and Yorktown units was also confirmed to have very low hydraulic conductivity that was at least 2 orders of magnitude lower than the overlying and underlying sands. Note that HPT was not able to collect data from the thin clay-silt layer above the Columbia sands because of its shallowness. The apparent water levels based on inspection of cores were between 4 and 7 ft bgs and were generally consistent with the start of the sandy water-bearing unit, indicating that this unit was not confined by the thin layer of overlying finer-grained surficial soils.

Based on field measurements, the groundwater was neutral (average pH = 6.6) and slightly reducing to slightly oxidizing (average dissolved oxygen = 1.5 mg/L; average ORP = 12 mV). In general, shallower groundwater was more oxidizing than groundwater collected from deeper intervals. Specific conductivity was below 1.0 mS/cm in all samples (average = 0.3 mS/cm). Methane was detected at low levels (< 1 mg/L) in most groundwater samples. Measurable organic carbon was present in all soil samples, with an average value of 0.5%.

Identification of Source Zone

Soil and groundwater concentrations of Total PFAS, PFOS, and PFOA with depth at each location along the primary transect in the direction are included in Figures 5-50, 5-51, and 5-52.

Higher soil concentrations are present near the source area and generally decrease in direction(s) of groundwater flow (Figure 5-53). For example, the highest total PFAS concentrations in soil are

observed at location L3 in the western portion of the site (maximum total PFAS concentration = 9,600,000 ng/kg; note that the actual concentration is likely higher due to PFOS exceeding the upper LOQ in this sample). Soil concentrations in samples from all other locations are more than an order of magnitude lower than those in the source area. Groundwater concentrations generally show a similar pattern (Figure 5-53); the maximum total PFAS concentration in groundwater (6,500,000 ng/L) was encountered in a shallow sample from Location L3; Figure 5-53). This location with the highest maximum soil and groundwater concentrations is immediately south of Building 20 (the former AFFF Storage and Transfer Area), and it is also the closest investigation point to Building 106 (the current AFFF Storage and Transfer Area).

Similarly, the highest PFAS concentrations in surficial soils were observed within the same general area (Figure 5-35). However, the near surface soil concentrations at locations L7 and L8 were consistently higher than those at locations L1, L3, SS1, SS2, and SS3 that are all much closer to the presumed source area. This pattern suggests that usage of AFFF may have occurred in areas beyond the immediate vicinity of the former/current AFFF Storage and Transfer Areas.

The highest PFAS concentrations in soil typically encountered in shallow depth intervals above the water table, and concentrations decreased with depth (Figure 5-54). Locations where this pattern was not observed were generally located outside of the source area. PFAS concentrations in groundwater also decreased with depth within the source area (e.g., location L3) but were more uniformly distributed in other locations.

This distribution supported the assumption that AFFF used in the vicinity of the former/current AFFF Storage and Transfer Areas is the primary source of PFAS (Figure 5-54), but that some AFFF may have been released in downgradient areas as well.

Transport Processes: Downgradient Transport

Figures 5-53 depicts total PFAS concentrations in soils from the shallow vadose zone and saturated zone. Figure 5-54 depicts total PFAS concentrations of groundwater samples. Additionally, the distribution of PFAS in soil and groundwater was evaluated laterally from the source zone and included PFAAs and polyfluorinated compounds, as well as distribution by charge (anions vs. cations + zwitterions (Figures 5-55, 5-56). Key preliminary findings to date suggest the following:

- PFAS concentrations generally decreased moving away from the source area, particularly in soil, which likely reflects where AFFF was released. The groundwater data also exhibited this pattern. This served as evidence of retardation-based attenuation of certain PFAS once they have reached groundwater.

- The spatial distribution across the site also provided evidence that electrostatic interactions influenced PFAS transport. For example, the highest concentrations of polyfluorinated compounds were encountered in the source area, as compared to further downgradient locations. Both the concentration and the percentage of total PFAS represented by polyfluorinated compounds generally decreased with depth. In all groundwater samples, greater than 97% of the total PFAS concentration was represented by anionic compounds (including both target and non-targets). Zwitterionic and cationic PFAS were detected in saturated soils collected from the far downgradient locations (L5 and L9). However, these were typically at lower concentrations relative to upgradient locations (e.g., L3, L7, L8) and partially reflect that zwitterionic/cationic PFAS were also detected in surficial (unsaturated) soils at these downgradient locations (Figure 5-53).

- In addition, higher concentrations of zwitterionic/cationic PFAS were measured in the soil samples from the source area relative to those measured in downgradient locations. Several shallow samples from location L3 had zwitterionic/cationic PFAS concentrations greater than 1,000,000 ng/kg that represented a relatively high percentage of the total PFAS (> 40%). However, zwitterionic/cationic PFAS were also represented a high percentage of the total PFAS in shallow soil samples in several downgradient locations, suggesting that source material was released and retained outside of the primary footprint of the AFFF Storage and Transfer Area. Zwitterionic/cationic PFAS were largely absent from groundwater samples collected in both the source area and at downgradient locations.

- Similarly, the spatial distribution data showed that hydrophobic partitioning to solid-phase surfaces has influenced the relative transport rates of individual PFAS. The primary evidence for this mechanism is the groundwater concentration vs. distance profiles of longer-chain PFAAs vs. shorter-chain PFAAs in the direction of groundwater flow. For example, PFOS in groundwater generally decreased across the transects, while PFBA and PFBS concentrations were still relatively high at downgradient locations L7 and L9. However, a statistical test of the overall influence of these processes on chain length distribution in groundwater was not able to conclude that the representative chain length at either the near downgradient locations (L4, L6, L7, L8) or the far downgradient locations (L5, L9) was statistically different than that the representative chain length at the source area locations (L1, L2, L3) (see below). In part, this is due to the inherent variability in aggregated data from multiple locations, as well as the possibility that surface releases

occurred at downgradient locations. Note that the isomeric profiles of PFAAs also exhibited significant variability with distance and therefore do not serve as strong evidence of differential transport in groundwater.

- As discussed previously, the presence of elevated levels of PFAS in surface soils outside of the AFFF Storage and Transfer Area suggests that PFAS may have entered the subsurface at various locations. This may have contributed mass to the aquifer at these downgradient locations through vertical transport as opposed to lateral transport, as evidence by the groundwater contours that show increases in total PFAS concentrations near location L7.

Figure 5-56. Distribution of PFAAs and Precursors (Top Panel) and Anions and Cations/Zwitterions (Bottom Panel) in Soil. Arrow shows general direction of groundwater flow.

Additionally, as seen in Figure 5-57 below, weighted average chain lengths vary across the site, with somewhat greater chain lengths in the source area (6.49-7.03) as compared to near downgradient (6.54-7.00) and far downgradient (5.86-7.10) areas. However, results of the Wilcoxon Rank Sum tests on these datasets indicated no statistically significant difference in the chain lengths in the downgradient areas as compared to the source zone.

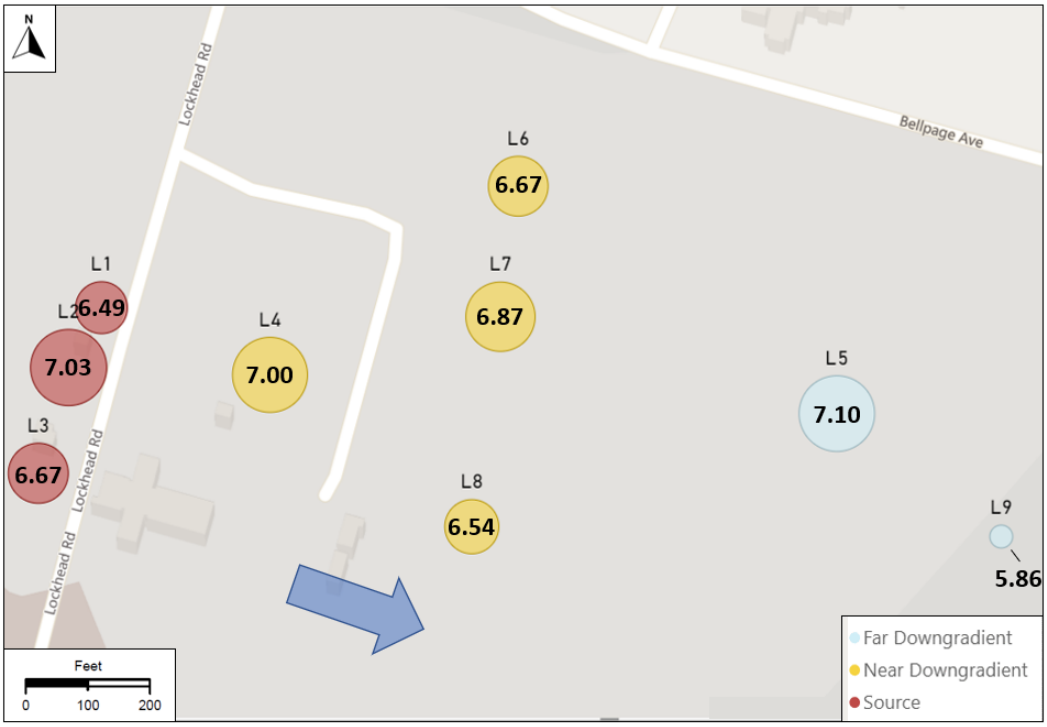

Figure 5-57. Distribution of Representative PFAS Chain Lengths in Groundwater.

Transport Processes: Retardation

Soil adsorption coefficients (apparent K_d values) were calculated for every sampling depth where both soil and groundwater samples were collected and similar sets of PFAS were detected in both matrices. Additionally, soil and groundwater characteristics were analyzed at those locations/depths in order to evaluate site-specific factors that may affect retardation. Due to the small dataset, statistical correlations with site characteristics could not be conducted, however, general trends were observed based on site data.

Table 5-6 below summarizes the soil adsorption coefficients and retardation factors for key PFAS per soil/groundwater sample pair and soil type at that depth interval. Appendix D includes K_d and retardation factors for all locations and compounds at NALF Fentress.

Similar to other sites, K_d and R values generally increased with increasing PFAS chain length and were higher for PFSAs than PFCAs, as expected. Apparent soil adsorption was generally greater in sands (SP) as compared to silts (SM) or clays (CL) for the key PFAAs listed in Table 5-6. However, there were only two groundwater samples collected from intervals that could be classified as clay, such that the representativeness of the data cannot be established.

Table 5-6. Summary of Adsorption Coefficients (K_d) and Retardation Factors (R) of Key PFAAs at NALF Fentress

Transport Processes: Vertical Transport

As noted previously, soil concentrations generally decreased with depth, with the highest PFAS concentrations in soil typically encountered in shallow depth intervals above the water table. There were a few locations where this pattern was not clearly observed (e.g., locations L4 and L9) where this pattern was not observed were generally located outside of the source area.

Higher concentrations of polyfluorinated compounds were encountered in the source area, as compared to further downgradient locations. Both the concentration and the percentage of total PFAS represented by polyfluorinated compounds generally decreased with depth. Given that the percentages of anionic PFAS measured in saturated soil samples (i.e., samples collected below the water table) were generally lower, this is evidence that the charges on PFAS were strongly influencing the partitioning between soil and groundwater.

These patterns were further evaluated using the Wilcoxon Rank Sum test to compare PFAS concentrations/distribution in soils from the saturated vs. unsaturated zone. In this case, all unsaturated soil samples were aggregated into one dataset and log transformed, while saturated soil samples with the highest PFAS concentration at each location were aggregated into another dataset. This ensured that a representative saturated soil sample from each location was included and that samples from deeper and/or less impacted intervals did not bias the comparison. This evaluation showed that the median total PFAS concentration and median total PFAA concentration was significantly higher in unsaturated soils than in saturated soils (Table 5-7; Figure 5-58). The median total zwitterionic/cationic PFAS concentration in unsaturated soils was also higher than in

saturated soils but did not meet the threshold for statistical significance, in part because there were fewer samples with measurable levels of zwitterions/cations to include in the analysis.

While location L3 is within the presumed source area where AFFF releases occurred because it exhibited the highest total PFAS concentrations at the surface, several other locations were also characterized by higher concentrations within the shallow unsaturated soils than in the underlying aquifer. It is unlikely that groundwater transport could have plausibly caused this concentration vs. depth pattern. A more plausible scenario is the release of AFFF to the ground surface at these locations, several of which are relatively distant from the presumed source area.

PFAS concentrations in groundwater also decreased with depth within the source area (e.g., location L3) but were more uniformly distributed in other locations. The only locations where the maximum groundwater concentration was encountered at a relatively deep interval (20 ft bgs or greater; locations L6, L9, and L5) were in the downgradient plume, suggesting some vertical migration within the groundwater-bearing unit during downgradient transport.

Table 5-7. Comparison of PFAS Concentrations in Saturated vs. Unsaturated Zone Soils

Saturated Zone Samples (max. conc. at each location; n=9)	Unsaturated Zone Samples (all samples; n=16)	Significantly Different? (p-value)
Median Total PFAS = 19 ng/g	Median Total PFAS = 90 ng/g	**Yes (p=0.02)**
Median Total PFAA = 13 ng/g	Median Total PFAA = 59 ng/g	**Yes (p=0.04)**
Median Total Zwitterion/Cation = 5.1 ng/g	Median Total Zwitterion/Cation = 24 ng/g	No (p=0.16)

Note: (1) Significant differences were evaluated based on $p<0.05$ for two-sided Wilcoxon Rank Sum test; (2) Log-transformed data were used in the comparison, meaning that the median values for zwitterion/cation category do not include samples with non-detectable levels.

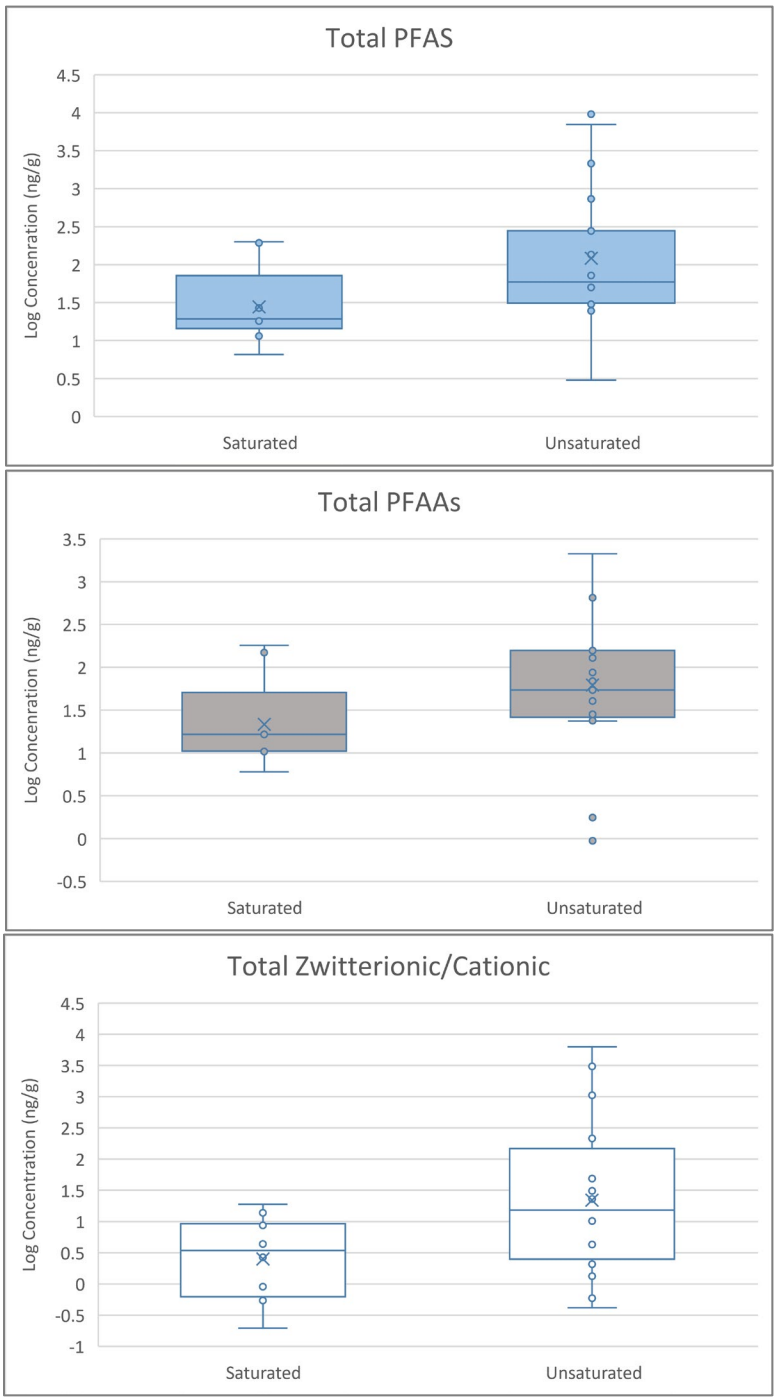

Figure 5-58. Distribution of Concentrations in Soil Samples from Saturated Zone (samples with max concentration at each location) vs. Unsaturated Zone (all samples from all locations). *(a) Total PFAS Concentrations; (b) Total PFAA Concentrations; and (c) Total Zwitterionic/Cationic Concentrations.*

Transport Processes: Evidence for Matrix Diffusion

Across the site, a thin clay and silt-rich layer is present immediately below the sandy surficial soils and above the top of the Columbia aquifer. This layer is generally less than 3 ft thick but likely slows the rate of vertical advection through the vadose zone. In addition, diffusion of PFAS into this shallow low-permeability soil is likely to promote long-term storage. PFAS was present in samples collected in samples from this clay/silt layer throughout the site, and the concentrations were generally higher than those in the underlying sands. This concentration pattern was distinct within the source area, such as location L3 where shallow soils had both elevated concentrations but also a high contribution from zwitterionic/cationic precursors (Figure 5-59). This confirms that PFAS has penetrated the shallow low-permeability soils, presumably from the top, and that further discharge to groundwater may be strongly influenced by slow back diffusion.

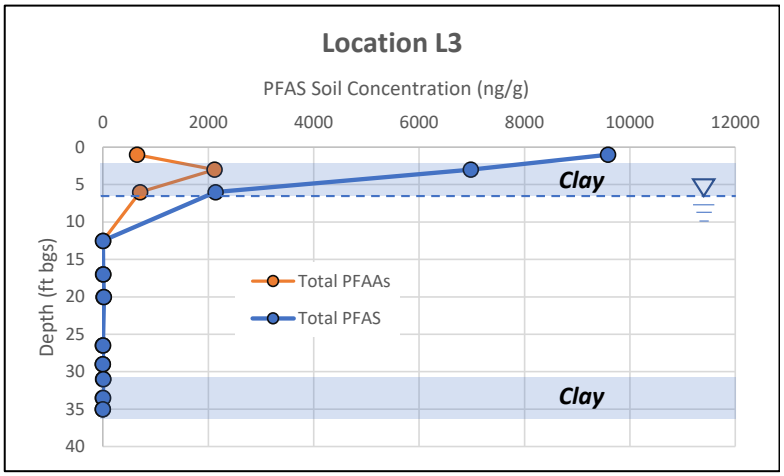

Figure 5-59. PFAS Profile with Depth at Location L3 (Source Area) Showing High Concentrations within Shallow Clay but Not Deeper Clay.

The Columbia aquifer is underlain by low-permeability clay layer that is first encountered at between 25 to 31 ft bgs. Based on the concentration vs. depth profiles, evidence that PFAS had diffused into this layer was observed at a few locations downgradient of the source area (L5, L6). Only limited penetration the deeper low-k layer at location L3 where the highest groundwater concentrations were observed, in part because vertical migration at this location appears to be limited as described above (Figure 5-59).

Evidence for Biotransformation of Precursors

Field measurements indicated that redox conditions in groundwater were slightly reducing to slightly oxidizing, such that oxygen availability may limit aerobic biotransformation (the presumed natural attenuation pathway for PFAS) at site at the time of the investigation. However, shallower groundwater appeared to be slightly more oxidizing, reflecting oxygen contributions from recharge.

Despite this limitation, several lines of evidence for PFAS biotransformation were observed at this site, including the detection of several presumed biotransformation products at multiple locations. These include the fluorotelomer sulfonates (6:2 FTS and 8:2 FTS primarily), which are at the highest concentrations of all fluorotelomer compounds in both soil and groundwater. These compounds are suspected intermediates the transformation of other precursors because they are generally not a major component of AFFF or other PFAS sources. The fluorotelomer sulfonates are present in both soil and groundwater, with the highest concentrations in both matrices generally found near the source (locations L3) within relatively permeable soils where groundwater was collected, as well as in soils both lower and higher permeable intervals (including the unsaturated

zone). They also represented a relatively higher percentage of the total PFAS in several groundwater samples from the location farthest downgradient (L9) of the source area. This pattern is consistent with biodegradation of polyfluorinated precursor compounds within the plume during transport.

In both groundwater and soil samples, PFOS was the highest-concentration PFAA in nearly all cases, such that the presence of PFOS precursors was also seen as a strong indicator of biotransformation at the site. Several C8 ECF-sulfonamides were routinely detected in soil samples from the source area and identified as possible precursors and transformation intermediates on the pathway to PFOS (e.g., Me-FOSA, Et-FOSA, FOSAA, MeFOSAA, EtFOSAA, Spr-FOSA, AmPr-FOSA, EtOH-AmPr-FOSA, TAmPr-FOSA, SPrAmPr-FOSA, CEtAmPr- FOSA, TAmPr-FOSAPrA, and FOSA). However, these were generally present only at trace levels in the downgradient locations, such that conversion of these precursors is likely occurring primary within the source area. This is consistent with the observation that concentrations of PFOS decrease with distance from the source area as well. It is also notable that many of these are zwitterionic/cationic PFAS and are absent from groundwater samples, suggesting that retention of these less mobile compounds within the source area is contributing to the observed attenuation patterns.

FHxSA was also consistently detected in both soil and groundwater at relatively high concentration when compared to other detected precursors (even the fluorotelomer sulfonates). For example, FHxSA was detected at 480,000 ng/L in the shallowest groundwater sample and 297 ng/g in the shallowest soil sample from source area location L3. FHxSA groundwater concentrations decreased with distance from the source but were still detected in multiple depths at all downgradient locations, suggesting that some transformation was occurring within the plume. All of the presumptive precursors to FHxSA described in the transformation pathway presented in Section 5.7.2 were detected at this site in both soil and groundwater (i.e., the-perfluorohexane sulfonamido propyl sulfonates), although they were primarily restricted to the source area. Several other compounds which contain the perfluoroalkyl sulfonamide chain and could therefore be precursors to FHxSA and ultimately PFHxS were detected. For example, zwitterionic TAmPr-N-MeFHxSA and TAmPr-FHxSA were among the highest concentration compounds detected in soil within the source area (at concentrations > 100 ng/g), although they were not detected in groundwater. In groundwater, anionic SPr-FHxSA and CMeAmPr-FHxSA were both detected at greater than 50,000 ng/L at the shallowest sample from source area location L3 (representing approximately 15% of the total PFAS detected in this sample). In general, these C6 precursor compounds were at the highest concentration in the vicinity of the source area and decreased (or were non-detect) in groundwater samples from farther downgradient, further emphasizing that biotransformation was most relevant within the source area.

The proportion of branched PFOA in many groundwater samples was < 20% (i.e., lower than the proportion expected from ECF-derived PFOA). This provides indirect evidence that some PFOA presently in the subsurface was derived from transformation of linear fluorotelomer precursors. Potential ECF-based precursors to PFOA could not be readily identified. For example, N-dimethyl ammonio propyl-perfluorooctane amide (AmPr-FOAd, a C8 amide) was detected at low levels (< 1 ng/g) in soil samples and absent from groundwater.

At this site, spatial trends in the contribution of precursors to the total PFAS concentration provided mixed evidence of biotransformation. In terms of total concentrations, precursors were generally

lower in soil and groundwater samples collected at locations moving away from the source area. When aggregating the data by location, the percentage of precursors at source area locations was relatively similar to that observed at downgradient locations, even though biotransformation to PFAAs during transport would be expected to decrease the contribution of precursors to the total PFAS concentration (Figure 5-47, Figure 5-48). Differences between precursor content in unsaturated soils vs. saturated soils were generally modest, with the exception of the source area location L3. The three highest precursor concentrations were all found in the unsaturated soils collected from this location (1400 – 8900 ng/g) and represented between 67-93% of all PFAS measured in this set of soil samples. In contrast, the shallowest three saturated soil samples from location L3 contained much lower percentage of precursor compounds (26-32%) as well as lower overall concentrations. This pattern likely reflects a combination of biotransformation and different transport rates when precursors migrate through the vadose zone.

Differentiate AFFF and non-AFFF Sources

PFAS compositional data, including precursor data, confirmed the use of multiple different types of AFFF products within the source area, including ECF-based foams as well as telomer-based foams. PFOA and PFHxS were typically the highest concentration PFAS in soil, along with PFOA, PFHxA, PFNS, and PFDS. PFCAs and PFSAs of multiple chain lengths were both well represented in most samples, with the latter generally at higher concentrations. ECF-based sulfonamides (predominantly C6 compounds) and other ECF-based derivatives were typically present at significantly higher concentration than fluorotelomers in soil and (to a lesser extent) in groundwater, The primary fluorotelomer sulfonates present were 6:2 FTS and 8:2 FTS.

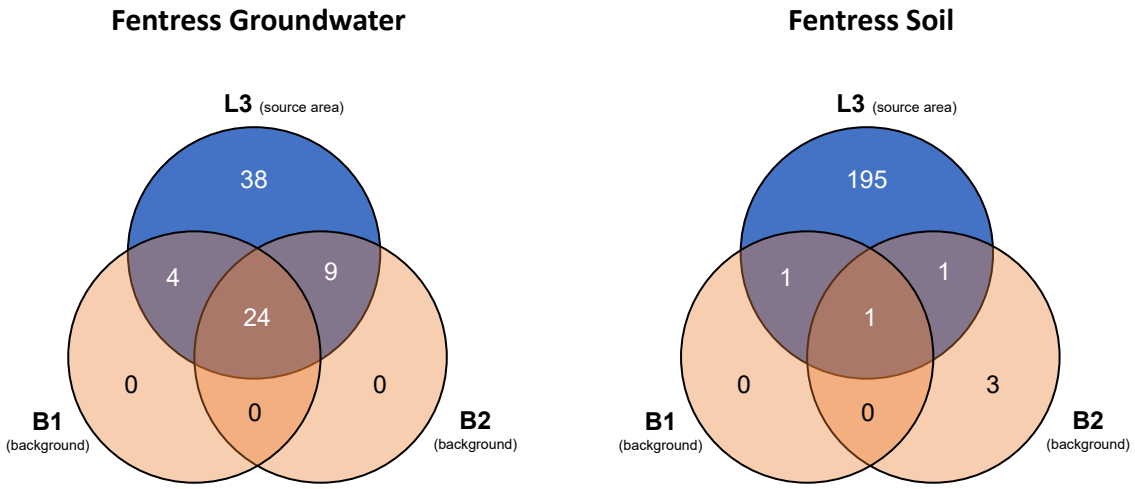
The isomeric data from the groundwater analyses provided corroborating evidence on source types. Specifically, the percentage of the branched isomer of PFOS was almost exclusively at or above 20%, consistent with ECF-based AFFF as the primary PFOS source. The branched isomer percentage for PFOA is consistently between 12 and 45%, which suggests that both telomer and ECF-based AFFF are contributing sources of PFOA at this site.

Soil samples from the source area locations, particularly location L3, also contained detectable levels of multiple substituted and/or unsaturated PFAA derivatives which spanned a wide range of chain lengths. These are compounds that have been reported based on analyses of AFFF and/or AFFF-impacted media and likely originated from electrochemical fluorination manufacturing (Barzen Hanson et al., 2017). Notable examples include F5S-PFOS (max concentration = 126 ng/g), F5S-PFNS (max concentration = 54 ng/g), O-PFDS (max concentration = 50 ng/g).

PFAS was present at all locations, including the background locations which are located between 0.5 and 1.5 miles away from the presumed source area in the opposite direction of groundwater flow. Most soil samples from the two background locations contained low PFAS (0 – 900 ng/kg), and all groundwater samples from these two locations contained measurable PFAS (1,200-16,000 ng/L). However, PFOS was not detected in the soil at background locations, and only in location B1 in groundwater. In addition, the number of different PFAS detected in some samples are consistent with not only multiple types of AFFF but also raise the possibility of other PFAS sources. For example, in the soil and groundwater samples from location L3 (the presumed source area), a total of 198 different compounds were detected in soil and 75 different compounds were detected in groundwater. These higher than the number of analytes detected at either of the

other two sites included in this project. All background soil samples were dominated by polyfluorinated, substituted, and/or unsaturated PFAS, particularly negatively charged ECF-based sulfonamides and other ECF-based derivatives, many of which were found in one or more locations closer to the AFFF Storage and Transfer Area. No compounds unique to the background locations were detected in groundwater samples (Figure 5-60) but several unique compounds were detected in soil samples (e.g., UPFOS, H-PFPeA).

The presence of these compounds suggests that alternative PFAS sources may have contributed to the observed PFAS, although a source cannot be readily identified. No other known or suspected sources of PFAS were reported in site documentation. Compounds that have been proposed to be diagnostic of landfill leachate and/or highly degraded household source, such as shorter chain fluorotelomer intermediates (5:3 FTCA) could not be detected at any location. Sulfonamides that are generally not expected to be associated with AFFF (e.g., MeFOSA, EtFOSA, corresponding sulfonamidoacetic acids) were detected sporadically in soil from the source area at trace levels, but not in groundwater or in any background locations. FOSA (a potential degradation product of these compounds) was detected more consistently at multiple locations in both soil and groundwater, and it frequently represented >10% of the total PFAS detected. As noted previously, many of the compounds that were unique to the source area and background locations were identified through suspect screening, so care should be taken when using these data for forensic purposes at this and other sites.



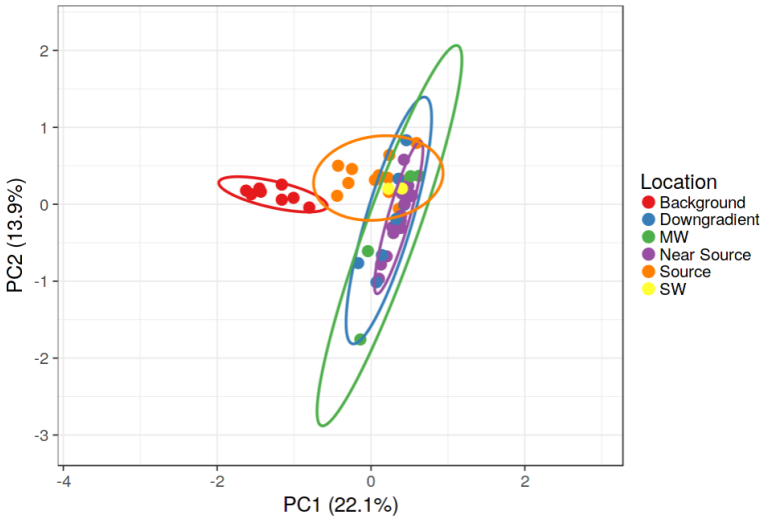


Figure 5-60. Comparison of Detected Compounds at Selected Locations in Groundwater (Left Panel) and Soil (Right Panel) from Fentress.

The relative absence of PFAAs in background locations serves as a secondary line of evidence for differentiating between the AFFF source and other diffuse sources. The majority of the PFAS detected in these background locations was anionic (and thus potentially more mobile), but there was no strong concentration gradient with depth that would suggest either localized surface releases or transport via groundwater.

Cluster analysis provided additional supporting evidence that different PFAS sources were contributing to the observed patterns at background locations. PCA results for unfiltered soil and groundwater data shown in Figure 5-61 show that the data from the background locations cluster

tightly. In groundwater, the background data form a distinct cluster with no overlap between the confidence intervals for either the source area or the near source/downgradient locations (which all cluster relatively closely with each other). In soil, the data from the background locations cluster tightly but still overlap with the confidence intervals for source area locations due to the higher variability in soil data from the source area. Like the analyses from the other two sites, only a small portion of the overall variability is explained by the first two principal components (PCA1 + PCA2 = 36% for groundwater; PCA1 + PCA2 = 23.6% for soil).

Fentress - GROUNDWATER
No filtering (all analytes)

Background = B1, B2
Near Source = L4, L6, L7, L8
Downgradient = L5, L9
Surface Soil = SS1, SS2, SS3 (near source)

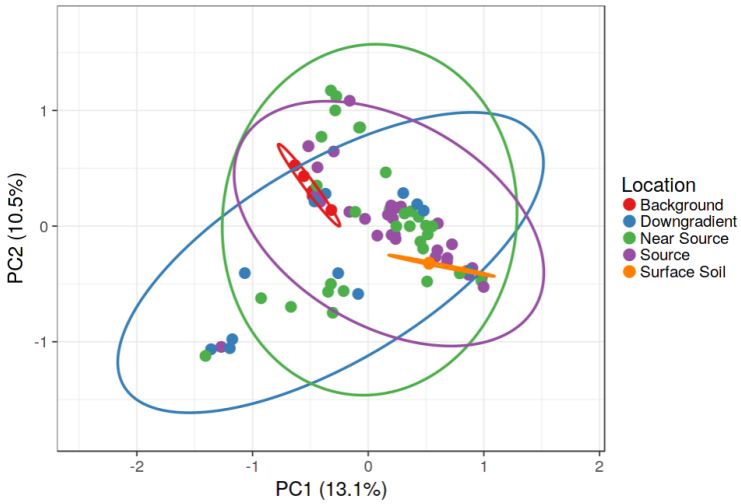

Figure 5-61. Principal Component Analysis for Groundwater Data (Top Panel) and Soil Data (Bottom Panel) from Fentress. *Analyses performed on transformed data from all locations and included all reported analytes (unfiltered).*

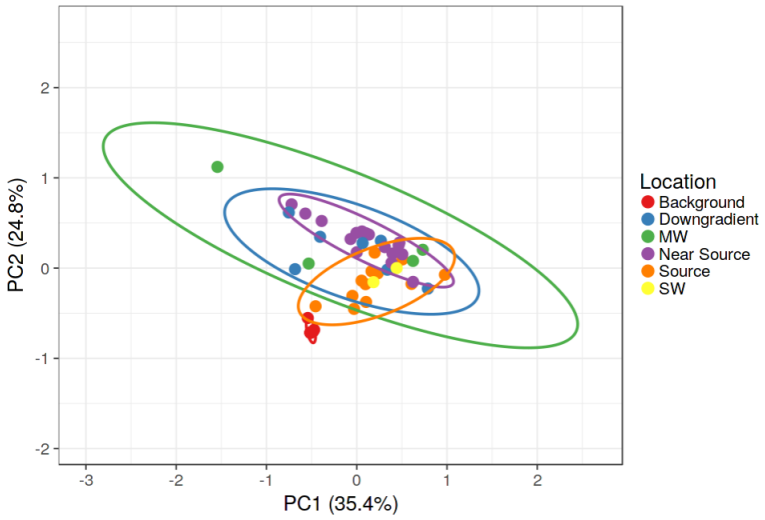

Rerunning the PCA after further data filtering provided additional resolution, particularly for the groundwater data. This included runs with only target analytes (Figure 5-62, top panel) and with only select locations (Figure 5-62, bottom panel). After reducing the number of variables to only target analytes, the background location groundwater data form an even tighter cluster that is

distinct from the source area data, which clusters similarly with the groundwater data from the near downgradient and downgradient locations. Note that the source area and plume datasets also cluster with groundwater data from existing monitoring wells at the site (all of which are located near the source) as well as surface water samples from impoundments which are located in the downgradient plume. This suggests that PFAS associated with AFFF releases in the AFFF Storage and Transfer Area are the source of PFAS detected in the plume, even after accounting for shifts in composition during transport. these results also suggest that runoff of PFAS from surficial soils (which exhibit high PFAS concentration relative to deeper soils at this site) is likely contributing to PFAS detected in the surface water impoundments, especially given that similar clustering occurred in the unfiltered groundwater data (Figure 5-63). This distinct clustering of the background location data becomes even more apparent when only the data from source area location L3 and background location B1 and B2 were included (Figure 5-63, bottom panel). The confidence intervals for the background data do not overlap with the confidence interval for the source area location. The variability explained by PCA1 and PCA2 is slightly higher for these two evaluations (60.2% for the run with only target analytes; 50.1% for the run with only select locations).

The HCA results are largely consistent with the PCA results, with the source area forming a grouping, although the background samples formed two groups, one of which was more closely related to the source area data than the other background data.

Collectively, these data support that the PFAS detected at the background locations at this site are unrelated to the releases associated with the AFFF Transfer and Storage Area, and that the PFAS may have come from non-AFFF sources.

PIGE vs. Total PFAS Concentration in Groundwater

Linear regression of the PIGE total fluorine results and the total PFAS concentrations measured in groundwater using LC-QTOF-MS yielded a strong linear correlation with an r^2 of 0.98 (Figure 5-64). These data were also evaluated using the Spearman's Correlation test and resulted in a statistically significant relationship (p=0.002). It is noteworthy that there were no false negatives using PIGE; false positives were not an issue because PFAS was detected in all groundwater samples. There was one datapoint that was a likely outlier due to a PIGE-based measurement that was several orders of magnitude higher than predicted value from linear regression.

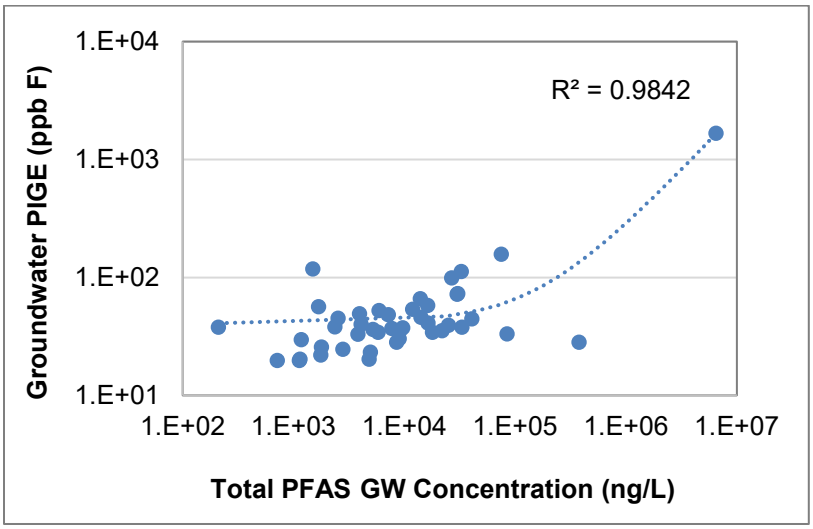

Figure 5-64. Total Fluorine Measured by PIGE vs. Total PFAS in Groundwater

Conceptual Site Model

The spatial patterns in PFAS data were used to evaluate relevant transport processes, the potential for migration, and active natural attenuation mechanisms at the site. This can include retardation due to various mechanisms, as well as biodegradation of polyfluorinated compounds which may serve as precursors to PFAAs. These are represented within the Conceptual Site Model shown in Figure 5-65. As noted above, one of the most noteworthy patterns observed in PFAS distribution at this site is that PFAS concentrations were generally highest in shallow unsaturated soils and then decreased with depth and distance downgradient. This is evidence of retention within the source area that can be attributed to mechanisms such as retardation due to the enhanced partitioning of PFAS at the air-water interface within the vadose zone, partitioning of PFAS to solid-phase surfaces as a result of hydrophobic and electrostatic interactions, and slow advection and diffusion into shallow lower-permeability soils. These processes contribute to attenuation of PFAS concentrations moving away from the primary source. However, the data also suggest that surface releases may have occurred in downgradient portions of the site, and thus serve as a secondary source of PFAS.

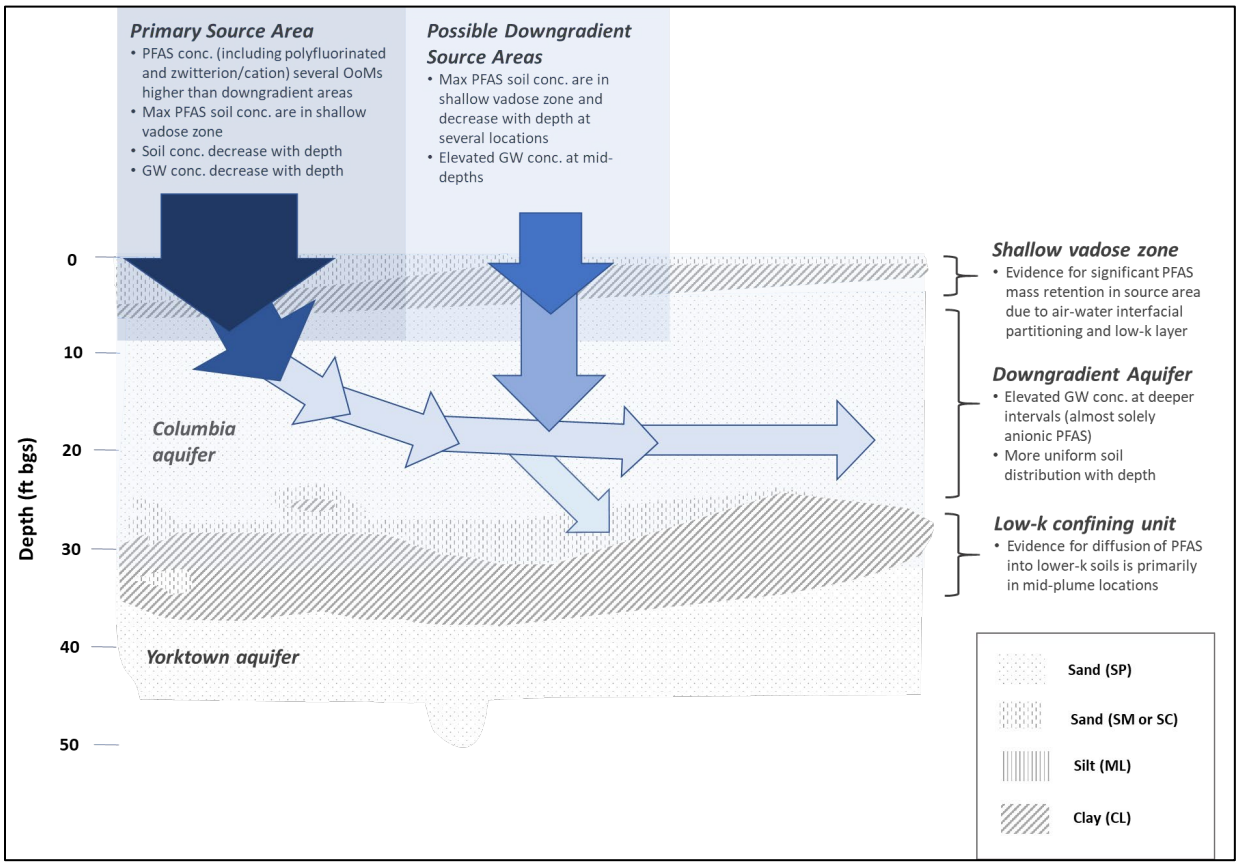

Figure 5-65. Conceptual Site Model for PFAS Source and Fate and Transport. *Shows representative cross section (A-A'; approximatley 1480 ft), with groundater flow direction from left to right (easterly).*

6.0 PERFORMANCE ASSESSMENT

This section provides an assessment of the established performance objectives described in **Section 3.0**. Each subsection describes a specific success criterion and provides supporting information for the evaluation of the technology relative to the criterion. In this discussion, the three sites are discussed and evaluated individually.

Table 6-1. Performance Objectives and Results

Performance Objective	Success Criteria	Site 1: NAS Jacksonville, FL	Site 2: NBVC Pt. Mugu	Site 3: NALF Fentress, VA
Determine presence of source zone(s)	Source soils contain greater abundance of long-chain anionic/zwitterionic and cationic forms compared to groundwater.	**PARTIALLY:** Relative contribution of longer-chain PFAS higher in source area but not statistically significant Relative contribution of zwitterionic/cationic PFAS higher in source area (statistically significant) Many other positive LOEs for source area identification	**PARTIALLY:** Relative contribution of longer-chain PFAS higher in source area (statistically significant) Relative contribution of zwitterionic/cationic PFAS higher in source area (statistically significant) Many other positive LOEs for source area identification	**PARTIALLY:** Relative contribution of longer-chain PFAS higher in source area but not statistically significant Relative contribution of zwitterionic/cationic PFAS higher in source area, but not statistically significant Many other positive LOEs for source area identification
Differentiate AFFF and non-AFFF sources	Statistically significant differences between soil/groundwater PFAS concentrations/composition from background (upgradient) wells and other PFAS sources	**YES:** Differences could be established using confidence intervals for clusters obtained through PCA Multiple lines of evidence that PFAS in background locations did not result from AFFF use in primary source area	**NO:** Differences could not be established using PCA	**YES:** Differences could be established using confidence intervals for clusters obtained through Principal Component Analysis (PCA) Multiple lines of evidence that PFAS in background locations did not result from AFFF use in primary source area

Performance Objective	Success Criteria	Site 1: NAS Jacksonville, FL	Site 2: NBVC Pt. Mugu	Site 3: NALF Fentress, VA
PIGE as cost-effective guidance tool for drilling and plume footprint	PIGE results correlate with LC-MS/MS measurements	**PARTIALLY (GW)**: r^2 of 0.57 (statistically significant) *PIGE provides some indication of the relative PFAS levels in groundwater.*	**YES (GW); PARTIALLY (Soil):** r^2 of 0.98 for groundwater (statistically significant), and r^2 of 0.13 for soil (statistically significant). *PIGE provides a representative indication of the relative PFAS levels in groundwater, but not for soil at this site.*	**YES (GW):** r^2 of 0.98 for PIGE comparison with groundwater (statistically significant). *PIGE provides a representative indication of the relative PFAS levels in groundwater.*
Natural attenuation-evidence from retardation factors, PFAS fingerprints, and spatial distributions	(i) Retardation factors estimated for PFASs are consistent with aquifer properties and PFAS properties (ii) PFAS identified as biodegradation intermediates are present and are consistent with field conditions and limited literature information	**YES:** Retardation factors followed expected patterns and correlated with site characteristics and PFAS characteristics Multiple additional lines of evidence obtained to support relevance of several different attenuation mechanisms, including transformation and matrix diffusion	**YES:** Retardation factors followed expected patterns based on site characteristics and PFAS characteristics Multiple additional lines of evidence obtained to support relevance of several different attenuation mechanisms, including transformation and partitioning to aquifer solids	**YES:** Retardation factors followed expected patterns based on PFAS characteristics Multiple additional lines of evidence obtained to support relevance of several different attenuation mechanisms, including transformation and air-water interfacial partitioning

6.1 DETERMINE PRESENCE OF SOURCE ZONE

High-resolution spatial characterization of PFAS using a comprehensive suite of analytical methods was completed, with the overall goal of establishing the PFAS distribution and compositional differences associated with the source zone vs. downgradient locations. This information provides the foundation for the conceptual site model and informs both risk assessments and remedial decision-making.

Success Criteria: *Source samples contain greater abundance of long-chained PFAS and zwitterionic and cationic PFAS compared to downgradient samples.*

6.1.1 Success Criteria Achieved?

Site 1: NAS Jacksonville, FL - ***PARTIALLY***

A representative carbon chain length for all PFAS at each location was estimated after weighted by the concentration of individual PFAS. As expected, the PFAS chain length generally decreased with distance from the source due to preferential sorption (retardation) of longer-chained compounds, but these chain length differences could not be established as statistically significant. In part, this reflects the relatively narrow range of representative carbon chain lengths at these site locations (all were between 5.8 and 6.8).

The concentrations of zwitterionic/cationic PFAS were higher in the source area than at downgradient locations, and this difference was statistically significant (p=0.01). These compounds are expected to more strongly retained within the source area due to favorable electrostatic interactions, as was confirmed by these data.

In addition, a number of other lines of evidence (discussed in detail in Section 5.7.2) confirmed that the former firefighter training area was serving as the primary PFAS source area, including: 1) highest total PFAS concentrations in both soil and groundwater were found in the immediate vicinity of the former firefighter training area; 2) highest PFAS concentrations in surficial soils were observed within the same general area; 3) relative abundance of PFOS precursors within source area; 4) usage of ECF-based AFFF based on site history and high concentration of PFOS typically at or above expected branching percentage; 5) usage of telomer-based AFFF based on abundance of fluorotelomer substances and low PFOA branching percentages; and 6) PFAS concentrations decrease rapidly in the direction of groundwater flow.

Site 2: NBVC Pt. Mugu, CA - ***PARTIALLY***

At this site, the PFAS chain length decreased with distance from the source due to preferential sorption (retardation) of longer-chained compounds, and the difference between source vs. far downgradient locations was statistically significant. The range for these representative carbon chain lengths were between 4.7 and 6.2 at this site.

Based on aggregated data, the concentrations of zwitterionic/cationic PFAS were higher in the source area than at downgradient locations, and the results were statistically significant (p=0.001). For example, the shallow unsaturated soil sample from location L5 exhibited the highest concentration of zwitterionic/cationic PFAS (1,013 ng/g). In addition, zwitterionic and cationic PFAS were largely absent from site groundwater. When coupled with several other site-specific

lines of evidence (discussed in detail in Section 5.7.3), the former firefighter training area was serving as the primary PFAS source area at this site.

Site 3: NALF Fentress

The PFAS chain length generally decreased with distance from the source due to preferential sorption (retardation) of longer-chained compounds, and the shortest representative value (5.86) was observed in the farthest downgradient location. However, these chain length differences could not be established as statistically significant. This site had the highest chain length values within the source and near source area (7.00 – 7.03) of any of the three sites that were investigated as part of this project.

The percentage of zwitterionic/cationic PFAS could not be established as higher in the source area than at downgradient locations. In part, this reflects the relatively low concentrations of these charged compounds in downgradient locations, particularly in groundwater. Like the other sites, the highest concentrations of zwitterionic/cationic PFAS were consistently measured in the source area at this site, particularly within shallow soils. However, a distinguishing characteristic at this site was data showing relatively high PFAS concentrations, including zwitterionic/cationic compounds, in shallow soils at mid-plume locations. These results suggest that surface releases and/or runoff of AFFF at downgradient locations may be serving as a secondary source of PFAS to groundwater. Regardless, the preponderance of data indicates the AFFF Storage and Transfer Area was the primary PFAS source area at this site, as detailed in Section 5.7.4

6.2 DIFFERENTIATE AFFF AND NON-AFFF SOURCES

The distributions of PFAS in groundwater and soil from the suspected source area were compared to those in locations where historic AFFF use is not suspected based on the site history. This evaluation provides information on the nature of PFAS sources at DoD sites, as well as concentrations and compounds potentially associated with background PFAS sources (that may impact source and plume delineation efforts).

Success Criteria: *Principal Component Analysis (PCA) and/or Hierarchical Cluster Analysis show differences between source zone composition and concentrations vs. background locations.*

6.2.1 Success Criteria Achieved?

Site 1: NAS Jacksonville, FL **- YES**

PCA results demonstrated that PFAS composition in samples from specific source area locations (Location 3) formed a distinct group that was different from those formed by the two background locations (Locations 16 and 17). The presence of zwitterionic/cationic PFAS in the source area and relative absence of zwitterionic/cationic PFAS in background locations serves as a secondary line of evidence for differentiating between the AFFF source and other diffuse sources. Specifically, this provides further evidence that the PFAS present in these locations derives from a non-AFFF source, potentially through a different application or transport route.

As described in detail in Section 5.7.2, PFAS compositional data and isomer branching patterns are consistent with the use of both ECF-based foams as well as telomer-based foams in the source

area. Background locations were dominated by non-PFAAs compounds in both soil and groundwater, and compounds identified during non-target analysis that were unique to the background locations included several longer-chain hydrido-perfluorosulfonates in soil (e.g., H-PFPeDA, H-PFTeDA, H-PFTrDA). The presence of these compounds suggests that other PFAS sources may have contributed to the observed PFAS, though a source cannot be readily identified. Compounds that have been proposed to be largely associated with non-AFFF sources (such as shorter chain fluorotelomer intermediates that have been proposed to be diagnostic of landfill leachate (e.g., 5:3 FTCA for landfill; MeFOSA and EtFOSA for industrial/commercial products) were generally not detected in soil and groundwater from any location. In addition, the variability in PFAS compositions observed at individual locations or within proximate areas (as reflected in the low amount of variability that could be described by PC1+PC2 during PCA) would complicate assigning the PFAS from background locations to any specific non-AFFF source.

Site 2: NBVC Pt. Mugu **- NO**

The data collected at this site suggested that the PFAS signatures in samples from the background locations at this site may be different than those in the primary source area. However, the data do not provide strong evidence that the PFAS at these locations would have derived from non-AFFF sources. The PCA results generally showed that data from background locations clustered within a tight confidence interval, although the boundaries still overlapped with those that were based on data from the source area. The two background locations were located cross gradient to groundwater flow but relatively close (800 ft) to the farthest downgradient location. As a result, PFAS resulting from AFFF releases in the firefighter training pits could have been the primary or sole contributor to the observed PFAS. Background locations were dominated by non-PFAAs compounds in both soil and groundwater, though they were largely similar to those detected in the source area groundwater. Compounds that were unique to the background locations were non-target analytes, including several longer-chain hydrido-perfluorosulfonates in soil (e.g., H-PFPeDA, H-PFTeDA, H-PFTrDA). Like the other sites investigated as part of this project, there was little or no contribution from compounds that are generally considered indicative of non-AFFF PFAS sources (e.g., 5:3 FTCA, MeFOSA, EtFOSA) at these background locations.

The PCA results also established that there was overlap between source area data and the data from near source and both downgradient directions, which supports that these areas represent similar PFAS sources even accounting for transport-related compositional shifts. As described in Section 5.7.3, there were several other lines of evidence confirming that the former firefighter training area was the primary source of PFAS at this site, including the use of both ECF-based AFFF and telomer-based AFFF.

Site 3: NALF Fentress **- YES**

At this site, the PCA results showed a clear distinction between specific source area locations and the two background locations, with no overlap in the confidence intervals. These analyses also suggest that the PFAS present in surface soils located downgradient of the AFFF Storage and Transfer Area are also highly similar in composition to those in the primary source area and thus likely associated with AFFF usage. There were several other lines of evidence that usage of both ECF-based AFFF and telomer-based AFFF were the primary source of PFAS in the source area locations and downgradient, and that these were not directly contributing to PFAS observed in background locations.

PFAS was detected at up to 900 ng/kg and 16,000 ng/L in soil and groundwater samples from the background locations. PFOS was absent in all soil samples and all but 1 groundwater samples from these locations. Compounds unique to the background locations were detected in groundwater samples but several unique compounds were detected in soil samples (e.g., UPFOS, H-PFPeA). The presence of these compounds suggests that alternative PFAS sources may have contributed to the observed PFAS at background locations, although a source could not be readily identified. No other known or suspected sources of PFAS were reported in site documentation, and compounds indicative of non-AFFF source (e.g., 5:3 FTCA, MeFOSA, EtFOSA) were detected very sporadically and only at trace levels.

6.3 PIGE AS COST-EFFECTIVE GUIDANCE TOOL

PIGE analysis was completed by the University of Notre Dame on the majority of aqueous samples and a subset of soil samples to determine how the total fluorine measurements generated by the method compare to the total PFAS concentrations generated by LC-MS/MS. While the latter method quantifies individual PFAS and thus provides more forensic information, PIGE has the potential to provide a quick, low-cost option to understand relative PFAS levels at a site.

Success Criteria:

Establish strong correlation between PIGE results and LC-MS/MS results using linear regression ($r^2 > 0.7$).

Established statistically significant relationship between PIGE and LC-MS/MS results using non-parametric test (Spearman's Correlation; $p<0.05$)

6.3.1 Success Criteria Achieved?

Site 1: NAS Jacksonville, FL **- PARTIALLY**

Using data from 43 aqueous samples, the PIGE results showed that there was a statistically significant relationship with the LC-MS/MS data based on the non-parametric test results, but linear regression yielded an r^2 value (0.57) that was slightly below the chosen threshold. In part, this was due to non-linear distribution of the data, particularly at the lower-end PFAS concentrations where PIGE appeared to provide less resolution. These data suggest that PIGE provides a reasonable indication of the relative PFAS levels in these groundwater samples but may be better suited as a screening tool to characterizing higher-concentration areas (i.e., source zones).

Site 2: NBVC Pt. Mugu – **YES** (groundwater)

At this site, there was sufficient data to evaluate correlations between PIGE groundwater data and LC-MS/MS measurements of total PFAS in groundwater as well as in co-located soil samples. In both cases, a statistically significant relationship could be established using the non-parametric test. This is consistent with the expectation that soil and groundwater PFAS concentrations in co-located samples should be similar, such that PIGE results would demonstrate some similarity to soil result despite the different matrices being analyzed. However, only the groundwater datasets demonstrated a correlation that was strong enough to meet the success criteria ($r^2 > 0.7$ from linear regression). The correlation coefficient between PIGE and soil data was low (0.13), such that the ability to actually predict soil concentration using PIGE appears to be low. There were a number

of samples where PIGE did not detect PFAS even though the total PFAS through the higher-resolution techniques was greater than 4000 ng/L in all samples. This was a result of the high limit of quantification for PIGE this site (approximately 5,000 ng/L) which was influenced by the high ionic strength of the groundwater. These data provide further confirmation that PIGE is likely better suited for source area characterization efforts at sites where the natural water chemistry is not overly complex.

Site 3: NALF Fentress - **YES**

A statistically significant relationship between the PIGE groundwater data and the LC-MS/MS groundwater could also be established at this site using Spearman's Correlation test. Linear regression also resulted in a high r^2 value that met the success criterion. In addition, there were no false negatives using PIGE. At this site, the correlation in lower-end range of concentrations (1000 to 100,000 ng/L) was relatively strong and likely to provide more predictive value than the higher-end range of concentrations. This is because one PIGE-based measurement was several orders of magnitude higher than any other measurements, such that it may not be representative. Regardless, the correlation was reasonable within a range that might be expected within a source area.

6.4 EVIDENCE OF NATURAL ATTENUATION

PFAS compositional data were generated, and spatial patterns were used to provide both qualitative and quantitative evidence for active natural attenuation mechanisms at the site. This can include retardation due to sorption, as well as biodegradation of polyfluorinated precursors.

Success Criteria:

(i) Estimate retardation factors for PFAS and evaluate if these values are consistent with site characteristics and known PFAS characteristics; and
(ii) Establish that PFAS degradation intermediates are present and/or other evidence of biodegradation.

6.4.1 Success Criteria Achieved?

Site 1: NAS Jacksonville, FL - **YES**

Soil adsorption coefficients and retardation factors were calculated for key PFAAs using co-located soil and groundwater data. Overall, values of Kd varied significantly with distance, both with depth and distance downgradient. Additionally, Kd values generally increased with increasing PFAS chain length and were higher for PFSAs than PFCAs, as expected. Retardation factors by soil type were between 1.7 and 10.4, and even shorter-chain PFAAs like PFBA and PFBS exhibited values that were consistently above 2.0.

For most PFAAs, a positive correlation between Kd and organic carbon could be established, indicating the importance of hydrophobic sorption as a mechanism for retardation. Little effect was observed for pH or EC, suggesting that partitioning due to electrostatic interactions may have been limited relative to hydrophobic sorption at this site. In contrast to the expected inverse relationship, cation exchange capacity (CEC) was positively correlated with K_d, but this is likely due to the increased organic carbon associated with soils with higher CEC.

The relevance of various retention mechanisms was established at this site, including the higher contribution of less mobile cationic/zwitterionic species to the total PFAS measured in the source area relative to downgradient areas. Matrix diffusion was also confirmed to be a key process at this site, with high concentrations of PFAS present in soils with relatively limited permeability. This contributed to decreases in the PFAS mass discharge with distance from the source.

Confirmation that transformation was occurring at this site was based on several lines of evidence, including trends in the percentage of PFAA end-products relative to other PFAS, with the assumption that the latter group represents all potential precursors. If biodegradation of precursors was occurring, the percentage of PFAA end-products would be expected to increase moving downgradient from the source area, which was observed. The percentage of degradation end-products (i.e., PFAAs) relative to precursors is higher in the groundwater samples from downgradient locations relative to both groundwater and soil samples from the source area. Additionally, suspected biodegradation intermediates (e.g., Spr-FHxSA) have been identified in downgradient samples that are absent from source area samples. There are several other lines of evidence for biodegradation, including the identification of specific biodegradation intermediates and high concentrations of intermediates (e.g., fluorotelomer sulfonates) that are not expected to be present in large quantities in AFFF sources.

Note that the dataset from this site was part of parallel study that performed a PFAS mass balance across the site (Adamson et al., 2020). That evaluation established that PFAS precursors were being converted to PFAAs at an annual rate of 2% or less, and that the relative contribution from precursors on a mass basis was decreasing with distance from the source (Figure 6-1).

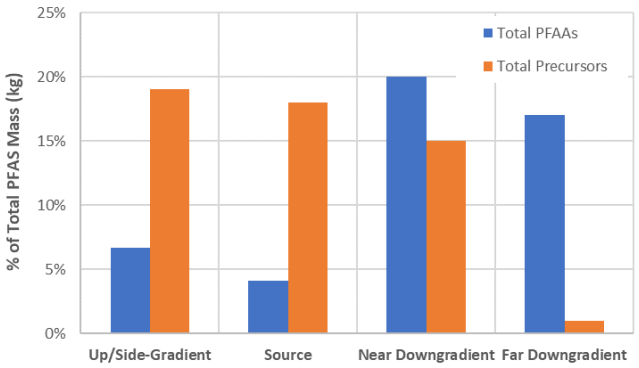

Figure 6-1. Comparison of Precursor vs. PFAA Distribution at NAS Jacksonville (from Adamson e al., 2020).

Site 2: NBVC Pt. Mugu - **YES**

Soil adsorption coefficients and retardation factors were calculated for key PFAAs. As expected, K_d values generally increased with increasing PFAS chain length and were higher for PFSAs than PFCAs. Retardation factors ranged from 1.7 to 46 for the various PFAS, confirming significant retardation relative to the seepage velocity for groundwater at the site. Soil adsorption was generally greater in sands (SP) as compared to clays (CL) for the key PFAAs, presumably due to the lower CEC of these soils. This trend indicated that electrostatic forces were a significant factor contributing to the adsorption onto sands compared to hydrophobic forces. Similarly, trends of f_{oc} and other anions detected in groundwater (e.g., chloride, fluoride, sulfate), indicated that groundwater collected in clayey soils typically had significantly higher concentrations of other anions, despite these soils also having greater f_{oc} values as compared to sands. As such, the high salinity of this site likely influenced adsorption due to electrostatic processes. It should be noted that only a limited number of groundwater samples from clayey soils could be obtained.

The high salinity and the abundance of lower-permeability soils apparently contributed to significant attenuation of PFAS concentrations that were observed with distance from the source area, as described in Section 5.7.3. In addition, the relatively high concentrations in shallow unsaturated soils provided evidence for vadose zone retention due to air-water interfacial sorption. Despite these factors, total PFAS concentration remaining well above 1000 ng/L across the site, including maximum soil and gr14,000 ng/kg), and groundwater samples from these locations also exhibited concentrations (7,500–136,000

Site 3: NALF Fentress **-YES**

Like the other 2 sites, retardation factors for key PFAAs estimated at this site generally increased with increasing chain length and were greater for PFSAs than PFCAs. One exception was an anomalously high R of 48 for PFPeA in sands. The retardation factors for the remaining compounds ranged from 1.8 to 18. Given that these estimates are based on a relatively limited number of co-located samples where compounds were detected in both matrices (soil and groundwater), some anomalous values can be expected. At this site, the limited number of K_d values meant it was not possible to establish correlations with other site characteristics like soil organic carbon. This was another site where the K_d values for sands were generally higher than those for clays despite the higher f_{oc} values for the latter soil type. While the dataset is small, this suggests that electrostatic interactions are playing a major role in the observed partitioning patterns.

The retardation factors also indicate that the PFAAs are moving at a slower rate than site groundwater. While PFAS was detected at all locations, the site also had several lines of evidence for attenuation of concentrations with distance that were attributable to retardation and other retention-based mechanisms, as described in Section 5.7.4. In particular, retention within the vadose zone due to air-water interfacial partitioning was evident based on vertical profiling that showed that PFAS concentrations decreased significantly between shallow unsaturated soils and the top of the saturated zone.

The compositional data also support the assumption that in situ transformation of PFAS has occurred at this site. Several suspected transformation intermediates (e.g., fluorotelomer sulfonates, FHxSA) were observed at increasing relative concentrations moving away from the source. In contrast, precursors to these intermediates were detected primarily in the source area. The source area location with the highest total PFAS concentrations also had the highest precursor concentrations, including three unsaturated soil samples that exhibited the highest precursor concentrations measured across the site. In these soil samples, precursors represented 67 – 93% of the total PFAS concentrations. The majority of these precursors were anionic, but their relative abundance in the source area is consistent with retention in the vadose zone due to air-water interfacial partitioning, along with slow transformation to other intermediates and PFAAs that may be more readily transported.

7.0 COST ASSESSMENT

A key objective of this project was to track costs associated with this technology demonstration to provide a basis for estimating costs of a full-scale implementation of the technology at any site.

7.1 COST MODEL

As part of the demonstration, the cost of implementing the field program was carefully tracked and this cost data was used to estimate the cost that would be associated with implementing this methodology at a generic site.

7.1.1 Cost Elements

The field demonstration included high-resolution characterization at up to 11 locations, with depth-discrete soil and groundwater samples obtained per location. Key cost elements that were tracked included: i) review of existing data and selection of locations; ii) development of a Work Plan, Health and Safety Plan, and coordination; iii) Field labor; iv) field program expenses; v) subcontractors; and vi) data evaluation and reporting (Table 7.1).

Table 7.1. Cost Model for Field Demonstration

Cost Element	Tracked Data
Review of Existing Data and Selection of Locations	Personnel labor hours required for document review/assessment.
Development of Work Plan, Health and Safety Plan, and Planning	Personnel labor hours required.
Field Labor	Two field staff needed.
Field Program Expenses	Expenses include: • PFAS analytical costs • Equipment rental • Travel costs • Miscellaneous supplies and consumables
Subcontractors	Utility Clearance Commercial laboratory unit costs (non-PFAS analytes) DPT rig for the full characterization program, including: • One day of HPT profiling. • Depth-discrete soil and groundwater sampling
Data Evaluation and reporting	Personnel labor hours required.

7.2 COST DRIVERS

The total costs of implementing this technology are primarily associated with the level of characterization performed at a site. The key cost drivers are the number of locations characterized per site, and the number of soil and groundwater samples collected per location.

7.3 COST ANALYSIS

The following sections describe the implementation costs at a standard site using cost data acquired during the field demonstration. In particular, these standard implementation costs are based on specific assumptions and are summarized below. The following assumptions were made for the cost analysis:

General Assumptions

- A typical site with unconsolidated media, and characterization to a depth of up to 40 ft bgs.
- Labor hours include typical time spent on site review, development of work plans, health and safety plans, project planning and on-site time based on field program experience by GSI personnel.
- Collection of 60 groundwater samples and 120 soil samples was assumed.
- PFAS analytical costs are assumed to be for a commercial laboratory. For this project, university partners performed all PFAS analyses; however, these would not necessarily be available on a commercial-basis for a typical site. As such, TOP analysis is assumed for all samples at $700/sample for 60 groundwater samples and 120 soil samples. It is noted that development of a method making use of the high resolution mass spectral library of PFAS is being undertaken by some commercial labs and that this method may be available in the future. Costs for such analyses are expected to be on the order of $700/sample. However, implementation of semi-quantitative analysis methods by the DoD is unlikely to be adopted since results are only estimates, and definitive data requires the use of standards. Implementation of TOP analysis is also unlikely to be adopted since that method is also results in estimated values.
- Equipment rental costs include those for YSI meter, turbidity meter, peristaltic pumps, etc.
- Assume field labor by two field staff, and all travel costs include airfare, per diem, lodging, etc.
- Subcontractors include: drillers (using DPT rig for 11 days and HPT tool for 1 day), utility clearance (conducted on first day), and a commercial laboratory (analysis of anions/cations/TOCs, etc).
- No waste disposal costs have been included, assuming all IDW (soil and groundwater) can be stored on-site.

Table 7.2 Cost Model for Implementing High-Resolution Characterization Program at a Generic Site

ITEM/DESCRIPTION	AMOUNT	ASSUMPTIONS
Review of Existing Data and Selection of Locations		
Principal	$1,500	
Senior Engineer	$5,550	
Geologist/Scientist II	$7,500	
Work Plan, Health and Safety Plan, Planning		
Principal	$1,400	Assume 6 total hours of oversight
Senior Engineer	$2,500	Assume 1 hr per day of oversight, 13 days
Field Labor		
Project Geologist	$20,800	Assume 13-day field program
Geologist/Scientist II	$11,000	"
Geologist/Scientist I	$10,200	"
Labor Subtotal	**$60,450**	
Field Program Expenses		
PFAS Analyses, Commercial Laboratory	$126,000	Assume commercial laboratory, TOP analysis for all samples at $700/sample: 60 groundwater, and 120 soil.
Equipment Rental	$3,600	YSI meter, turbidity meter, peristaltic pumps, tubing, etc.
Travel Costs	$12,900	Assume 2 field staff, per diem/logding for 20 nights total for 2 people, airfare
Misc. field supplies and Shipping	$6,900	
Expenses Subtotal	**$149,400**	
Subcontractors		
Drilling	$69,900	DPT Rig with HPT tool for one day
Utility Clearance	$2,100	
Commercial Laboratory, Other Analytes	$17,600	QA/QC (subset), anions, cations, CEC
Waste Disposal	$0	Assume on-site storage
Subcontractor Subtotal	**$89,600**	
Data Evaluation and Reporting		
Principal	$12,150	
Senior Engineer	$14,800	
Project Geologist	$11,600	
Geologist/Scientist II	$10,000	
Labor Subtotal	**$48,550**	
TOTAL	**$348,000**	

8.0 IMPLEMENTATION ISSUES

This technology is focused on collecting high-resolution characterization data for a large suite of PFAS analytes per depth/sample. As such, the following represent key considerations that should be evaluated for the implementation of these methods at a generic site.

8.1 FIELD CHARACTERIZATION

The methods for subsurface drilling are familiar and unlikely to be subject to additional regulatory oversight or permitting other than those associated with standard site investigations. However, the following key categories describe considerations to evaluate prior to implementation:

- **Site Conditions:** it is envisioned that high-resolution characterization for PFAS be implemented primarily at those sites with unconsolidated media, and target characterization of up to 40 ft bgs or where direct-push techniques for depth-discrete sampling are viable. Sites requiring other drilling methods such as hollow stem auguring or sonic drilling will be more expensive to investigate. Additionally, sites with well-delineated source zones and downgradient points are preferable to ensure that data collection is focused and cost-efficient.

- **Waste Disposal:** IDW containing soil cutting, soil cores, and extracted groundwater will be generated with these characterization methods. Due to PFAS impacts, some states may require incineration, or shipping of wastes to those regions that accept PFAS-impacted wastes for disposal in a landfill. Other sites may have viable storage options for solid and liquid IDW drums. Overall, waste disposal can become costly for IDW containing PFAS depending on the state and regulatory drivers at the site.

- **Decontamination:** due to the potential for cross-contamination between locations, drilling equipment (e.g., rods) needed to be thoroughly cleaned using both liquinox/water and a high-pressure steam wash.

8.2 PFAS ANALYSES

For this project, university partners provided analyses for both soil and groundwater for a large suite of PFAS (including precursors), that are otherwise not commercially available at this time. In order to evaluate this large suite of analytes at a generic site, a research lab would need to be identified that could provide a similar level of high-resolution data capabilities. If not, it is likely TOP assay analysis may be the only viable way to capture all precursors and some targeted analytes. This analytical method is expensive to implement, particularly for a large amount of soil and groundwater samples. In addition, the TOP assay would provide only bulk data on total PFAS and little information on relative chain lengths (and no data on the presence and magnitude of individual PFAS, including precursors. Information on the abundance of non-anionic PFAS would also be missing. Also, the TOP assay is an estimate of precursor concentration and is therefore non-definitive, as is the semi-quantitative results for non-targeted PFAS by MS methods. As an alternative to TOP, Total Organofluorine (TOF) methods may provide a more economical and potentially more inclusive estimate of total PFAS since it does not rely on a chemical conversion of precursors to PFCAs as does TOP, and should capture all species regardless of charge. In

addition, TOF methods are becoming increasingly available by commercial analytical laboratories. Generally though, environmental restoration projects in the DoD require that definitive data be generated, so TOP, TOF, and non-targeted MS will likely remain in the realm of research projects for the foreseeable future.

8.3 REGULATORY

No special permits are required to implement this approach. Obtaining approval from applicable regulatory bodies to collect the required data is likely to be straightforward because it involves collecting samples that could be described using standard work plans. The primary hurdle would be agreeing on an analytical program that would meet regulatory requirements. As noted above, the robust datasets collected as part of this project were obtained using methods that are research based and not yet commercially available. As a result, efforts are likely to rely on methods that have been approved by USEPA and that meet DoD QSM requirements, meaning that they would be performed by commercial labs with a more limited analyte list. Consequently, some loss in data resolution should be expected, particularly at sites where non-target analytes comprise a larger portion of the total PFAS concentration.

8.4 OTHER PROCUREMENT ISSUES

This approach can be implemented by experienced field personnel using standard equipment. No procurement issues are anticipated.

8.5 END-USER CONCERNS

This approach can be completed during relatively short period of time, on the order of several weeks to several months depending on the scale of the site and the scope of work. No significant disruptions to normal site operations are anticipated during implementation. The primary end-user concern would be the cost associated with data collection efforts, which can be significant due to the number of samples required and the unit costs associated with analysis. In addition, the data objectives would have to be clearly defined. For example, these data are primarily aimed at informing conceptual site model development. Therefore, this approach may be of less value at sites where data collection efforts are focused on compliance issues.

APPENDIX A: ANALYTICAL METHODS

A.1 Analytical Methods for Soil (Colorado School of Mines)

A.2 Analytical Methods for Groundwater (Oregon State University)

A.1 Analytical Methods for Soil (Colorado School of Mines)

APPENDIX A.1:
ANALYTICAL METHODS FOR SOIL ANALYSIS
(COLORADO SCHOOL OF MINES)

OVERVIEW

The following analytical methods are provided in Nickerson et. al., (2020) and summarized below. Nickerson et al., (2020) includes additional supplemental material related to internal standard matching, analyte lists, etc.

MATERIALS

All PFAS analytical standards were purchased from Wellington Laboratories Inc (Table A1.1). TCEP-d12 (from Sigma-Aldrich) and atrazine-d5, diuron-d6, triphenyl phosphate-d15, metolachlor-d6, and carbamazepine-d10 (fromCDN Isotopes) were used as ESI+ injection standards. The AFFF solution used in the spike-recovery experiment was a mixture of previously characterized AFFFs: a 1999-era 3M AFFF, 1989 3M AFFF, Buckeye AFFF (Backe et al. 2013), Capstone 1157 (Dupont, 2012) and Chemguard 2010 (Backe et al. 2013). All AFFFs were diluted 5000x in 1:1 Optima high-performance liquid chromatography (HPLC)-grade methanol (Fisher Scientific) and Optima HPLC-gradewater (Fisher Scientific). Unless otherwise noted, all solvents were Optima HPLC grade and purchased from Fisher Scientific. Soils A−C were collected by hand shovel from source zones of three different AFFF-impacted U.S. Department of Defense sites. Soil D is a non-impacted soil from an archived collection at Oregon State University, referred to as “soil 1” in Barzen-Hanson et al. (2017a) Soil cores E and F are from two different AFFF-impacted FTAs. Soil cores were collected by applying direct push technology (DPT) methods and samplers that were appropriate for the local subsurface conditions. Soil geology was logged and recorded after obtaining the soil cores. DPT rods and sampling equipment were decontaminated between each location using an Alconox solution and plastic brush, followed by extensive rinsing by pressure washing. All soil samples were air-dried and homogenized with a mortar and pestle, and surface samples were sieved to 2 mm. The water content of soils was determined by drying overnight at 105 °C.

Table A1.1. Targeted analytes for ESI- PFAS analysis. All standards were obtained fromWellington Labs.

Chemical Name	Acronym	Neutral Molecular Formula	Internal Standard
Perfluoroalkanoic acids			
Perfluoro-n-butanoic acid	PFBA	C4HO2F7	13C4-PFBA
Perfluoro-n-pentanoic acid	PFPeA	C5HO2F9	13C5-PFPeA

i. Exist in the standard as the linear and branched isomers.

ii. PFHxDA, FOSAA, MeFOSAA, and EtFOSAA excluded from high-level (>3.85 ng/mL) calibration standards toprevent instrument carryover.

iii. Stored in 100% Optima HPLC-grade isopropanol (IPA) to limit potential degradation. (All other compoundsstored in 100% HPLC-grade methanol.)

METHOD VALIDATION

Method Comparisons Using Field-Collected Soils. Preliminary spike-recovery experiments demonstrated enhanced extraction of cationic and zwitterionic PFAS with strongly acidic conditions, in agreement with previous findings (Munoz et al. 2018; Barzen-Hanson et al. 2017a). A comparison of numerous solvents and extraction conditions revealed that the strong acid alone yielded low recoveries of anionic species and caused undesirable matrix effects, in agreement with Munoz et al. (2018). A brief summary of the preliminary conditions tested is found in Table A1.2. Ultimately, a combined method that released PFASs from solids with two rounds of extraction by basic (NH4OH) methanol followed by two rounds of extraction by acidic (HCl) methanol was found to be the most comprehensive for the wide variety of PFASs detected in field-collected soils. This method was chosen based on the increase in extraction efficiency for a wide variety of PFASs as well as the consistency in results between replicates. To confirm that the comprehensive method provided significant improvements in PFAS extraction from AFFF impacted source zone soils, it was compared to a more commonly applied method that used only basic methanol extractions. PFAS were extracted in triplicate via both methods from Soils A-C. The basic-only method is based on Higgins and Luthy (2006) and subsequent studies that have used variations of this extraction (Houtz et al. 2013; Munoz et al. 2016; Mejia-Avendaño et al. 2017). In the basic-only method, approximately 0.5 g of soil was weighed into a 50 mL polypropylene centrifuge tube, and then 4 mL of 0.1 M ammonium hydroxide (NH4OH) in methanol ("basic methanol") was added to the tube, which was vortexed for 30 s, sonicated for 15 min at 30 °C, and centrifuged at 2470 rcf for 20 min. Finally, the supernatant was decanted and the next extraction round was begun. After four extraction rounds, the supernatants were pooled and passed through ENVI-Carb (Sigma-Aldrich, 250 mg) solid-phase extraction (SPE) cartridges. The resultant pooled extract was evaporated to dryness under nitrogen (N_2) in a 30 °C water bath and reconstituted in 1.5 mL of 1% acetic acid in methanol. One method blank, containing only extraction solvents and PFAS internal standards, was prepared alongside each extraction batch.

Table A1.2. Extraction conditions tested during method development. Condition #14 was chosen as thefinal method.

condition #	round 1	round 2	round 3	round 4
1	10 mL 0.1 M NH4OH MeOH	10 mL 0.1 M NH4OH MeOH	10 mL 0.1 M NH4OH MeOH	
2	10 mL 0.1 M NH4OH MeOH	10 mL 0.1 M NH4OH MeOH	12 mL EtAc, 3 mL 1M CaCl2 in water	
3	10 mL EtAc	10 mL 0.1 M NH4OH MeOH	12 mL EtAc, 3 mL 1M CaCl2 in water	
4	10 mL EtAc	10 mL MeOH	12 mL EtAc, 3 mL 1M CaCl2 in water	
5	10 mL 0.1 M NH4OH MeOH	10 mL 0.1 M NH4OH MeOH	12 mL EtAc, 3 mL 1M CaCl2/0.1 M HCl in water	
6	10 mL EtAc	10 mL MeOH	12 mL EtAc, 3 mL 1M CaCl2/0.1 M HCl in water	
7	10 mL EtAc	10 mL 0.1 M NH4OH MeOH	12 mL EtAc, 3 mL 1M CaCl2/0.1 M HCl in water	
8	7 mL 0.1 M NH4OH MeOH	7 mL 0.1 M NH4OH MeOH	7 mL 0.1 M NH4OH MeOH	
9	7 mL 0.1 M HCl	7 mL 0.1 M HCl	7 mL 0.1 M HCl	
10	7 mL 0.5 M HCl	7 mL 0.5 M HCl	7 mL 0.5 M HCl	
11	7 mL 0.1 M NH4OH MeOH	7 mL 0.5 M HCl	7 mL 0.5 M HCl	
12	7 mL 0.1 M NH4OH MeOH	7 mL 0.1 M NH4OH MeOH	7 mL 0.5 M HCl	7 mL 0.5 M HCl
13	4 mL 0.1 M NH4OH MeOH	4 mL 0.5 M HCl	4 mL 0.1 M NH4OH MeOH	4 mL 0.5 M HCl
14	4 mL 0.1 M NH4OH MeOH	4 mL 0.1 M NH4OH MeOH	4 mL 0.5 M HCl	4 mL 0.5 M HCl

In the comprehensive method, the first two extraction rounds were identical to the basic-only method. However, after the second extraction round, two more rounds were performed in which the basic methanol was replaced with 4 mL of 0.5 M hydrochloric acid (Fisher Scientific Trace Metal grade) in methanol ("acidic methanol"). After the four extraction rounds (two basic, two acidic), the basic and acidic extracts were passed through separate ENVI-Carb (Sigma-Aldrich, 250 mg) SPE cartridges. The extract was passed through ENVI-Carb prior to evaporation due to the precipitation of salt after neutralization of the acidic extract (which clogged the SPE tube if

performed prior to ENVI-Carb cleanup during preliminary experiments). A neutralization step ofo the acidic extract was performed prior to evaporation so as not to lose PFASs during evaporation. The acidic extracts were cooled at −20 °C for at least an hour prior to neutralization with 1:1 NH4OH:methanol (7 M NH_4OH). The basic and acidic extracts were then evaporated separately, reconstituted in 1.5 mL of 1% acetic acid in methanol, and recombined with a glass pipette. Finally, the combined extract was transferred to a microcentrifuge tube while avoiding the transfer of precipitants formed during the acidic extract neutralization and evaporation. Precipitants were also observed in extraction blanks and therefore assumed to consist of primarily ammonium chloride.

The extracts were centrifuged for 10 mins at 17,000 rcf followed by dilution of 100 µL of supernatant to 400 µL total volume (20% aqueous/80% methanol composition) in an HPLC autosampler vial. Internal standards (Table S1) were added to each autosampler vial before LC−QTOF-MS analysis for the method comparison experiments; surrogate standards were not added prior to extraction to use the same extracts for TOP analysis. Other samples such as cores E and F had surrogate standards added prior to extraction. When highly concentrated samples or excessive matrix effects causing unacceptable injection standard recoveries were encountered, a smaller volume of extract (e.g., 20 µL) was diluted. The extracts of Soils A−C prepared with the comprehensive method were sent to SGS AXYS (Sidney, BC) for TOP analysis, as well as the extracts of Soil A prepared with the basic-only method (Chandramouli 2018). Briefly, aqueous samples were exposed to persulfate and heat under basic conditions to convert PFAA precursors into perfluorinated end products. The efficiency of the oxidation was measured using both recovery and extent of the disappearance of isotopically labeled compounds.

Spike Recovery of Standards. After confirming that the comprehensive method improved the extraction of PFASs from source zone soils, the recovery of spiked target PFASs (anions only) was assessed in a clean soil matrix. Four autoclaved replicates of 0.5 g of a soil sample were weighed into 50 mL polypropylene tubes spiked with a methanol solution of all target PFAS standards (Table A1.1). The solvent was allowed to evaporate for 1 h prior to adding 2 mL of synthetic groundwater (0.5 mM CaCl2 in water). Wetted soils were equilibrated for 24 h on a shaker table. This allowed spiked PFASs to equilibrate with the wetted soil matrix to simulate the extraction of field-collected or aged samples. A 5 µL aliquot of 1:1 NH4OH:methanol was added to all vials to limit the evaporation losses of PFASs. Once dry, 4 ng of all PFAS internal standards (Table A1.1) was added to each tube and the soil was extracted via the comprehensive method.

Spike Recovery of the AFFF Mixture. To evaluate the recovery of a broader suite of PFASs than the target list, including cations and zwitterions, a spike-recovery experiment using a mixture of AFFFs was performed. An equilibration step with an aqueous phase was again employed to mimic field conditions. The use of AFFF also allowed the identification of potential transformation reactions during extraction that would not be evident when solely spiking with analytical standards. Once prepared, 50 µL of the AFFF spiking solution (5000× dilution in 1:1 methanol/water) and 1 mL of synthetic groundwater were added to triplicate polypropylene tubes containing autoclaved 0.5 g Soil D. Triplicate tubes containing Soil D and 1 mL of water were extracted as controls, as well as triplicate tubes with water only as method blanks. All polypropylene tubes were vortexed, sonicated, centrifuged, and placed on a shaker table to shake vigorously for 1 week in an upright position. After equilibration, samples were dried under N_2 in a water bath (30 °C) and extracted via the comprehensive method. Internal standards (Table A1.1)

were added to each autosampler vial before LC-QTOF-MS analysis for AFFF spike-recovery experiments.

Site Sample Analysis. All soil samples from Jacksonville, Mugu, and Fentress NAS were extracted via the comprehensive method described above. A mixture of surrogate standards, containing all available isotopically-labeled PFAS standards (Table A1.1), was spiked onto each dry, homogenized sample prior to addition of extraction solvents.

INSTRUMENTAL ACQUISITION

All PFAS analyses were performed by LC−QTOF-MS (X500R; SCIEX, Framingham, MA). Each extract was analyzed twice: once for anionic and zwitterionic PFASs with negative mode electrospray (ESI−) analysis and once for cationic and zwitterionic PFASs with ESI+ analysis. Both analyses used 100 μL injection volumes and identical chromatographic conditions, except for the guard columns used. A Gemini C18 analytical column (3 mm × 100 mm × 5 μm; Phenomenex, Torrance, CA), one Security Guard C18 guard cartridge (4 mm × 2 mm I.D.; Phenomenex), andeither two Zorbax DIOL guard columns (4.6 mm × 12.5 mm × 6 μm; Agilent, Santa Clara, CA) for ESI− mode or one Zorbax SIL guard column (4.6 mm × 12.5 mm × 5 μm; Agilent) for ESI+ mode were used for all injections. All data were collected via SWATH data-independent acquisition. Details of chromatographic and mass spectral parameters canbe found in the Supporting Information (SI). A calibration curve of anionic target PFASs (Table S1), ranging from 0.02 to 2000 pg (mass/100 μL), was run with all ESI− analytical runs. For ESI− analysis, $^{13}C_2$-PFOA was used as an injection standard, added directly to the autosampler vials to check for consistency of injections and matrix effects. Since no isotopically labeled PFAS standards are currently available that ionize by ESI+, compounds with a variety of retention times and chemical structures were selected as injection standards in ESI+: atrazine-d5, diuron-d6, TCEP-d12, triphenyl phosphate-d15, metolachlor-d6, and carbamazepine-d10. Data were only used when the recorded peak area of injection standards in samples was within 50% of the average peak areas recorded during the calibration curve. In addition, dilutions of Capstone 1157 were run as a semiquantitative calibration curve alongside each set of samples in ESI+ analysis, prior to the availability of three ESI+ PFAS analytical standards: n-dimethyl ammonio propyl perfluorohexane sulfonamide (AmPr-FHxSA), n-trimethylammoniopropyl perfluorohexane sulfonamide (TAmPr-FHxSA), and 6:2 FTSA-PrB (see Nickerson et al., (2020) for structures, formulas, and neutral masses). Once these standards became available, they replaced the Capstone 1157 dilution as the calibration curve. Instrument blanks, solvent blanks, and continuing calibration verification (CCV) standards were run after every 10 samples. Sample concentrations were only reported if the CCV standards run before and after were within 30% accuracy. A mixture of AFFFs was injected alongside samples as chromatographic reference points for suspect screening hits.

DATA ANALYSIS

SCIEX OS (SCIEX) was used for data acquisition and processing to quantify targeted analytes and identify suspect PFASs from a custom extracted ion chromatogram (XIC) list containing molecular formulas for >1400 PFASs (D'Agostino et al. 2014; Barzen-Hanson et al. 2017b). Target analytes were defined as any compound for which an analytical standard was available, excluding the three ESI+ analytes since no isotopically labeled ESI+ PFAS standards were

currently available. Suspect matches were defined as compounds lacking analytical standards but meeting certain criteria specified below (confidence levels 2−4 based on Schymanski et al. (2014). The XIC list included well characterized PFASs, PFASs reported in the literature, and theoretical homologs (Nickerson et. al., (2020)). Mass spectra were also screened against a custom MS/MS spectral library of >300 AFFF-associated PFAS spectra.

QUANTITATIVE ANALYSIS AND QUALITY CONTROL

A list of target analytes and internal standards used for quantitation is provided in Table A1.1. Target analyte peaks were only considered when retention times were within 30 s of analytical standards, mass error <10 ppm from the nominal isotopic m/z (XIC window 0.01 Da), and the peak signal-to-noise ratio >10. Internal standard recoveries were calculated based on the average internal standard peak areas recorded during the calibration curve and were used to correct for matrix effects and extraction losses of target analytes. Target PFAS concentrations were only reported when they were at least three times higher than all instrument and method blanks' concentrations.

SUSPECT SCREENING

HRMS data were screened for the compounds in the XIC list, which were assumed to be present as the deprotonated molecular ion ([M − H]−) in ESI− and the protonated molecular ion ([M + H]+) in ESI+, to identify suspect matches beyond the targeted analytes. Mass spectral features were integrated with an XIC width of 0.01 Da, baseline subtraction over 2 min, and a Gaussian smoothing width of 1.0. Only peaks with a signal-to-noise ratio >25 were considered for compound matching. Mass spectral features were considered XIC matches when associated with a compound on the XIC list with <5 ppm mass error, <10% isotope ratio difference, and <70% spectral library match based on the SCIEX OS algorithm (or a higher library score with only the precursor ion matching upon visual inspection). Mass spectral features were considered library matches when associated with a compound on the XIC list with <10 ppm mass error, <20% isotope ratio difference, and >70% spectral library match, as well as visual confirmation of at least one matching fragment. Since MS/MS spectral matching gives higher confidence in identification, library matches were allowed to have a wider range of acceptable values for mass error and isotope ratio difference. Broadly, a library match would be considered to have a confidence level of 2, while an XIC match is of level 4 confidence (Schymanski et al. 2014). Both XIC and library matches were considered suspect matches. All structural isomers were reported when several fit the XIC match criteria and a single isomer could not be definitively identified. If a feature was associated with an XIC list compound as a library match, all other isomer matches for that feature were discarded. If a feature was matched with FT- and ECF-derived compounds, the presence or absence of peak branching was used as an indication of which match was more likely (branching from ECF and linear only from FT). However, if the peak area was low (<104), the absence of branching was not used to rule out the FT match. All branched isomers were integrated when present and reported as a single area or semiquantitative concentration. Compound matching also considered other class members; for example, the presence of odd-numbered homologues (eg. C5, C7) was used as evidence for the ECF-derived matches, as FT-derived compounds are typically present in even-numbered homologues. Finally, suspect matches were only considered valid if homologous series members eluted in reasonable order (increasing LC retention time with increasing chain length

within a PFAS class). Suspect matches were reported only if the area counts were three times higher than all instrument and method blank area counts.

SEMIQUANTITATION OF SUSPECT MATCHES. ESI-

The concentration of compounds identified as suspect matches was estimated by a semiquantitation (SQ) procedure that associated each XIC list compound with a target calibrant and internal standard based on commonly shared ionizable functional groups and perfluorinated chain lengths. Next, suspect match compound concentrations were calculated as a function of the response factor of the associated target calibrant/internal standard pair (response factor being the slope of the calibration curve), the molar mass of the target calibrant, the molar mass of the suspect compound, the observed peak area of the suspect compound-matched peak, the observed peak area of the internal standard, and the nominal spiked mass of the internal standard (eq 1). The target calibrant and internal standard pairs associated with each suspect compound match are shown in Nickerson et al., (2020). As additional standards became available, the matching process was updated to include new standards.

$$"mass"_{suspect} = \left(response\ factor_{\mathrm{target-IS}}\right) \times \frac{molar\ mass_{suspect}}{molar\ mass\ _{target}} \times \frac{area_{suspect}}{\mathrm{area_{IS}}} \times nominal\ mass_{\mathrm{IS}} \quad (1)$$

ESI+. Dilutions of Capstone 1157, an AFFF containing the X:2 FTSA-PrB class at previously published concentrations,(Backe et al. 2013) were run alongside soils A−C and all Jacksonville NAS samples. Suspect matches were assumed to have an equal molar response factor to either 6:2 or 8:2 FTSA-PrB, depending on the peak area of the suspect match, due to a ∼100-fold higher concentration of the 6:2 homologue in the calibration mixture. SQ concentrations of ESI+ suspect match compounds were calculated by eq 2, based on the slope and intercept of the linear regression between area and concentration (1/concentration weighting).

After Jacksonville NAS samples and Soils A-C had been analyzed, analytical standards for three ESI+-ionizable PFASs (6:2 FTSAPrB, AmPr-FHxSA, and TAmPr-FHxSA) became available from Wellington Laboratories. The AFFF spike experiment, Mugu samples, and Fentress sampleswere run with a calibration curve containing these three standards (all ESI+-analyzed PFASs were associated with one of the three newly available standards based on the similarity of ionizable functional group (Nickerson et al., (2020)) while all other ESI+ samples were run with the Capstone 1157 calibration curve. Once the three ESI+ PFAS standards became available, the 6:2 FTSA-PrB standard was used to correct the previously estimated ESI+ concentrations, which were based on 6:2 FTSA-PrB in Capstone 1157. A dilution of Capstone 1157 was run alongside a calibration curve of the 6:2 FTSA-PrB standard once it became available. It was determined that the previously estimated concentration of 6:2 FTSA-PrB in Capstone 1157 was in error by a factor of 2; therefore, all samples that had been run with the Capstone 1157 calibration curve had their ESI+ concentrations retroactively corrected to be 2 times higher. The most straightforward and accurate approach is to use all available ESI+ analytical standards for semiquantitation; as more standards become available, the calibrant matching will continue to evolve with time.

$$"mass"_{suspect} = \frac{area_{suspect} - intercept}{slope} \times \frac{molar\ mass_{suspect}}{\text{molar mass}_{\text{target}}} \quad (2)$$

A.2 Analytical Methods for Groundwater (Oregon State University)

APPENDIX A.2:
ANALYTICAL METHODS FOR GROUNDWATER ANALYSIS (OREGON STATE UNIVERSITY)

OVERVIEW

Groundwater samples were analyzed using methods described in Schwichtenberg et al. (2020), and briefly summarized below.

METHODS

Sodium chloride and HCL were added to 6 mL of groundwater and spiked with 0.75 ng of 30 isotopically labeled surrogate standards. The water was extracted three times with ethyl acetate and trifluoro ethanol; the final extract was spiked with 1.5 ng of M2PFOA and M8PFOS. No positive mode surrogates were spiked into samples. The extracts were analyzed in negative and positive mode by liquid chromatography quadrupole time of flight mass spectrometry. The instrument was calibrated with 44 negative-mode target PFAS, three positive-mode PFAS (AmPr-FHxSA, TAmPr-FHxSA, and 6:2 FTSA-PrB), and 30 negative mode, stable-isotope labeled surrogate standards (see Schwichtenberg et al. 2020 for which target-surrogates used for quantification in negative mode).

The three positive mode target PFAS were calibrated using area counts for the native area counts (external calibration). The data was analyzed for 47 target PFAS and 1400 suspect PFAS as described in Schwichtenberg et al. (2020) and Nickerson et al. (2020). Information on the levels of uncertainty as well as mass errors, isotope ratios, and library matching was defined as described by Nickerson et al. 2020.

GSI ENVIRONMENTAL

APPENDIX B: QUALITY ASSURANCE/QUALITY CONTROL RESULTS

APPENDIX B:
QUALITY ASSURANCE / QUALITY CONTROL

1.0 SAMPLING PROCEDURES

Groundwater samples submitted for laboratory analysis were collected in accordance with Standard Operating Procedures (SOPs) routinely utilized by GSI, or sample collection methods validated during previous field programs.

Groundwater samples from all sites were analyzed by Oregon State University, and soil samples from all sites were analyzed by Colorado School of Mines. All samples were analyzed in accordance with applicable SOPs, laboratory guidelines, and the chain-of-custody.

2.0 CUSTODY PROCEDURES, HOLDING TIME, ARRIVAL TEMPERATURES

All samples submitted for analysis were received within the required holding times and within the limits specified for temperature for groundwater samples (i.e., ≤ 4° C). All samples were submitted under chain-of-custody control with no indication of any losses of custody. Chain of custody documentation was provided by the final recipient of the samples to document the complete series of custody transactions.

3.0 PRECISION ASSESSMENT

The precision assessment evaluates the agreement in analytical results between duplicate samples (field duplicates and laboratory duplicates).

3.1 Field Duplicates

Field precision was evaluated by calculating the relative percent difference (RPD) between duplicate samples for each site.

3.1.1 Groundwater

Relative percent difference values for duplicate samples of groundwater at the NAS Jacksonville site were calculated for 82 paired PFAS analytes for 2 duplicate samples. Of these, 21 analytes failed to meet the acceptance criteria of ≤ 30% (EDQW, 2020). The minimum RPD calculated was 4.9%, with a median of 109.1% and a maximum of 192%.

Relative percent difference values for duplicate samples of groundwater at the NBVC Point Mugu site were calculated for 46 paired PFAS analytes for one duplicate sample. Of these all analytes met the acceptance criteria of ≤ 30% (EDQW, 2020). The minimum RPD calculated was 3.4%, with a median of 6.7% and a maximum of 27.3%.

Relative percent difference values for duplicate samples of groundwater at the NALF Fentress site were calculated for 113 paired PFAS analytes for 5 duplicate samples. Of these, 32 analytes failed to meet the acceptance criteria of ≤ 30% (EDQW, 2020). The minimum RPD calculated was 1.03%, with a median of 26.92% and a maximum of 200%. Note that the maximum RPD of 200% was obtained from parent samples with measured PFAS concentration and duplicate samples with no measured PFAS concentration and accounted for 22 out of the 32 analytes that did not meet the acceptance criteria.

Overall, for groundwater samples: the NAS Jacksonville, Point Mugu, and NALF Fentress sites had 76%, 100%, and 93% of RPD values within the RPD success criteria, respectfully. Results of the field duplicate analysis are summarized below in Table 1.

3.1.2 Soil

At NAS Jacksonville, relative percent difference values for duplicate soil samples were calculated for 282 paired PFAS analytes for four duplicate samples collected. Results show that 21 analytes from three of the four duplicate samples failed to meet the acceptance criteria of ≤ 30% (EDQW, 2020). The lowest RPD value was 0.16%, with a median of 25.7% and a maximum of 200%. Note that the 200% RPD values accounted for two of the 21 analytes that did not meet acceptance criteria.

At Point Mugu, relative percent difference values for duplicate soil samples were calculated for 229 paired PFAS analytes for five duplicate samples collected. Results show that seven analytes from two of the five duplicate samples failed to meet the acceptance criteria of ≤ 30% (EDQW, 2020). The lowest RPD value was 0.2%, with a median of 23.3% and a maximum of 82.7%.

At NALF Fentress, relative percent difference values for duplicate soil samples were calculated for 239 paired PFAS analytes for the 8 duplicate samples. Results show that 38 analytes from seven of the eight duplicate samples failed to meet the acceptance criteria of ≤ 30% (EDQW, 2020). The lowest RPD value was 0.005%, with a median of 33.6% and a maximum of 200%. Note that the 200% RPDs accounted for 11 out of the 38 analytes that did not meet the acceptance criteria.

Overall, for soil samples: the NAS Jacksonville, Point Mugu, and NALF Fentress sites had 98%, 99%, and 97% of RPD values within the RPD success criteria, respectfully. Results of the field duplicate analysis are summarized below in Table 1.

Table 1: Summary of Field Duplicate Precision

Site	Media	Total Number of Samples	Total Duplicate Analyses	Relative Percent Difference (RPD)			% RPD Less Than 30%
				Min.	Median	Max.	
Site 1 – NAS Jacksonville	Groundwater	2	82	4.9	109.1	192	76%
	Soil	4	282	0.16	25.7	200	98%
Site 2 - Point Mugu	Groundwater	1	46	3.4	6.7	27.3	100%
	Soil	5	229	0.2	23.3	82.7	99%
Site 3 - NALF Fentress	Groundwater	5	113	1.03	26.9	200	93%
	Soil	8	239	0.005	33.6	200	97%

3.2 Laboratory Analysis Precision (Matrix Spike, Matrix Spike Duplicates, Laboratory Control Sample, Laboratory Control Sample Duplicate)

3.2.1 Oregon State University (Groundwater)

Laboratory precision was assessed as the percent Relative Standard Deviation (%RSD) from n=4 replicates from each of four batches. Thus, %RSD was calculated using 3 to 16 observations (Table 2). The limit of quantification ranged from 10-20 ng/L for most target PFAS (Schwichtenberg et al. 2020).

Table 2: Precision, as indicated by %RSD

Analyte	%RSD	n
PFBA	31	10
PFPeA	9.4	15
PFHxA	13	16
PFHpA	11	15
PFOA	7.7	16
PFNA	16	10
PFPrS	21	16
PFBS	26	16
PFPeS	43	15
PFHxS	6.9	16
PFHpS	15	9
PFOS	11	16
PFNS	17	3
PFDS	17	3
PFEtCHxS	13	13
FBSA	34	8
FHxSA	16	16
FOSA	39	8
MeFOSAA	38	8
6:2 FTS	13	16
8:2 FTS	11	16

Note: Results are for n=3-16 replicates. Values are shown only for analytes found in actual groundwater samples.

3.2.2 Colorado School of Mines (Soil)

NAS Jacksonville: one method blank was extracted alongside each batch of samples. 20% of all samples were extracted in triplicate with %RSD<30% (if above, result was flagged).

Point Mugu: one method blank, one laboratory control sample, and one matrix spike sample were extracted alongside each batch of samples. 20% of all samples were extracted in triplicate with %RSD<30% (if above, result was flagged).

NALF Fentress: one method blank, one laboratory control sample, one laboratory control sample duplicate, and one matrix spike were extracted alongside each batch of samples. 10% of all samples were extracted in triplicate with %RSD<30% (if above, result was flagged).

Method Blank: clean soil spiked with surrogate standards; if any native PFAS detected, reporting limit set to 3x the concentration.

Laboratory Control Sample (LCS) and Laboratory Control Sample Duplicate (LCS-dup): clean soil spiked with native and surrogate standards; recoveries 70-130%, otherwise flagged

Matrix Spike: field sample spiked with native and surrogate standards; native recoveries 70-130% of expected concentration.

4.0 ACCURACY ASSESSMENT

4.1 Field Accuracy

The evaluation of field accuracy was based on the analytical results obtained for groundwater trip blanks, field blanks, and equipment rinsate samples. Field accuracy will be met if the concentrations of the constituents are below project quantitation limits.

4.1.1 Equipment Rinsate Blanks

At NAS Jacksonville, PFAS was detected in two samples of the 16 equipment rinsates collected. PFOS (320 ng/L), 6:2 FTSAPr-DiMeAn (80 ng/L), and TAmPr-FHxSA (22 ng/L) were detected in the same sample, while PFHxS (20 ng/L) was detected in the other sample.

AT NBVC Point Mugu, all six equipment rinsate samples successfully met accuracy criteria, meaning PFAS was not detected in any of the equipment rinsate samples collected.

At NALF Fentress, all 10 equipment rinsate samples successfully met the accuracy criteria, meaning PFAS was not detected in any of the equipment rinsate samples collected.

Results of equipment rinsate sample analysis are summarized below in Table 3.

Table 3: Equipment Rinsate Detections

Site	No. of Samples	No. of Detected Samples	Detection Range (ng/L)
Site 1 – NAS Jacksonville	16	2	20 – 320 (PFOS, 6:2 FTSAPr-DiMeAn, TAmPr-FHxSA, PFHxs)
Site 2 - Point Mugu	6	0	n/a
Site 3 - NALF Fentress	10	0	n/a

4.1.2 Trip Blanks

At NAS Jacksonville, PFAS was detected in one trip blank sample (PFHxA at 11 ng/L) of the 14 trip blank samples analyzed.

At Point Mugu, all seven trip blank samples successfully met the accuracy criteria, meaning PFAS was not detected in any of the trip blank samples analyzed.

At NALF Fentress, PFAS was detected in one trip blank sample (PFOA at 34 ng/L; PFHxS at 14 ng/L; and PFOS at 15 ng/L) of the total 11 trip blank samples analyzed.

Results of trip blank sample analysis are summarized below in Table 4.

Table 4: Trip Blank Detections

Site	No. of Samples	No. of Detected Samples	Detection Range (ng/L)
Site 1 - JAX	14	1	11(PFHxA)
Site 2 - Point Mugu	7	0	N/A
Site 3 - NALF Fentress	11	1	14 – 34 (PFOA, PFHxS, PFOS)

4.1.3 Field Blanks

Field blanks were also collected to evaluate the potential for impacts to a sample, from another chemical source not associated with the sample collected.

All 10 field blanks at NAS Jacksonville successfully met the accuracy criteria, meaning PFAS was not detected in any of the field blanks collected.

All seven field blanks at Point Mugu successfully met the accuracy criteria, meaning PFAS was not detected in any of the field blanks collected.

At NALF Fentress, PFAS was detected in one field blank sample (PFHpA at 11 ng/L) of the total 10 field blanks collected.

Results of the field blank sample analysis are summarized below in Table 5.

Table 5. Field Blanks

Site	No. of Samples	No of Detected Samples	Detection Range (ng/L)
Site 1 - JAX	11	0	N/A
Site 2 - Point Mugu	7	0	N/A
Site 3 - NALF Fentress	10	1	11 (PFHpA)

4.2 Laboratory Accuracy

4.2.1 Oregon State University (Groundwater)

Laboratory accuracy was assessed based on percent recoveries from Matrix Spike/ Matrix Spike Duplicate (MS/MSD), Laboratory Control Samples (LCS), and surrogate samples. The accuracy of the method, as indicated by recovery, was 70-112% for most target PFAS spiked into blank water with five target PFAS that lacked matched surrogate standards giving recoveries from 56-65% (Schwichtenberg et al., 2020). The average MPFOA and MPFOS recoveries from groundwater were 88 to 106%, with MPFOA ranging from 49.7-120% and MPFOS ranging from 65.3-147%.

4.2.2 Colorado School of Mines (Soil)

Due to changing QA/QC requirements throughout the time of this project, samples from Mugu and Fentress were analyzed with additional QC samples. Injection standards recoveries in ESI- and ESI+ were required to be within 50-150% accuracy, otherwise samples were rerun or diluted and rerun. Surrogate standard recoveries (ESI- only) were also 50-150%; results outside of this range were flagged but still used for analysis.

5.0 COMPLETENESS ASSESSMENT

The data quality exceptions noted in the data quality review are typical of environmental field programs, and none of these exceptions limit the usability of the results obtained. The results of the data quality review are summarized below in Table 6.

Table 6. Summary of Data Evaluation Results

Data Quality Objective	Results of Data Quality Evaluation
Sampling Procedures	Acceptable
Custody Procedures	Acceptable
Holding Time	Acceptable
Temperature on Arrival	Acceptable
Field Duplicate Samples	Acceptable*
MS/MSD Samples	Acceptable*
LCS/LCSD Samples	Acceptable
Blank Analysis	Acceptable
Completeness Assessment	Acceptable
Overall Data Usability	**Acceptable**

Notes:

1. Acceptable = This Data Quality Objective was evaluated and found to have met the requirements outlined in the Quality Assurance Project Plan.
2. Acceptable* = This Data Quality Objective was evaluated and found to have deficiencies or exceptions as discussed in the text; however, the data was determined to be usable.

C.3 Groundwater Field Parameters

GSI ENVIRONMENTAL

Low-Flow (Minimal Drawdown)
GROUNDWATER SAMPLING RECORD

Client: Navy/ESTCP Date: 7-26-18 GSI Job No. 4500-000 Page: 1 of 1

Project: PFAS Well Number: Loc-26-50' Well Depth: 50' Screen Interval: 47.5-50'

Personnel: JAL/BAS Starting SWL: 10.1 btoc Well Diam: 2" Volume Purged: ~3 gal

Sample meth: Low-flow Tubing Type: Poly-HDPE Other:

SAMPLE INFORMATION

Time	SWL	Pumping Rate	Sample Appearance/Odor	Temp. (°F/C)	pH	Spec. Cond. (mS/cm)	Turbidity (NTU)	Diss.Oxygen (mg/L)	Redox (mV)	Remarks
1730	10.80	0.300	Cloudy/yellow No odor	24.55	5.80	0.166	132	1.50	55.6	
1733	10.90	0.300	" " " "	24.59	5.73	0.165	130	0.70	57.9	
1736	10.91	0.300	" " " "	24.60	5.71	0.165	129	0.59	60.7	
1739	10.91	0.300	" " " "	24.53	5.69	0.165	132	0.55	62.4	
		Sample @ 1740 - for SGS and OSU								
* Stopped purging early ~~due~~ due to time constraints - i.e. had to get to FedEx to ship coolers.

Field Notes

Project: NESDI		**Weather:** Sunny / Isol. t-storms
Date: 7/23/18		**Temperature:** 74-87°F
Location: NAS JAX FFTA		**Precipitation:**
Summary of Field Activities: Well cluster installation		**Wind:** 5-10 mph
		Humidity: 73-94%
Field Personnel:		
Time In/Out:	**Name:**	**Company/Affiliation:**
6:30a - 3:30p 9a ↓	Joran Popovic Justin Long Brian Strusert Dan Mullin Brian Thomas	NAVFAC EXWC GSI GSI Cascade Cascade
Samples Collected:	Drill cuttings from well cluster #24 → 0-3 ft. BGS, 5'-30' BGS, 45'-55' BGS	

Field Notes:

- Initial date of discrete PFAS sampling @ well clusters 24, 25, 26, and 26 at which 4 depths will be sampled, alongside background clusters 16 + 17.
- Met with David Ferel at around 6:45-7a at Yorktown gate to get escorted to FFTA.
- Mentioned that field operations interrupted 7/30, and any sampling closer to the tree line should be rescheduled.
- GSI & Cascade arrived around 9 am after badging, and we covered safety concerns @ the site.
- Use of PFAS-free field items covered - all natural sunscreen and insect repellent used in field.
- #24 cluster was probed first & 0-3 ft was hand augured. Cuttings were collected for independent lab sampling. Remainder was collected in 5 gal bucket & prepared for shipping.
- Cascade followed hand augering with 0-55 ft drilling using geoprobe. Cascade had to use another method to get past 50 ft, as their rig was having trouble getting past the depth.
- Cuttings up to 45-55 ft. BGS were collected, and I left site to ship cuttings @ 3:30p.
- GSI & Cascade finished installing all 4 well clusters (5', 10', 85', & 50' depth) after intermittent Rainfall

Completed By: Joran Popovic

Field Notes

Project: NESDI			**Weather:** Sunny
Date: 7/24/18			**Temperature:** 75-86°F
Location: NAS JAX FFTA			**Precipitation:**
Summary of Field Activities: Well cluster Installation			**Wind:** 5mph
			Humidity: 95%
Field Personnel:			
Time In/Out:	**Name:**	**Company/Affiliation:**	
6:50a - 2:30p 6:50a ↓	Jovan Peporic Justin Long Brian Stewart Dan Mullin Brian Thomas	NAVFAC EXWC GSI GSI Leascrest Cascade	
Samples Collected:	Drill cluster from well cluster #25 at 0-3, 5-35, and 40-50 ft BGS		

Field Notes:

- Second day of field effort. Began day with safety briefing
- Drilling rods were Steam cleaned off site before drilling well cluster #25
- Began developing wells at cluster #24 (at 5, 10, 35, 50 ft) around noon. Performed multiple purge & surge cycles until turbidity diminished.
- Collected roughly 1 gal of IDW from well development @ 35 ft depth from cluster #24. This was then packaged/prepared for delivery. → Noticed slight foaming on top of water surface during collection
- I left the site to ship soil + IDW, then I made stops at Lowe's and Walmart to gather additional field supplies / containers.

Completed By: Jovan Peporic

Field Notes

Project: NESDI			**Weather:** Partly Cloudy
Date: 7/25/18			**Temperature:** 75-90°F
Location: NAS JAX FFTA			**Precipitation:**
Summary of Field Activities: Well cluster installation			**Wind:** 9 mph
			Humidity: 75%
Field Personnel:			
Time In/Out:	**Name:**	**Company/Affiliation:**	
7am - 7pm ↓	Jovan Peporic Justin Carey Brian Streadt Dan Mullin Brian Thomas	NAVFAC EXWC GSI GSI Cascade Cascade	
Samples Collected:	Drill cuttings from well cluster #26 → 0-3 ft, 5-35', 40-50' BGS; Groundwater from all 4 wells at cluster #24		

Field Notes:
- Arrived at gate at 6:45 and waited to be escorted for another 45 minutes
- Had safety meeting & the plan for the day was covered after arrival at site.
- Cascade began work by steam cleaning drilling rods off site.
- During this time, I caught roughly 20 tadpoles from former FFTA lined pit which had accumulated water. Those were stored on ice in their original "pond" water.
- Rain and thunderstorms occurred intermittently from 12:30 PM onwards.
- Well cluster 26 drilling was halted due to being too close to an electrical junction box.
- Vern from environmental contacted a contractor to test the wires, and it was determined that they were not live.
- As a safety precaution, drilling was moved 15 ft. away from junction box.
- Vern also attempted to assist us with determining if any utility lines were under locations for clusters 16 & 17. Said it would take up to two weeks, but he submitted an emergency order.
- Intermittent lightening throughout afternoon created some delays.

Field Notes

Project: NESDI		**Weather:** partly cloudy, Rain 1pm
Date: 7/26/16		**Temperature:** 75-86°F
Location: NAS JAX FFTA		**Precipitation:**
Summary of Field Activities: Well cluster Installation		**Wind:** 5mph
		Humidity: 89%
Field Personnel:		
Time In/Out:	**Name:**	**Company/Affiliation:**
7am - 5:30p	Jovan Popovic Justin Lacy Brian Stewart Dan Mullin Brian Thomas	NAVFAC EXWC GSI GSI Cascade Cascade
Samples Collected:	Groundwater from cluster #25; wastewater influent + Effluent; 10 gals of GW from old MW.	

Field Notes:
- ~~Field~~ Field Safety meeting + Plan for the day was covered
- Drillers finished installing wells @ cluster #26 + began developing those wells.
- GSI Sampled GW from wells @ cluster #25; Groundwater Sampling from cluster #26 followed after well development.
- Contractors from Fluor arrived to locate utilities for clusters ~~#~~ #16 + 17. However, they only located 1 out of the 5 lines that were buried at that location, so no drilling took place this day.
- Cascade began pouring concrete pads for well clusters #24 + 25
- I collected samples from wastewater influent + post-Chlorination wastewater effluent (Roughly 1.5 L each)
- I collected an additional ~10 gallons of Groundwater from a pre-existing monitoring well for another project.
- all of those samples were packaged + shipped to base.
- Left NAS JAX at ~5:30.

Total Organic Carbon by Method USDA LOI					
TOC (Total organic carbon)	**1410**	**2060**	**2420**	**1790**	**1220**
Cation Exchange Capacity					
Cation exchange capacity (meq/100 g)	**0.900**	**2.20**	**2.50**	**1.80**	**1.80**

Notes:
1. Detections are shown in **bold**.
2. < = Constituent not detected at specified Sample Quantitation Limit.
   -- = Not analyzed or not applicable.
   J = The identification of the analyte is acceptable; the reported value is an estimate.
   J4 = The associated batch QC was outside the established quality control range for accuracy
