## Preface

The X hot wire probe is commonly used in anemometry for determining the mean flow direction of a generalized flow field. The problem frequently faced by the experimenters is the accurate alignment of the X sensor relative to the mean flow direction which is normally not known. In this report, I have investigated the performance of two typical cross wire arrangements--one having the sensor "X" lying normal to the probe plane and the other having "X" lying in the probe plane. The two dimensional free jet facility existing in the Aero-Mechanical Engineering Department of the Air Force Institute of Technology (AFIT) was used to conduct this study. A Thermo Systems, Inc. constant temperature Anemometer system and the related accessories were used as the primary instrumentation.

I have attempted to make the report as comprehensive as possible so that it could be useful, I hope, for further research in this area. All the calibration data is tabulated in the appendix and typical example calculations are outlined wherever necessary.

I am grateful to my thesis advisors, Dr. Harold E. Wright, Dr. William C. Elrod and Dr. Andrew J. Shine for providing me the opportunity to work on the anemometer and for invaluable guidance, support and encouragement throughout the course of study.

Mr. William Baker and Mr. John Flahive were very helpful in setting up the laboratory equipment and I am thankful for their valuable assistance.

I am also grateful to Mrs. Joyce Clark for her moral support and for the typing of this thesis.

Fazal B. Kauser

Abstract

This thesis reports the results of an experimental investigation of rotation tests conducted with two X wire sensor arrangements in the potential core of a free jet and the influence of small temperature variations on the linearized response of a hot wire sensor.

The tests were performed in the free jet issuing from a 10 cm x 1 cm nozzle having turbulence intensity of 0.3 per cent at the exit plane. The two X wire sensors used were TSI Model 1240 and TSI Model 1241. Each sensor arrangement consisted of two platinum coated, tungsten wires, having 3.81 micron diameter, active sensor length 1.25 millimeter and separated by 1 millimeter apart. The X sensor Model 1240 was yawed and pitched through  $\pm 30$  degrees and  $\pm 10$  degrees respectively. The size of the potential core, however, limited the movement in yaw and pitch of the Model 1241 to  $\pm 10$  degrees. The tests were conducted at three values of Reynolds Number 7.2, 14.54 and 21.8 based upon the wire diameter.

The investigation showed that both the X sensors had a strong preference for the direction of mean motion, and the error due to misalignment in yaw was largest at very small misalignment angles. The Model 1240 showed insensitivity to misalignment in pitch in the upper range of Reynolds Number but the Model 1241 was highly sensitive to the misalignment in pitch. In the second part of the

study, the air temperature was increased from 4°F to 20°F above the reference and its influence on the linearized response of the upstream sensor of Model 1240 was observed. The test results showed a strong influence of the variations in air temperature on the linearized sensor response at velocities below approximately 100 feet per second.

PERFORMANCE AND EVALUATION OF AN X  
HOT WIRE SENSOR IN A TWO DIMENSIONAL  
FREE JET IN THE PRESENCE OF  
CROSS FLOW COMPONENT

I. Introduction

Background

In many fluid flow problems of practical interest, for example, flow existing over the wing surface of an airplane, in the air intake of an air breathing engine, or in the test section of a subsonic wind tunnel, one is often required to measure the mean flow direction using an X hot wire sensor. Normally, the X hot wire sensor is aligned such that each sensor is at 45 degrees relative to the mean flow direction (Fig. 1). This particular orientation offers maximum sensitivity to the changes in the flow direction, interference caused by the prongs of one sensor over the sensitive part of the other sensor in a minimum and the sensor response equation is somewhat simplified. The X hot wire sensor, however, cannot be aligned as such when the mean flow direction is not known. It is, therefore, desirable to determine the magnitude of error incurred due to misalignment of the X hot wire sensor in a generalized fluid flow field.

Fig. 1. Orientation of the X Sensor Model 1240 Relative to the Mean Flow Direction. Both Sensors Are Calibrated with the Flow from Either the "U" or "V" Direction (i. e.  $45^\circ$  to the Stream)

Another problem closely associated with the mean flow direction measurements using a constant temperature hot wire anemometer is directly related to the convective cooling effect of the flow passing over the wire and is dependent upon the temperature difference between the wire and the flow. The constant temperature anemometer, as its name implies, is designed to maintain the temperature of the sensing element constant under varying fluid temperature. Mere observation of the voltage output does not tell us whether the change in the output has been caused by a change in the flow velocity or change in the fluid temperature. A typical example of this problem is the changes in the air temperature of a closed circuit wind tunnel where the air temperature rises slowly due to viscous action.

Similarly, when one is dealing with the study of free flows such as jets, wakes and mixing zones, the fluid temperature may vary appreciably from the value at which calibration was performed or it may change during experiment due to drift in the ambient conditions. In any event, it is necessary to apply correction to the measured data particularly when the variations in the fluid temperature are appreciable.

This thesis is an experimental investigation of:

1. The error involved in the measurement of mean flow direction due to misalignment of the X hot wire sensor.
2. The error involved in the linearized response of a constant temperature hot wire anemometer system due to small variations in

fluid temperature.

The tests were conducted in the potential core of a two dimensional free jet resulting in a cross flow component.

### Objectives

The primary objectives were:

1. Using a two dimensional free jet of known direction, evaluate the error incurred in the mean flow direction as the X sensor was yawed and pitched inside the potential core of the free jet. Yawing is defined as the movement of the instantaneous velocity vector in the plane of X called the probe plane. Pitching, on the other hand, represents the movements of the instantaneous velocity vector out of the probe plane. The error was to be evaluated at three values of Reynolds numbers based upon the sensor diameter, namely 7.2, 14.54 and 21.7.

2. To evaluate the error involved in the linearized voltage output of the X sensor as the fluid temperature was changed by 20°F.

Secondary objectives were:

1. To evaluate the value of King's Law exponent  $n$  and compare with the published literature.
2. To repeat the primary objective item number 1 in the shear flow region downstream of the free jet.

The organization of this report is as follows: Section II covers the theoretical background including the sensor response equation,

measurements of the mean and fluctuating velocity components using X hot wire sensor, and a review of the existing methods available for applying correction to the sensor response to account for the variations in fluid temperature. Section III describes the test apparatus, instrumentation and types of the sensors employed for the present research. Section IV deals with the data reduction techniques adopted. Section V contains an explanation of the techniques adopted for calibrating the sensors, optimization of the anemometer system for maximum frequency response, linearizing the voltage velocity relationship of the sensor and the measurement techniques. Section VI includes the discussion of the results. Conclusions and recommendations are contained in Section VII.

## II. Theoretical Considerations

Measurements of the mean flow direction using an X hot wire sensor is complicated by many factors. Some of these are deviation of the sensor response from a simple cosine law (Ref 4, 8, 11, 12), thermal wake interference (Ref 13), probe interference effects (Ref 9), the presence of a velocity component in the direction perpendicular to the plane of X and mean flow direction, spatial resolution limitations and slip flow effects (Ref 12, 24). The problem would not lend itself to simple experimental investigation unless certain simplifying assumptions are made. In the present study, following fundamental assumptions were made:

1. The flow was assumed to be incompressible. This assumption gives a maximum error of less than 2% in the dynamic pressure under sea level standard conditions for the range of velocity under consideration (0-300 ft/sec).

2. During the measurements, the air pressure and temperature were assumed to remain constant. This assumption is quite valid in the case of measurements in a free jet exiting to atmosphere.

3. Simple cosine law cooling was assumed to be valid. According to this law, the sensor is sensitive only to the velocity component normal to the sensor and is independent of the tangential velocity components. This would indeed be true up to quite large yaw angles if

the wire was infinite in extent and maintained at a constant temperature throughout its length. Unfortunately, real hot wires must be finite in length, and possess non-uniform temperature distribution due to heat conduction to the supports.

4. The turbulent fluctuations of the flow velocity component acting on the hot wire are small compared to its time average. This requirement is satisfied inside the potential core of a free jet but the results are subject to increasing error with high turbulence intensities (Ref 11).

5. The flow is assumed to be continuum and the slip flow effects are negligible. A condition for the flow to be continuum is that the Knudsen Number should be less than 0.01 (Ref 10). The 3.8 micron diameter hot wire sensor while operating at 70°F and standard atmospheric pressure has Knudsen Number equal to 0.0173 and therefore may operate in slip flow regime. This implies a decrease in the value of heat transfer coefficient  $h$  between the hot wire and the cooling stream of air. The decrease in the value of  $h$  is caused by the "temperature jump" effect arising as a consequence of the failure of the molecule to "accommodate" to the surface temperature (Ref 10). The slip flow effects may be observed in the range of Reynolds Number  $7 \leq Re \leq 22$  and give an error in Nusselt Number varying between 6% to 12%, approximately for 3.8 micron diameter, platinum coated tungsten wire (Ref 7) which is quite substantial.

### Sensor Response Equation

The constant temperature hot wire anemometer works on the principle that the rate of heat loss by the sensor is equal to the amount of electrical energy needed to maintain the sensor temperature at constant. In general, heat transfer takes place by all three modes namely conduction, convection and radiation. Writing down the heat balance equation, one has

$$\text{Heat Input} = \frac{E^2}{R_W} = H_R + H_C + H_{FC} + H_{NC} \quad (1)$$

Where E is Bridge voltage output,  $R_W$  is operating resistance of the sensor.  $H_R$  is the heat loss due to radiation. This is generally very small for tungsten or platinum wire operated below 300°C.  $H_C$  is the heat loss by conduction to the wire support needles and usually constitutes about 10% of the total energy loss.  $H_{FC}$  is the heat lost due to forced convection. It is a function of Reynolds Number, Mach Number, Prandtl Number, Knudsen Number, wire temperature, wire geometry, and its orientation relative to the flow. For a hot wire sensor operating in a continuum, low subsonic flow,  $H_{FC}$  can be represented by:

$$H_{FC} = C_1 + C_2 (U_{eff})^n \quad (2)$$

Where  $U_{eff}$  is the effective cooling velocity,  $C_1$ ,  $C_2$ , and  $n$  are constants which are determined experimentally. Noting that equation (2) is similar to well known King's Law for which  $n = \frac{1}{2}$ .

$H_{NC}$  is the heat loss due to natural convection. This heat loss is quite small and negligible for Reynolds Number greater than 0.5 (Ref 11). The heat loss due to conduction to the supports is taken into account in the calibration process. Therefore, overall response equation can be expressed as:

$$E^2 = C_1 + C_2 (U \text{ eff})^n$$

or

$$E^2 - E_0^2 = C_2 (U \text{ eff})^n \quad (3)$$

Where  $E_0$  is the bridge voltage output at zero flow.

In order to evaluate the value of exponent  $n$  from the calibration data, assume cosine law to be valid and take natural logarithm of both sides of equation (3),

$$\ln (E^2 - E_0^2) = \ln C_2 + n \ln \bar{V}_p$$

where  $\bar{V}_p$  is the mean velocity component normal to the sensor. The first term on the right hand side can be replaced by another constant  $D$ .

$$\therefore \ln (E^2 - E_0^2) = D + n \ln \bar{V}_p \quad (4)$$

A plot of  $\ln (E^2 - E_0^2)$  versus  $\ln \bar{V}_p$  enables one to calculate the value of exponent  $n$ . Collis and Williams investigations of the heat transfer from heated wires of very large aspect ratio gave values of  $n$  equal to 0.45 for  $.02 < Re < 44$  and equal to 0.51 for  $44 < Re < 144$  (Ref 3).

More recently, Klatt (Ref 15) carried out calibration of a large number

of commercially available hot wire probes and found value of  $n$  varying between 0.25 and 0.42 corresponding to maximum Reynolds Number of 13. The values of  $n$  determined in the present investigation are tabulated on page 53.

Determining Mean Velocity Components with X-Sensor. The X-hot wire sensor offers a convenient way of determining mean velocity components  $\bar{u}$  and  $\bar{v}$  due to the fact that both of the components can be obtained in a single operation. A further simplification to the analysis is afforded by operating each sensor at 45 degree relative to the mean flow direction which has the added advantage of offering maximum directional sensitivity (Ref 6). For a linearized system, the output is proportional to velocity. Assuming simple cosine law cooling,  $u$  and  $v$  can be expressed in terms of  $V_{P1}$  and  $V_{P2}$ .

Fig. 2. Determination of Velocity Components

For the case of the flow only within the probe plane,

$$\bar{u} = \bar{q} \cos(\phi - \alpha) = \bar{q} (\cos \phi \cos \alpha + \sin \phi \sin \alpha) \quad (5)$$

$$\bar{v} = \bar{q} \sin(\phi - \alpha) = \bar{q} (\sin \phi \cos \alpha - \cos \phi \sin \alpha) \quad (6)$$

If the sensor is oriented such that yaw angle  $\phi = 45^\circ$ , then  $\cos \phi = \sin \phi = 0.707$ . Also

$$V_{P_1} = \bar{q} \sin(90 - \alpha) = \bar{q} \cos \alpha$$

$$V_{P_2} = \bar{q} \sin \alpha$$

$$\therefore \bar{u} = 0.707 (V_{P_1} + V_{P_2}) \quad (7)$$

$$\bar{v} = 0.707 (V_{P_1} - V_{P_2}) \quad (8)$$

For a linearized system,  $V_{P_1}$  and  $V_{P_2}$  are directly proportional to the voltage output of the two anemometers.

$$\therefore \bar{u} = 0.707 K(E_{L_1} + E_{L_2}) \quad (9)$$

$$\bar{v} = 0.707 K(E_{L_1} - E_{L_2}) \quad (10)$$

Where  $E_{L_1}, E_{L_2}$  are voltage signals from the sensors 1 and 2 respectively, and  $K$  is the constant of proportionality between the voltage and velocity for the linearized anemometer.

Determination of Fluctuating Velocity Components. For the measurements of velocity fluctuation, the wire must exchange heat at the frequency of the velocity fluctuations. A finite time is, however, required for the wire to come in to thermal equilibrium with its surroundings, and hence its resistance to reach a value corresponding to the conditions in the fluid medium. This is due to the thermal inertia of the sensor which, at high frequencies, decreases its sensitivity and

shifts the signal out of phase. A constant temperature hot wire system minimizes the effect of thermal inertia by keeping the sensitive element at a constant temperature and hence resistance and using the heating current as the measure of heat transfer, and, therefore, of the velocity. The linear frequency range of the constant temperature anemometer increases with the mean velocity and within the velocity range  $10 \leq \bar{q} \leq 100$  meter per second, the upper frequency limit  $f_0$  (-3 db) is approximately given by:

$$f_0 = (10 + 0.5 \bar{q}) \text{ K C/S} \quad (11)$$

Where  $\bar{q}$  is the mean velocity in meter per second (Ref 19).

Assuming the system possesses satisfactory arrangement for optimizing its frequency response, if the turbulence intensity is less than 10%, equations (9) and (10) would give the fluctuating velocity components provided AC values of the voltages are used instead of DC voltages. For highly turbulent flows, Hinze (Ref 11) has suggested the following correction applicable to isotropic turbulence with velocity components being normally correlated:

$$f(u'_1, u'_2) = - \frac{7}{128} \frac{u'^2}{\bar{q}^2} \quad (12)$$

This implies the linearized theory would predict too high a value for the turbulence intensity. The errors arise primarily from non-linear character of the instrumentation response to fluctuations in magnitude and direction of the fluid velocity and in the fluid temperature (Ref 20).

If a linearizer is incorporated in the electronic circuit, the curvature of the basic calibration curve can be handled conveniently. However, linearization does not always improve the accuracy of measurements (Ref 21). In fact, for small fluctuations, accuracy can be improved by not linearizing since the elimination of analogue electronics equipment normally removes a source of possible uncertainty in the data.

Effect of Fluid Temperature Variations. In almost all the experiments on velocity measurements using a constant temperature hot wire anemometer, it is very difficult to maintain the fluid temperature constant and equal to the temperature at which the calibration was performed. In some cases, appreciable changes in the fluid temperature may take place even during the experiment as for example, in a closed circuit wind tunnel where slow increase in temperature takes place before reaching an equilibrium state. Bearman (Ref 2) suggested the following corrections.

For the non-linear system,

$$E_{\text{Corr}} = E_M / (1 + \epsilon/2\sigma)^{1/2} \quad (11)$$

Where  $E_{\text{Corr}}$  and  $E_M$  stand for corrected and measures values of DC voltage output respectively.  $\epsilon$  and  $\sigma$  are functions of overheat ratio ( $\theta$ ) defined as:

$$\epsilon = \frac{T_{a1} - T_{a2}}{T_{a1}}$$

$$\sigma = \theta - 1$$

For the linearized constant temperature system,

$$E_{L_{\text{corr}}} \cong E_{L_M} \left(1 - \frac{\sigma T}{T_{a1}} F\right) \quad (12)$$

where  $E_{L_{\text{corr}}}$  and  $E_{L_M}$  are corrected and measured values of the linearized DC voltage output respectively.  $F$  is the correction function dependent upon  $n$ ,  $\sigma$  and voltage ratios.  $T_{a1}$ ,  $T_{a2}$  are the original and new values of fluid temperature respectively. Bearman concluded that for a linearized hot wire system, his correction formulae give an accuracy of 1% up to a temperature rise of 10°C. He assumed that the properties of the fluid adjacent to the wire are related to the wire surface temperature. Kanevce and Oka (Ref 14) dealt with the low velocity range (0.1 to 11 m/sec) and recommended the following correction for the non-linear constant temperature hot wire system:

$$E_C^2 = E_M^2 \frac{(R_W - R_C)}{(R_W - R_M)} \quad (13)$$

Where  $R_W$ ,  $R_C$  and  $R_M$  are the hot wire resistances at wire operating temperature, cold wire resistance during calibration and cold wire resistance during measurement respectively.

In the present investigation, only the influence of fluid temperature variation on a linearized hot wire system was determined experimentally. The formulae used as well as the example calculations are given in Appendix B.

### III. Test Apparatus

#### Free Jet Facility

The free jet facility used for conducting experiments consisted of a 10 cm by 1 cm nozzle having a turbulence intensity of approximately 0.3% in the nozzle exit plane. A schematic of the flow field is shown in Fig. 3. The calming chamber had a diameter of 27 cm and was 2.13 meter in length. Flow was first directed over two 7,000 watts electric resistance type heaters which could raise the air temperature by 90°F at exit Mach Number equal to 0.8 (Ref 23). An orifice 10 cm in diameter was placed just downstream of the heaters to induce turbulent mixing. A replaceable paper filter prior to the nozzle entrance was used to prevent foreign particles striking against the sensor and resulting in sensor breakage. The nozzle had an area contraction ratio of 50:1 which was partially responsible for the low turbulence flow in the nozzle exit plane.

#### Cathodometer

A Gaertner Scientific Company three dimensional traversing mechanism (Fig. 4) was used to position the sensor within  $\pm 0.001$  inch of desired position in X, Z directions and within  $\pm 0.001$  centimeter in the Y direction.

## Sensors

Figure 5 shows the types of sensors used in the present investigation. All the sensors used were cylindrical, platinum coated tungsten wire type having diameter of 3.8 micron and 1.25 millimeter active sensor length, separated by a distance of 1 millimeter. The nomenclature used by Thermo-Systems for different types of sensors is as follows:

The number code identifies the diameter of the cylindrical sensor. For example, T1.5 implies tungsten wire sensors having 0.00015 inch diameter. Similarly -20 refers to a hot film type sensor having diameter of 0.002 inch. The Model number identifies the probe configuration. For example, Fig. 5(a) shows the Model 1210 standard straight probe whereas Fig. 5(b) shows Model 1214 probe which is streamlined wedge shape suitable for supersonic flow.

T1.5 Models 1210 and 1214 were used for gaining experience in the calibration technique as well as for performing a number of secondary experiments. The T1.5 Model 1240, which has two wires mounted at right angle to each other, was used for measurements of velocity components in the XY plane. For velocity measurements in the XZ plane, T1.5 Model 1241 X wire sensor was used. This sensor has two wires arranged such that they are orthogonal to each other but the "X" lies parallel to probe axis. The spacing between the wires of both X type sensors was one millimeter.

Owing to engineering tolerances, the angular arrangement of the two wires of X type sensors is not normally exact. Careful

observations under microscope may reveal an error of about  $\pm 5$  degrees in the arrangement.

### Instrumentation

The primary instrumentation used consisted of Thermo-Systems, Inc. Model 1125 calibrator (Fig. 6), Model 1050 dual, constant temperature hot wire system (Fig. 7) equipped with TSI Model 1052 Linearizer and TSI Model 1057 signal conditioner. Thermo-Systems Model 1015C correlator (Fig. 8) was available separately.

### Calibrator

The flow diagram illustrates the sequence of operation of the TSI Model 1125 calibrator. A low turbulence level (less than 0.17 percent) free jet was provided by the 0.15 inch diameter nozzle having speed range varying between 3 feet per second to Mach No. 1. The Uni Slide three dimensional sliding mechanism provided means of supporting the probe in the exit plane of the nozzle. The pressure regulator and needle valve provided good control of the velocity through the calibrator. The pressure port on the calming chamber provided a means of recording stagnation temperature.

system. The non-linear bridge voltage output of the two sensors from their respective channels are each fed into a linearizer. The linearized output signals are then fed to TSI Model 1015C correlator. The mean velocity components were read on DC voltmeter and fluctuating velocity components on RMS voltmeter after selecting the power switch to AC position.

### Correlator

The TSI Model 1015C correlator which is capable of performing a number of analogue computations was used to separate the two velocity components of the X hot wire sensor. For a linearized system, sum of the voltages was proportional to the velocity component parallel to mean flow direction whereas the difference was equal to the velocity component normal to the mean flow direction (Ref 26).

### Oscilloscope

A Tektronix Inc. Type 531 oscilloscope was used to test the anemometer system for maximum frequency response.

### Voltmeters

Two Digitec Model 268 DC Millivoltmeters and two Hewlett Packard Model 3400A RMS voltmeters were used for measuring DC linearized output and AC linearized output respectively. The DC output was proportional to mean velocity and AC output proportional to fluctuating velocity.

### Manometer

A Mariam 20 inch water micro manometer was used to measure the total pressure in the settling chamber during calibration and experimentation.

### Thermocouple

A Honeywell Model 2732 potentiometer and copper-constantan thermocouple was used to measure the stagnation temperature in the calming chamber of the test nozzle assembly based on the assumption that velocity in the calming chamber was negligible.

### DC Power Supply

It was determined that an external power source provided a more stable voltage when compared to the internal voltage source of the linearizer. An HP Model 6205B dual DC power supply was, therefore, used to provide the necessary external voltage input of 10.000 volts to the linearizer.

### Variac

In order to control the heating of the flow, a General Electric Radio Co. Type 50-B variac was used. This variac provided adequate control to vary the voltage across the two 7,000 watt electric resistance type heaters between 0-200 volts.

#### IV. Data Reduction

##### CDC 6600 Computer

The potentiometer coefficients for the TSI Model 1052 Linearizer supplied by Thermo-Systems, Inc. for the desired velocity range (0-300 feet per second) for T1.5 hot wire sensors (Ref 25) were found to be unsatisfactory due to the fact that they did not yield an acceptable linear voltage velocity relationship. A computer programme was developed to provide a fourth order least square polynomial curve fit to the data points obtained from the calibrator. This programme is given in Appendix D. Standard procedure as recommended by Thermo-Systems (Ref 25) was employed for the determination of the polynomial coefficients. The programme gave non-normalized polynomial coefficients which were normalized manually prior to feeding into the potentiometers of the linearizer of the constant temperature anemometer system. During the normalization process, 10 volts of the linearized system were taken to correspond to full scale flow of 300 feet per second. These coefficients are tabulated in Appendix C. The Air Force Institute of Technology data link system was used to tie into Air Force Aeronautical Systems Division control Data Corporation 6600 computer for data plotting.

## V. Experimental Procedures

### Control of Test Conditions

A hot wire sensor, strictly speaking, is sensitive to the mass flow rate rather than velocity. As the range of speeds of interest (0-300 feet per second) was almost in the incompressible flow regime, the sensor was assumed to be sensitive to velocity instead of mass flow rate. The calculation of velocities was also based upon incompressible Bernoulli's Equation.

The variations in the ambient air temperature on day to day basis were taken into account by adjusting the fine "span control" on the linearizer. Constant pressure in the calming chamber of the free jet facility was maintained by adjusting the compressed air bypass valve which was vented to the atmosphere until a steady flow at the desired pressure was obtained, with the compressor running continuously under constant load conditions.

### Calibration

Single Sensor. The main purpose of calibration is to reproduce the test environment as accurately as possible. In the present investigation, calibration of the sensors constituted the most important phase of the research due to many reasons. Firstly, by calibrating the sensor, the heat conduction losses to the sensor supports become part

of the calibration. Secondly, small variations in the sensor temperature, imperfect sensor geometry, dirt accumulation and aging effects etc. are all taken into account. The single sensors TSI T1.5 Model 1210 and Model 1214 were calibrated normal to the mean flow direction using TSI Model 1125 calibrator. An overheat ratio of 1.5 was used which gave good sensor sensitivity to velocity variations and signal to noise ratio of the anemometer system.

The normal orientation of the sensor was first attained visually and then fine adjustments were made at some low constant airspeed. until the non linear bridge output was a maximum. This technique was considered essential because the sensor response was highly dependent upon its orientation relative to the mean flow direction; necessitating that the same orientation should be used during actual tests as that employed during calibration.

As a secondary test, the single sensor model 1210 was calibrated at two additional overheat ratios, namely 1.2 and 1.8 with the intention of determining the influence the overheat ratio on the linear and non linear bridge outputs and the error involved in case the overheat ratio is inadvertently set to an incorrect value during actual test. The calibration curves are shown in Fig.50 and results are tabulated in Appendix C.

#### X Wire Sensor.

(1) Model 1240. Each wire of the Model 1240 sensor was calibrated independently; first, normal to the mean flow direction and then

each wire aligned 45 degrees to the mean flow direction. The 45 degrees orientation was achieved by rotating the sensor from its normal orientation until the linearized voltage output was 7.07 volts with 10.00 volts corresponding to full scale flow conditions of 300 feet per second. The same procedure when repeated using the cathodometer before conducting actual tests corresponded to sensor orientation of 48 degrees with the sensor operating in the potential core of the free jet. In order to maintain consistency, the X hot wire sensor was oriented 48 degrees relative to the mean flow direction for all subsequent tests. A further check was made on the Model 1240 sensor orientation relative to the mean flow direction using TSI Model 1015C correlator. Using the fact that X hot wire sensor would be at 45 degrees relative to the mean flow direction when the difference between the voltage outputs of the linearized system were zero (see Equation 10), the X sensor was again rotated in the potential core of the free jet. This test gave the same result, that is, the difference  $(E_{L_1} - E_{L_2})$  corresponded to the sensor orientation of 48 degrees instead of 45 degrees. The X probe calibration technique used by Thermo-Systems (Ref 25) was tried but it did not yield satisfactory results.

(2) Model 1241. The calibration of Model 1241 was relatively simple. The orientation of this sensor offered no difficulties since the

two sensors were arranged such that each sensor was at 45 degrees relative to the mean flow direction with the "X" lying parallel to the probe axis as opposed to Model 1240 in which case "X" lies normal to the probe axis (see Fig. 5(c) and (d)).

#### Optimizing Frequency Response

The frequency response of the anemometer system was optimized according to the procedure recommended by the manufacturer (Ref 25). In order to observe the output test signal shape, a Tektronix Inc. Type 531 oscilloscope was connected to the Bridge Output jack. With the probe exposed to the flow at maximum speed (300 feet per second), trim control on (5:1) Bridge and stability control of the anemometer were adjusted initially with 1 KHZ square wave signal across the bridge circuit and then 20 KHZ signal. Ref Set control was not normally used for optimization purposes. However, very slight movements of the Ref Set control was found to be helpful in improving upon the output signal shape. The output signal for a hot wire sensor should appear as shown in Fig. 10 if the system has been optimized properly. With sufficient practice, it was possible to attain the desired output signal shape.

#### Linearization

Once an accurate calibration curve had been obtained, the next step was to determine the four polynomial coefficients to be set into the linearizer potentiometers. For this purpose, a fourth order least

Fig. 10. Square Wave Test Signal on a 3.8 Micron Tungsten Hot Wire (From Ref 30)

square polynomial curve fit was applied to the data points. Only 20 data points at approximately equal interval were selected from the calibration curve. These values were fed in as data to the programme listed in Appendix D. The first and the last data points were weighted heavily where second, third, fourth, fifth and sixth data points were given 80, 60, 40, 20 and 10 percent weighting respectively. All the remaining data points were allotted 1% weighting only.

Figure 11 shows a typical fourth order least square curve fit to the selected data points. The technique was repeated for every sensor calibrated for the present study. These polynomial coefficients were in disagreement with those provided by Thermo-Systems (Ref 28). In fact the polynomial coefficients supplied by Thermo-Systems did not

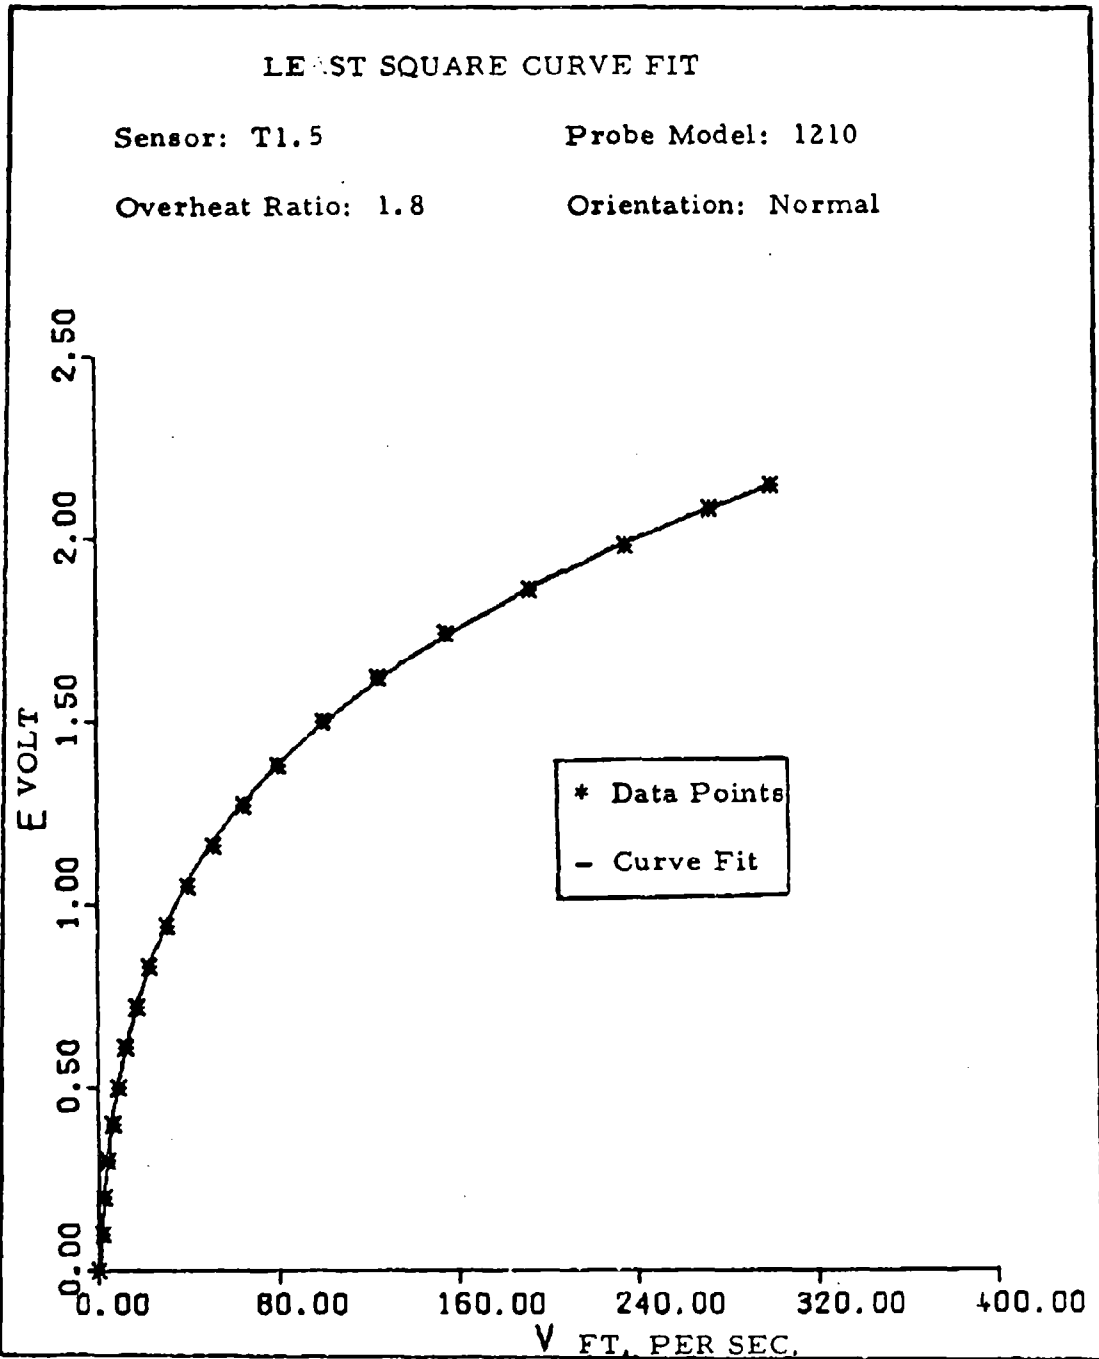

Fig. 11. Fourth Order Least Square Polynomial Curve Fit for Evaluation of Linearized Coefficients

yield linear bridge voltage output and were, therefore, discarded. Standard procedure for setting up the polynomial coefficients in the linearizer potentiometers was adopted (Ref 25). The accuracy of linearization was found to be highly dependent upon the linearizer coefficients and the precision with which these coefficients were set. The coefficients were found to drift and a check was made each time before collecting any data.

### Experimental Measurements

Experimental Arrangement. Rotation in yaw, which was defined as the movement of the resultant velocity vector within the probe plane, was performed by rotating the sensor itself and noting the amount of angular displacement on the fixed table (see Fig. 12a). The fixed table located in XY plane was graduated in 1 degree interval and the pointer attached to the probe provided reasonably accurate control of the angular displacements of the probe and hence of the sensor.

Rotation in pitch, which was defined as the movement of the resultant velocity vector out of the probe plane, in the case of Model 1240 was achieved by the movements of the turn-table located in XZ plane. The figure 13 explains the technique adopted for conducting pitch movements with the X sensor Model 1240. The moment arm  $l$  was measured accurately in the School Shop and was equal to 7.068 inches. For clockwise rotation in pitch, the probe was moved by

Fig. 12a. Definition of Yaw Angle

Fig. 12b. Definition of Pitch Angle

$\Delta x = l \sin \beta$  downstream and by  $\Delta z = l (1 - \cos \beta)$  downwards in order to coincide with the initial reference location. For counterclockwise rotation in pitch, the probe must be moved by  $\Delta x = l \sin \beta$  upstream and  $\Delta z = l (1 - \cos \beta)$  downwards in order to coincide with reference location. Similar technique was adopted for the rotations in yaw and pitch with the sensor Model 1241.

Fig. 13. Pitch Movement of the Sensor

### Flow Direction Measurements

Measurements in Potential Core. The X sensors Model 1240 and 1241 were located in the potential core at 1 centimeter downstream of the nozzle exit plane and at the center line. The turbulence intensity

at this location was 0.32 percent. The X sensor Model 1240 was employed to measure the mean velocity components  $\bar{u}$ ,  $\bar{v}$  and hence the flow direction in XY plane, whereas Model 1241 was used to determine  $\bar{u}$ ,  $\bar{w}$  and, therefore, the flow direction in XZ plane. The sensor orientation relative to the mean flow direction during calibration corresponded to 48 degrees instead of 45 degrees. This orientation was, therefore, used as reference for all the measurements in the potential core. The sensors were yawed and pitched inside the potential core through  $\pm 30$  degrees and  $\pm 10$  degrees respectively. The clockwise rotation in a plane was defined to be positive and the counterclockwise rotation negative. The size of the potential core limited the rotation in pitch to  $\pm 10$  degrees because the probe support was almost touching the nozzle edges at pitch angles of  $\pm 10$  degrees. The rotations in yaw and pitch were made at three values of Reynolds Numbers, namely 7.2, 14.54 and 21.8. These Reynolds Numbers corresponded to nozzle exit velocities of 100 feet per second (30.48 meters per second), 200 feet per second (60.96 meters per second), and 300 feet per second (91.44 meters per second) respectively under standard sea level conditions. While performing rotation experiments in yaw with Model 1240 in the potential core, the turbulence intensity was observed to vary from 0.32 percent to a maximum of 0.81 percent as the sensor was yawed through +30 degrees but the turbulence intensity nearly remained constant at 0.3 percent when the sensor was rotated in the counterclockwise direction. This indicated strong sensor

prongs and supporting structure interference effect on the sensitive portions of the two sensors and led to the idea of repeating all the above rotations in yaw starting with a new reference orientation of 135 degrees instead of 48 degrees. These rotation tests inside the potential core at the three Reynolds Numbers of interest are shown in Figures 15 thru 28. The calibration of each sensor at 135 degrees reference orientation was checked and found to be satisfactory. The same was repeated for the other reference orientation prior to and after conducting each rotation experiment. Slight shift in the calibration curve was observed due to aging of the wire but the deviations in the sensor sensitivity was found to be less than 0.1 percent. The rotation of the sensor was performed manually by rotating the probe itself in steps of 2 degrees interval. For measurements of  $\bar{u}$  and  $\bar{w}$  with the Model 1241, the sensor was mounted on a 90 degree elbow and oriented such that the sensor faced the flow direction and the sensor "X" was parallel to the probe plane. The rotations in yaw and pitch were repeated at the three values of the Reynolds Numbers mentioned earlier. As opposed to the sensor Model 1240, rotation in yaw in the potential core was restricted to  $\pm 10$  degrees due to limited size of the potential core (1 centimeter). In order to prolong the sensor life, the sensor was not exposed to the flow until the velocity in the nozzle exit plane had attained a steady value. Normally, the time taken for the flow to attain a steady state was more than 30 minutes.

Measurements in Shear Flow Region. One of the secondary objectives of the present investigation was to repeat the rotation tests in the shear flow region of the free jet. To achieve this goal, the X sensor Model 1240 was used. The sensor was located downstream of the nozzle exit plane at 25 centimeters from the center line. At Reynolds Number of 21.8 based upon the flow conditions at the nozzle exit plane, the mean velocity at this location was 200.7 feet per second (61.73 meters per second) and turbulence intensity 15.85 percent. The X sensor was yawed through  $\pm 30$  degrees and pitched through  $\pm 10$  degrees at the three values of Reynolds Numbers of interest for each value of the reference orientations, namely 48 degrees and 135 degrees. These rotation tests in shear flow regions are shown in Figures 41 thru 46.

Measurement of the Influence of Fluid Temperature Variations on the Linearized System

The second objective of this investigation was to determine the error involved in the linearized bridge output of the constant temperature anemometer system due to small variation in the fluid temperature. To achieve this goal, the sensor Model 1240 (No. 1) was oriented 48 degrees to the mean flow direction at 1 centimeter from the nozzle exit plane and at the center line. The two electric heaters installed inside the calming chamber of the free jet facility were used to provide the necessary heating. The heating was controlled by a variac and the fluid temperature was increased in steps of 4°F up to a

maximum value of 20°F. The amount of voltage drop across the two heaters to yield a given temperature rise of the fluid was precalculated. The calculations are given in Appendix B. The stagnation temperature was measured by a copper-constantan thermocouple as well as by an ordinary mercury bulb thermometer. As the flow in the calming chamber was stationary for all practical purposes, and since the temperature was measured under steady state only, the temperature measured by the thermocouple was assumed to represent the stagnation temperature of the fluid. The tests were conducted in the velocity range from 25 feet per second (7.62 meters per second) to 300 feet per second (91.44 meters per second).

In order to prolong the sensor life, the sensor was not exposed to the flow until it had attained a steady value of temperature at a given velocity. Normally, the time taken by the flow to attain a steady value of temperature was more than 45 minutes.

## VI. Discussion of Results

In this section, discussion of the rotation tests performed with the X sensors Model 1240 and Model 1241 in the potential core of the free jet is covered first. The second part covers the discussion on the influence of the air temperature variations on the linearized response of the hot wire. Lastly, a number of secondary tests performed during the study are considered.

### Measurements in the Potential Core with the X Sensor Model 1240

The X sensor Model 1240 consisting of two platinum coated, tungsten wires, having 0.00015 inch (3.8 micron) diameter, 0.05 inch (1.25 millimeter) active length, separated by 1 millimeter was yawed through  $\pm 30$  degrees and pitched through  $\pm 10$  degrees in the potential core (turbulence intensity 0.3 per cent) of the free jet. The free jet facility existing in the Aero Mechanical Engineering Department of Air Force Institute of Technology (AFIT) was used mainly because it provided potential core of sufficient size.

### Rotation in Yaw

For rotation tests in yaw with the X sensor Model 1240, the sensor was located on the center line and at 1 centimeter downstream of the nozzle exit plane. The results of these tests are tabulated in Appendix A.

Figures 14 through 19 show the variations of the mean velocity components  $\bar{u}$  and  $\bar{v}$  with the yaw angle  $\phi$ . The "actual velocity components" are also plotted in these figures in order to illustrate the error in  $\bar{u}$  and  $\bar{v}$  for a given angle  $\phi$ . The actual mean velocity component in X direction was defined as  $\bar{q} \cos \phi$  and in the Y direction as  $\bar{q} \sin \phi$  where  $\bar{q}$  denotes the resultant mean velocity vector and  $\phi$  the yaw angle. A summary of the error analysis in  $\bar{u}$  and  $\bar{v}$  due to misalignment in yaw is given in Table I.

Table I  
Rotation in Yaw (Potential Core)  
(Reference Orientation 48 deg)

Re. No.	Misalignment Angle (deg)	Percent Error in			
		$\bar{u}$		$\bar{v}$	
		Clockwise Rotation	Counter Clockwise Rotation	Clockwise Rotation	Counter Clockwise Rotation
7.2 (100 ft/ sec)	$\pm 10.0$	+1.33%	+6.9%	+2.0%	-10%
	$\pm 20.0$	+4.7%	+1.78%	+17.49%	-1.7%
	$\pm 30.0$	+10.33%	+1.02%	+28.7%	-6.46%
14.54 (200 ft/ sec)	$\pm 10.0$	+1.18%	+1.0%	+21.0%	+20.4%
	$\pm 20.0$	+4.49%	+8.3%	+21.9%	+16.19%
	$\pm 30.0$	+9.7%	+9.7%	+29.98%	+14.93%
21.8 (300 ft/ sec)	$\pm 10.0$	+2.8%	-2.58%	+24.24%	+7.33%
	$\pm 20.0$	+8.25%	-3.1%	+32.17%	+15.83%
	$\pm 30.0$	+15.48%	-4.1%	+35.64%	+19.66%

The angle through which the sensor is yawed can be regarded as the misalignment angle relative to the reference orientation and the percent error in mean velocity being defined as:

Fig. 14. Error in  $\bar{u}$  Due to Misalignment in Yaw (Re. No. = 7.2)

Fig. 15. Error in Mean Velocity Component  $\bar{U}$  Due to Misalignment in Yaw (Re. No. = 14.54)

Fig. 16. Error in  $\bar{v}$  Due to Misalignment in Yaw (Re. No. = 21.8)

FIG. 17. Error in  $\bar{v}$  Due to Misalignment in Yaw (Re. No. = 7.2)

Fig. 18. Error in  $\bar{v}$  Due to Misalignment in Yaw (Re. No. = 14.54)

Fig. 19. Error in  $\bar{v}$  Due to Misalignment in Yaw (Re. No. = 21.8)

$$\left[ 1 - \frac{\text{measured mean velocity component}}{\text{actual mean velocity component}} \right] \times 100$$

The positive yaw (misalignment) angle is associated with clockwise rotation of the sensor in XY plane and negative yaw (misalignment) angle corresponds to counterclockwise rotation. From Table I, the following observations are made:

In the range of Reynolds Numbers  $7.2 \leq Re \leq 21.8$ :

1. The per cent error in the measurement of  $\bar{u}$  and  $\bar{v}$  is not the same and vary with the sense of rotation.
2.  $\bar{u}$  is relatively insensitive to misalignment in yaw.
3. Relatively large errors due to misalignment of the X sensor occur in  $\bar{v}$ .

As regard observation 1, it can be remarked that the asymmetry in the sensor response curves is mainly responsible for the unequal per cent error incurred with one rotation or the other. There are many factors which might contribute to the skewness in the X sensor response curves. The two wires of the X sensor may not be aligned accurately at right angle to each other. In fact, a discrepancy of approximately 3 degrees was observed in the sensor arrangement. Comte-Bellot, Strohl and Alcaraz (Ref 5) observed similar asymmetry in the sensor response curves. They discovered that the wires had the tendency to slide to the one side of the prongs or the other each time new wires were soldered. A similar problem was observed by

Gilmore (Ref 9). Other possible causes of skewness in the sensor response curves are unequal lengths of the active part of the sensor, poor plating at the tips or poor joints. In order to further investigate the asymmetry in the X sensor Model 1240 response curve, the reference orientation was changed to 135 degrees and the rotation tests were repeated. The results of these rotation tests are tabulated in Appendix A. Figures 20 thru 22 show a comparison of the sensor response curves for the two reference orientations. The asymmetry is seen to persist even with this new reference orientation. The crosswire arrangement was also observed under a microscope (Fig. 73) having magnification of 50. It was found that the two sensors were indeed not aligned accurately relative to each other. Another factor which might have contributed to the asymmetry is the fact that the two wires of the X sensor do not operate in a single plane (perpendicular to the probe axis). This leads to the influence of the support of one sensor on the other occurring sooner with one direction of rotation than the other. Figures 23 thru 25 show the error incurred in the mean flow direction due to misalignment in yaw in the range of Reynolds Number  $7.2 \leq Re \leq 21.8$ . The results are tabulated in Appendix A. The mean flow direction is given by  $\tan^{-1} \frac{\bar{v}}{\bar{u}}$  where  $\bar{u}$  and  $\bar{v}$  are the mean velocity components in the X and Y direction, respectively. Table II gives a summary of the errors in the flow direction associated with misalignment in yaw. It can be seen that in the Reynolds Number range  $7.2 \leq Re \leq 21.8$ .

Fig. 20. Comparison of Yaw Response Curves (Re. No. = 7.2)

Fig. 21. Comparison of Yaw Response Curves (Re. No. = 14.54)

Fig. 22. Comparison of Yaw Response Curves (Re. No. 721.8)

Fig. 23. Error in Mean Flow Direction Due to Misalignment in Yaw (Re. No. = 7.2)

Fig. 24. Error in Mean Flow Direction Due to Misalignment in Yaw (Re. No. = 14.54)

Fig. 25. Error in Mean Flow Direction Due to Misalignment in Yaw (Re. No. = 21.8)

1. Large error in the flow direction occurs at very small misalignment angles (1 to 4 degrees).
2. The per cent error is not constant and depends upon the direction of rotation.
3. For a given misalignment angle greater than 4 degrees, the per cent error increases with Reynolds Number.

The conclusion drawn from these tests is that the X sensor should not be misaligned in yaw at very small angle. If the misalignment is unavoidable, it would be better to misalign the sensor by say 8 to 10 degrees! This remark is applicable particularly in the range  $7.2 \leq Re \leq 14.54$ .

	$\pm 30$	+19.59%	+14.54%
21.8 (300 ft/sec)	$\pm 4$	+16.77%	+4.0%
	$\pm 10$	+21.73%	+9.5%
	$\pm 20$	+24.7%	+17.27%
	$\pm 30$	+20.99%	+19.96%

### Rotation Tests in Pitch

In order to investigate the error involved due to misalignment of the X sensor in pitch, the X sensor Model 1240 was pitched through  $\pm 10$  degrees in the potential core of the free jet at the three values of the Reynolds Numbers of interest. The results of these tests are given in Appendix A and plotted in Figures 26 thru 28. A summary of the test results is given in Table III. Following comments are applicable to these test results:

1. The error due to misalignment in pitch depends upon the sense of rotation.

2. The error is a function of Reynolds Number. At small Reynolds Numbers, the error is relatively large.

The relatively large error at small Reynolds Number is probably caused by the fact that the frequency of the vortices being shed by the sensor prongs is small at low speed but the fluctuations possess the tendency to spread laterally to a larger extent. This causes a relatively greater reduction in the sensor sensitivity at low speed than when the sensor is operated at high speed. From the error analysis shown in Table III, it can be concluded that the X sensor Model 1240 is relatively insensitive to misalignment in pitch in the range of Reynold Number  $14.54 \leq Re \leq 21.8$ . For  $\pm 10$  degrees sensor misalignment in pitch, the error may vary between 0.4 per cent to as high as 13 per cent depending upon the sense of rotation.

Rotation Tests With the X Sensor Model 1241

X sensor Model 1241 having two sensors arranged at right angles to each other with the sensor "X" lying in a plane normal to the probe axis was yawed and pitched through  $\pm 10$  degrees in the potential core. The sensor dimensions were identical to those of Model 1240 described earlier. The results of the rotation tests in X are tabulated in Appendix A. Figures 29 thru 34 show the variations of  $\bar{u}$  and  $\bar{w}$  with the yaw angle  $\phi$ . A summary of these tests is given in Table IVa. From Table IVa, it can be observed that in the range of Reynolds Number  $7.2 \leq Re \leq 21.8$ :

1. The error due to misalignment in yaw is not constant and changes with the direction of rotation.

FIG. 29. Error in  $\bar{u}$  Due to Misalignment in Yaw (Re. No. = 7.2)

Fig. 30. Error in  $\bar{u}$  Due to Misalignment in Yaw (Re. No. = 14.54)

Fig. 32. Error in  $\bar{W}$  Due to Misalignment in Yaw (Re. No. = 7.2)

Fig. 33. Error in  $\bar{w}$  Due to Misalignment in Yaw (Re.No. = 14,54)

Fig. 34. Error in  $\bar{w}$  Due to Misalignment in Yaw (Re. No. = 21.8)

Table IVa  
Rotation in Yaw (Potential Core)  
(Reference Orientation 48 deg)

Re. No.	Misalign- ment Angle (deg)	Per Cent Error in			
		$\bar{u}$		$\bar{w}$	
		Clockwise Rotation	Counter Clockwise Rotation	Clockwise Rotation	Counter Clockwise Rotation
7.2 (100 ft/ sec)	$\pm 4$ $\pm 10$	-0.48% -1.47%	-1.2% -3.4%	+20.9% +28.5%	+14.55% +15.79%
14.54 (200 ft/ sec)	$\pm 4$ $\pm 10$	-0.78% +0.177%	-0.49% -1.79%	+6.3% +16.3%	+18.8% +20.4%
21.8 (300 ft/ sec)	$\pm 4$ $\pm 10$	-0.45% -1.8%	-0.157% -1.25%	+21.8% +27.9%	+35.0% +34.7%

2. The per cent error in  $\bar{u}$  due to  $\pm 10$  degrees misalignment in yaw is less than 3.5 per cent.

3. Large error occurs in  $\bar{w}$ , particularly at high Reynolds Number. Comparison with the X sensor Model 1240 (Table I) shows that for misalignment angle of 10 degrees in yaw, both the X sensors behave in somewhat similar manner. In general, it can be remarked that the mean velocity component  $\bar{u}$  can be determined quite accurately with both the X sensor arrangements in the range of Reynolds Number  $7.2 \leq Re \leq 21.8$ . However, very large error (up to 35 per cent) may occur in the measurements of  $\bar{v}$  or  $\bar{w}$  for the same misalignment angle in the same range of Reynolds Number. Figures 35 through 37 show the curves of the variations in the mean flow direction with the rotation in

Fig. 35. Error in Mean Flow Direction Due to Misalignment in Yaw ( Re. No. = 7.2

Sensor: X T1.5  
 Probe Model: 1241

Fig. 36. Error in Mean Flow Direction Due to Misalignment in Yaw (Re. No. = 14.54)

Fig. 37. Error in Mean Flow Direction Due to Misalignment in Yaw (Re. No. = 21.8)

yaw for three values of the Reynolds Numbers of interest. A summary of the error analysis is presented in Table IVb.

Table IVb  
Rotation in Yaw (Potential Core)  
(Reference Orientation 48 deg)

Re. No.	Misalignment Angle (Deg)	Per Cent Error in Mean Flow Direction	
		Clockwise Rotation	Counterclockwise Rotation
7.2 (100 ft/sec)	$\pm 4$	+15.55%	+21.42%
	$\pm 10$	+18.31%	+29.2%
14.54 (200 ft/sec)	$\pm 4$	+19.25%	+5.6%
	$\pm 10$	+21.6%	+16.2%
21.8 (300 ft/sec)	$\pm 4$	+35.17%	+22.15%
	$\pm 10$	+35.16%	+28.9%

From these figures, it can be inferred that the performance of the X sensor Model 1241 is again somewhat similar to that of the Model 1240. Comparison of Tables II and IV indicates that the Model 1240 resulted in an error of 5-20 per cent due to misalignment angle of  $\pm 10$  degrees in the range of  $7.2 \leq Re \leq 21.8$ , whereas the Model 1241 yields an error which varies from 16-32 per cent approximately in the same range of Reynolds Numbers. Thus it can be remarked that it is advantageous to place the two wires out of the plane of the prongs. In other words, the X sensor Model 1240 is relatively superior for mean flow direction measurements. This conclusion is further supported by the rotation tests in pitch carried out with the Model 1241 in the potential core. The results of these tests are tabulated in Appendix A. These tests

revealed that the sensor Model 1241 was sensitive to the misalignments angles in pitch at all the three values of Reynolds Numbers of interest. From practical point of view, this represents another objectionable feature of the X sensor Model 1241.

#### Influence of the Air Temperature Variations on the Linearized Response

The second objective of the present research was to investigate experimentally the per cent error involved in the linearized bridge voltage output of the constant temperature anemometer system due to small variations in the air temperature. The results of these tests are tabulated in Appendix B and presented graphically in Figure 38. The tests were conducted in the speed range 25 feet per second (7.62 meter per second) to 300 feet per second (91.44 meter per second) in the potential core of the free jet. The air temperature was increased from 4°F to 20°F above the reference temperature (77°F). Table V shows the error analysis. For a given temperature rise  $\Delta T$ , the per cent error in the linearized bridge output is observed to remain approximately constant at airspeeds above 100 feet per second (30.48 meter per second). Below 100 feet per second, however, the per cent error in the linearized bridge output is relatively high. This is probably due to greater sensitivity of the sensor caused by rapid variations in the thickness of the thermal boundary layer in the lower range of Reynolds Number. The correction to the linearized bridge output obtained from these tests was applied to the test data and was found to yield good

Fig. 38. Influence of Fluid Temperature Variations on Linearized Constant Temperature Anemometer System.

Table V  
Influence of Fluid Temperature Variations  
on Linearized Response

$\Delta T$	Air Velocity (ft/sec)	25	50	100	150	200	250	300
4°F	Per Cent Error in the Linearized Bridge Voltage Output	-12.5	-8.1	-3.3	-2.4	-4.97	-2.8	-2.5
8°F	Per Cent Error in the Linearized Bridge Voltage Output	-22.98	-15.0	-6.96	-8.4	-10.1	-8.6	-5.4
12°F	Per Cent Error in the Linearized Bridge Voltage Output	-33.4	-19.37	-12.91	-12.0	-15.37	-12.85	-10.0
16°F	Per Cent Error in the Linearized Bridge Voltage Output	-41.79	-25.0	-22.5	-16.4	-19.47	-18.45	-15.0
20°F	Per Cent Error in the Linearized Bridge Voltage Output	-47.76	-33.12	-26.12	-21.8	-24.59	-21.72	-19.5

results. In addition, a comparison of these test results was made with similar tests performed by Bearman (Ref 2), and relatively large disagreement was observed at higher values of  $\Delta T$ . Bearman, however, used an overheat ratio of 1.8 and assumed the value of King's Law exponent  $n$  equal to 0.465. Nevertheless, these tests have indicated a very strong influence of the variations in the air temperature on the linearized response of the constant temperature anemometer system particularly when the temperature changes are higher than  $4^{\circ}\text{F}$ . At low speeds (below 100 feet per second), error as high as 48 per cent in the linearized bridge output might occur, and correction to the experimental data assumes paramount importance.

#### Secondary Tests

The use of a constant temperature hot wire anemometer system for measuring the mean (and fluctuating) components of any flow requires high degree of precision and accuracy in the calibration technique. The importance of accurate calibration cannot be overemphasized and is well recognized by many experimenters. In order to gain experience and achieve perfection, a number of hot wire sensors were calibrated in the early stages of this research. During these calibrations, a number of secondary tests were conducted. These tests had significant bearing on the actual research and contributed immensely in arriving at meaningful results. The first of these tests is depicted in Fig. 39 which shows a comparison of the linearized bridge voltage output of

Fig. 39. Comparison of Linearized Bridge Output With and Without Cosine Law Cooling Assumption

the X sensor No. 1 (outer) Model 1240 with and without the assumption of "cosine law." According to this law, the sensor responds to the velocity component normal to the sensor only and is independent of the tangential velocity component. As shown by Champagne (Ref 4) and many other investigators, this assumption is valid only for wire having infinite aspect ratio. From a practical point of view,  $l/d$  ratio of 600 and above can be regarded to behave like a wire having infinite aspect ratio. In the present investigation, all the sensors had  $l/d$  ratio of approximately 333 and consequently tangential cooling effect can no longer be ignored. The calibration test, however, indicated an error of less than 1 per cent in the sensitivity of the sensor. Therefore, use of cosine law is well founded unless a high degree of accuracy is desired and one is willing to pay for it. In the second test, the single sensor Model 1210 was calibrated at three overheat ratios 1.2, 1.5 and 1.8 and its linear and non-linear calibration curves were compared. Figure 40 shows that provided relevant linearizer coefficients are used for each overheat ratio, all the data points fall on a single curve and no correction to the slope of the linearized curve is needed. On the other hand, if appropriate linearizer coefficients are not used, large error in the sensor sensitivity and hence in the velocity (both mean and fluctuating) measurement should be expected. The conclusion drawn from these tests is that it is essential to maintain the same overheat ratio during calibration and actual tests as it has significant influence on the sensor sensitivity. As the calibration data on a number of sensors was

Fig. 40. Linearized Response Curve at Different Overheat Ratios

available, it was considered worthwhile to calculate the value of King's Law exponent  $n$  and compare it with the published literature. Calibration of the different sensors at overheat ratio of 1.5 gave the following results over the range of  $7.2 \leq Re \leq 2.18$ .

Table VI  
Value of King's Law Exponent  $n$

Sensor	Orientation	Overheat Ratio	$n$
T1.5 Model 1214	Normal	1.5	0.245
T1.5 Model 1210	Normal	1.5	0.25
T1.5 Model 1240 (No. 1)	Normal	1.5	0.254
T1.5 Model 1210	Normal	1.2	0.404
T1.5 Model 1210	Normal	1.8	0.210
T1.5 Model 1240 (No. 1)	45 Deg	1.5	0.288
T1.5 Model 1240 (No. 2)	45 Deg	1.5	0.285

This value of  $n$  differs considerably from that quoted by Collis and Williams (Ref 3). In the range  $0 \leq Re \leq 44$  Collis and Williams obtained value of the King's Law exponent  $n$  equal to 0.45 for wires having very large aspect ratios. More recently, Klatt (Ref 15) carried out calibration of a large number of commercially available hot wire sensor in the speed range 1-40 meter per second and suggested that the value of  $n$  lies in the range 0.26-0.42. The value of  $n$  obtained from the present investigation is seen to be in excellent agreement with the results of similar tests conducted by Klatt. Table VI clearly indicates that the King's Law exponent  $n$  is dependent upon the sensor orientation and overheat ratio, in addition to the sensor aspect ratio and the range of Reynolds Number. The dirt accumulation and aging effects may also

change the value of  $n$ . Thus it is always advisable to determine the value of  $n$  from the actual calibration data rather than relying on empirical data if better accuracy of the test results is desired.

#### Rotation Tests in Shear Flow Region

One of the secondary objectives of the present investigation was to repeat the rotation tests in the shear flow region of the free jet. To achieve this goal, the X sensor Model 1240 was located at the center line and 25 centimeter away from the nozzle exit plane. The maximum turbulence intensity at this location was measured to be 15.8 per cent. Like the tests conducted in the potential core, the X sensor was yawed through  $\pm 30$  degrees and pitched through  $\pm 10$  degrees at three values of Reynolds Numbers, namely 7.2, 14.54 and 21.8 respectively. The results of these rotations are tabulated in Appendix C and represented graphically in Figures 41 thru 46. A summary of the error incurred in the mean flow direction measurement due to sensor misalignment in yaw is presented in Table VII.

As before, the per cent error is not constant for a given misalignment angle and strongly depends upon the direction of rotation. In other words, the X sensor has a strong preference for the direction of rotation in the shear flow region as well. The second feature which is common with the test results obtained in the potential core is that relatively large error occurs at very small misalignment angles. The fundamental difference between the results of the rotation tests

Re. No.	Misalignment Angle (Deg)	Per Cent Error in the Mean Flow Direction	
		Clockwise Rotation	Counterclockwise Rotation
7.2	4.0	-37.5%	-12.7%
	10.0	-29.8%	-16.23%
	20.0	-29.36%	-20.29%
	30.0	-28.9%	-21.25%
14.54	4.0	-33.75%	-28.1%
	10.0	-14.08%	-26.02%
	20.0	-17.93%	-25.59%
	30.0	-18.73%	-26.15%
21.8	4.0	-13.35%	-23.4%
	10.0	-16.6%	-21.89%
	20.0	-17.77%	-22.70%
	30.0	-20.29%	-23.76%

performed in the potential core and the shear flow regions is that the per cent error practically remains constant at approximately 22 per cent (on the average) in the range  $14.54 \leq Re \leq 21.8$  and at 25 per cent at  $Re$  equal to 7.2. In other words, the interference effects of the sensor prongs on the active portion of the downstream sensor are not as severe. The large error encountered in the mean flow direction measurements leads to the conclusion that the assumption of fluctuating velocity components being negligible as compared to their respective mean values is no longer valid.

### Rotation Tests in Pitch

The X sensor Model 1240 was pitched through  $\pm 10$  degrees in the shear flow region at the location mentioned earlier. The results of these rotation tests are tabulated in Appendix C and represented graphically in Figures 44 thru 46. These tests revealed that the Model 1240 sensor was insensitive to the misalignment in pitch up to angles as high as 30 degrees in the range  $7.2 \leq Re \leq 21.8$ .

## VII. Conclusions and Recommendations

### Conclusions

The sensor rotation tests carried out with the two X wire arrangements (TSI Model 1240 and TSI Model 1241) in the potential core of the free jet have led to the following conclusions:

1. Both the X sensor arrangements possess a strong preferred direction of mean motion resulting in errors which vary considerably with rotation in one direction than the other. This trend existed throughout the Reynolds Number range  $7.2 \leq Re \leq 21.8$ . This asymmetry in the sensor response makes it difficult to quote a single value for the per cent error due to misalignment in yaw or pitch and that only the range of errors due to a certain misalignment can be specified.

2. The mean velocity component  $\bar{u}$  can be measured within 4 per cent error approximately with both the sensor arrangements for misalignment in yaw up to 10 degrees in the range of Reynolds Number  $7.2 \leq Re \leq 21.8$ . However, for the same misalignment angle in yaw, errors in  $v$  and  $w$  are quite large and vary between 2-35 percent depending upon the sense of rotation and Reynolds Number.

3. The X sensor Model 1240 resulted in 5-20 percent error approximately in the mean flow direction due to 10 degrees misalignment in yaw in the range of Reynolds Number  $7.2 \leq Re \leq 21.8$ . The X

sensor Model 1241, on the other hand, resulted in 19-32 per cent error for the same misalignment angle in yaw in the same Reynolds Number range. From these figures, it appears that the X wire arrangement having sensors out of the probe plane is relatively superior.

4. At very small misalignment angles (1-4 degrees) in yaw, both the sensors displayed large error (up to 28 per cent approximately). This leads to the conclusion that the very small misalignments in yaw should be avoided.

5. The X sensor Model 1240 is less sensitive to misalignment in pitch as compared to Model 1241. With the Model 1240, misalignment in pitch of  $\pm 10$  degrees resulted in 0.3-10 per cent error in the range  $14.54 \leq Re \leq 21.8$ . This proves another useful characteristic of the X wire arrangement of Model 1240 as compared to Model 1241.

Conclusions from the second part of the research are:

1. Large errors in the linearized response of the hot wire sensor occur due to variations in the air temperature particularly if the changes in the fluid temperature are in excess of  $4^{\circ}\text{F}$ .

2. At low speeds (below 100 feet per second), the error in the linearized sensor response is considerably higher even at low values of  $\Delta T$ .

From the secondary tests conducted during this research, the following conclusions are drawn:

1. The linearized response of a hot wire sensor is highly dependent upon the precision and accuracy of calibration.

2. For normal laboratory investigation, simple cosine cooling law gives adequate accuracy.

3. The value of King's Law exponent  $n$  is not only a function of Reynolds Number, sensor aspect ratio, dirt accumulation, aging effects but it also depends upon the overheat ratio and the sensor orientation relative to the mean flow direction.

4. Overheat ratio has significant effect on the sensor response, both linear and non-linear. Care must, therefore, be exercised to maintain the same overheat ratio during calibration and actual tests.

5. The tendency of the X sensor to have preference for the direction of mean motion exists in the shear flow region to a larger extent.

6. The per cent error in the mean flow direction due to sensor misalignment in yaw is much greater than that in the potential core for the same yaw angle. However, spread in the data is considerably less as compared to potential core.

7. At very small misalignment angles, the performance of the X sensor is identical to that in the potential core.

8. The X sensor Model 1240 is insensitive to the misalignment in pitch up to pitch angle of 10 degrees in the shear flow region.

9. The assumption of negligible fluctuating velocity components relative to their respective mean values is no longer valid in the shear flow region.

## Recommendations

After investigating the performance of the X sensors in the potential core and the shear flow regions of the free jet, the following recommendations are made for further research:

1. A number of X sensors can be tested in the potential core of the free jet and "active" lengths of the two wires varied appropriately in order to investigate if it results in improved sensor response as far as asymmetry of the sensor response curves is concerned.

2. The sensor was assumed to operate in continuum flow and slip flow effects were neglected. It would be illuminating to investigate the X sensor performance in the potential core and in the shear flow regions of the free jet when slip flow effects are taken into account.

3. The variac Model 50-B had the capacity of raising the air temperature up to 50°F. It would be interesting to extend the range of correction to the linearized bridge voltage output of the constant temperature anemometer system to variations in the air temperature of 50°F and above, both in the potential core and shear flow regions of the free jet.

4. It would be desirable to improve upon free jet facility settling chamber pressure control system. A pressure regulating valve and a needle valve if incorporated in the system would offer considerable time saving and improve the accuracy.

5. The cathodometer and the sensor attachment system may be improved upon so that the sensor can be aligned relative to the mean flow direction with a high degree of precision.

## Appendix B

### Influence of Air Temperature Variations on Linearized Sensor Response

The energy balance between the power supplied to the heaters and heat gained by the air moving past it gives:

$$\frac{E_1^2}{R_1} + \frac{E_2^2}{R_2} = \dot{m}_a c_{\text{Pair}} (T_{T_2} - T_{T_1}) \quad (14)$$

Where  $T_{T_1}$ ,  $T_{T_2}$  are the bulk fluid temperatures and  $R_1$ ,  $R_2$  are the resistances of the heating elements.

In the present case,

$$E_1 = E_2 = E$$

$$R_1 = 8.5 \Omega$$

$$R_2 = 8.0 \Omega$$

$$\therefore E^2 = \frac{\dot{m}_a \times 0.24 \times \Delta T_T \times 10^4}{9.481 \times 0.24 \times 26470588}$$

$$\text{or} \quad E^2 = 32.29914542 \sqrt{\dot{m}_a \Delta T_a} \quad (15)$$

$$\text{Now } \dot{m}_a = \sqrt{\frac{k g_c}{R}} \frac{P_{T_e}}{\sqrt{T_{T_e}}} A_e \frac{M_e}{\left(1 + \frac{k-1}{2} M_e^2\right)^{\frac{k+1}{2(k-1)}}} \quad (16)$$

But  $A_e = 10$  sq cm

$$\therefore \dot{m}_a = 0.0098991618 \frac{P_{T_e}}{\sqrt{T_{T_e}}} \frac{M_e}{(1 + 0.2 M_e^2)^{3.0}} \quad (17)$$

For a given  $\dot{m}_a$  and  $\Delta T$ , equation (14) gives the value of Voltage setting required on the variac. The calculations are tabulated in Table XXVI.

Appendix C  
Calibration--Set Up

For the purposes of illustration, the set up procedure for the single sensor T1.5 Model 1214 is explained below:

$$P_a = 29.241 \text{ ins Hg} = 2069.3630 \text{ P. S. F. O.}$$

$$T_a = 68^\circ\text{F} = 528^\circ\text{R}$$

$$P_a = \frac{P_a}{RT_a} = \frac{2069.363}{53.3 \times 528 \times 32.2} = 0.0022835982 \text{ slug/ft}^3$$

$$V_a = \sqrt{\frac{2 \times 1.94 \times 32.2 \times \Delta h}{12 \times 0.0022835982}}$$

or

$$V_a = 67.52 \sqrt{\Delta h} \quad \text{ft per sec}$$

where

$\Delta h$  is in inches of water.

$$R_{\text{Sensor}} + R_{\text{Probe}} + R_{\text{Holder}} = 5.74 + 0.18 + 0.02 = 5.94 \Omega$$

$$R_{\text{Sensor}} + R_{\text{Probe}} + R_{\text{Holder}} \text{ measured} = 6.33 \Omega$$

$$R_{\text{Sensor alone}} = 6.33 - 0.2 = 6.13 \Omega$$

$$\text{Overheat Ratio} = 1.5$$

$$\therefore \text{Operating Resistance} = 1.5 \times 6.13 = 0.195 \Omega$$

### Temperature Correction

For small variations in fluid temperature, the temperature correction recommended by Ref 25 for non linear bridge output is given by:

$$\left[ \frac{t_s - t_{e2}}{t_s - t_{e1}} \right]^{1/2}$$

where  $t_s$  is the sensor operating temperature,  $t_{e1}$  and  $t_{e2}$  are the calibration temperature and new environment temperature respectively.

$$T_{e1} = 528^{\circ}\text{R}$$

$$T_{e2} = 530^{\circ}\text{R}$$

$$R_H = R_e [1 + \alpha_R(t_s - t_e)]$$

$$9.195 = 6.13 [1 + 0.0023 (t_s - 528)]$$

$$t_s = 745.39^{\circ}\text{R}$$

$$\begin{aligned} \text{Temperature Correction} &= \left[ \frac{745.39 - 528}{745.39 - 530} \right]^{1/2} \\ &= 1.0046320 \end{aligned}$$

### Vita

Flight Lieutenant Kauser was born on 15 November 1943 at Multan, Pakistan. He graduated from Emerson College, Multan in 1961. In 1962, he joined Loughborough University of Technology, Loughborough, U.K. from where he obtained his Bachelor Degree in Aeronautical Engineering with Honours in 1966. He joined Pakistan Air Force in 1966 and was assigned to Pakistan Air Force College of Aeronautical Engineering (P.A.F. C.A.E.). After teaching at the school for nine years, he was selected to go to the United States to do M.S. in Aeronautical Engineering from the Air Force Institute of Technology and entered the Graduate Aeronautical Engineering program in June, 1975.

20. ABSTRACT (Continue on reverse side if necessary and identify by block number)  This thesis reports the results of an experimental investigation of rotation tests conducted with two X wire sensor arrangements in the potential core of a free jet and the influence of small temperature variations on the linearized response of a hot wire sensor. The tests were performed in the free jet issuing from a 10 cm x 1 cm nozzle having turbulence intensity of 0.3 per cent at the exit plane. The two X wire sensors used were TSI Model 1240 and TSI Model 1214. Each sensor arrangement consisted of two platinum coated,

020225

tungsten wires, having 3.81 micron diameter, active sensor length 1.25 mm millimeter and separated by 1 millimeter apart. The X sensor Model 1240 was yawed and pitched through  $\pm 30$  degrees and  $\pm 10$  degrees respectively. The size of the potential core, however, limited the movement in yaw and pitch of the Model 1241 to  $\pm 10$  degrees. The tests were conducted at three values of Reynolds Number, 7.2, 14.54 and 21.8, based upon the wire diameter. The investigation showed that both the X sensors had a strong preference for the direction of mean motion, and the error due to misalignment in yaw was largest at very small misalignment angles. The Model 1240 showed insensitivity to misalignment in pitch in the upper range of Reynolds Number but the Model 1241 was highly sensitive to the misalignment in pitch. In the second part of the study, the air temperature was increased from  $4^{\circ}\text{F}$  to  $20^{\circ}\text{F}$  above the reference and its influence on the linearized response of the upstream sensor of Model 1240 was observed. The test results showed a strong influence of the variations in air temperature on the linearized sensor response at velocities below approximately 100 feet per second.
