20. ABSTRACT (Continue on reverse side if necessary and identify by block number)

A Nike-Javelin rocket (NJ-74-1) was launched at Poker Flat, Alaska, on 11 Apr 74 at 0801 hours UT during a non-auroral condition. A near-zenith spectral radiance profile was obtained from 54 km to an apogee of 118 km on ascent, and from 118 km down to about 85.6 km on descent, using a circular variable filter spectrometer. About 464 spectral scans were obtained during flight, covering the range from 1.7 to 5.4 μm at a resolution of about 4 percent. The dominant emission feature was at 4.3 μm, which is attributed to → next page

Foreword

A High Altitude Effects Simulation (HAES) Program is being conducted by the Defense Nuclear Agency. Under HAES, several related but distinct measurement programs have been or will be conducted to provide information for the development and test of predictive computer codes that will be used to assess and evaluate the operation of critical DOD radar and optical infrared systems in nuclear disturbed environments. The Air Force Geophysics Laboratory's work under the HAES program will be reported under the HAES series as AFGL Environmental Research Papers. The reports will also identify the measurement program (for example, ICECAP, EXCEDE, SPIRE, and so forth) so that related reports and results can be correlated and utilized.

This report presents the data for the NJ74-1 Circular Variable Filter (CVF) spectrometer and includes a description of the processes involved in completing the data reduction. A presentation of the CO_2 data will be given that includes altitude profiles and peak wavelength positions as a function of altitude. Included are actual scans of spectrometer data with indications of spectral resolution, dynamic range, and minimum detectable signal levels.

A.T. STAIR, JR.
HAES Project Scientist

J.C. ULWICK
HAES Technical Director

Preface

The authors wish to express appreciation to the many scientists, engineers, program directors, computer programmers, and clerical personnel that were responsible for the design and calibration of the rocket instruments, execution of the field program, reduction of the data and preparation of this report. Those who made special contributions were W. F. M. Grieder, C. L. Wyatt, K. D. Baker. In particular we wish to commend the efforts of Messrs. Robert E. McInerney, John Kotelley, Edward Robinson of the AFGL Computations Center (SUYA) for the design and management of data processing system used in rendering the data and Messrs. Dennis Dolorey, Niel Grossbard, and Miss Carol Foley of the Space Data Analysis Laboratory, Boston College, Boston, Mass., for developing and implementing data analysis routines used in the data processing system. In addition appreciation is extended to Mrs. Visniewsky of AFGL and Mrs. Gloria Foss of SRL for their superior effort in the technical typing of the manuscript and to SUSRP for editing and compiling the report.

Rocket-Borne Spectral Measurement of Atmospheric Infrared Emission During a Quiet Condition in the Auroral Zone

I. INTRODUCTION

At wavelengths beyond about 2.5 μm balloon- or rocket-borne instruments are necessary for studying infrared emission features in the aurora because of thermal radiation from the lower atmosphere and strong absorption in a number of important spectral regions. Attempts have been hampered in extending to any great degree auroral spectroscopic measurements into the near infrared by the lack of high-sensitivity detectors for the region beyond about 1 μm.

During quiet conditions at auroral altitudes the dominant species are N_2, O_2, and O. Infrared active species exist in the spectrum beyond 2 μm that are rich in vibration-rotation bands. Significant enhancement in the intensity of ν_3 fundamental of CO_2 at 4.26 μm is expected because of strong collisional coupling of $N_2(v = 1)$ with $CO_2(00^o1)$.[1] The significance of this report is that this enhancement is obviously not present because of the quiet auroral condition but a definite knee can be observed at approximately 86 km as shown in Figure 1. These data concern quiet auroral conditions essential to correct modeling of the atmosphere.

2. INSTRUMENTATION

2.1 Rocket Payload Configuration

The primary flight instrument on this rocket was a Short Wave Infrared Radiation (SWIR) Spectrometer designed and built by the Electro-Dynamics Laboratory of Utah State University. A cutaway view of this instrument is shown in Figure 2. The SWIR spectrometer about which this report is written consists of three distinct parts, that is, electronics, cryogen, and optical compartments. The cryogen capacity was 1/2 liter which provided a 3-hr operating time before refilling was necessary. A block diagram of the SWIR spectrometer system is shown in Figure 3. The optical axis passes through a window which provides a seal between the radiation source environment and the optical cold compartment. This is necessary to allow backfilling the cold optical compartment to a pressure of approximately 1/3 atmosphere with dry nitrogen gas which accelerates the cooling process of the circular variable filter. The circular variable filter must be cooled to a temperature below 130°K in order for the cold mask on the filter to provide a zero signal (minimum noise equivalent radiance) reference. The window has a 1/2-in. aperture and together with the positive meniscus lens provides an effective f/1 system. The f number being defined as the focal length divided by the entrance aperture size. The optical axis after passing through the lens goes through the filter where the energy is resolved into its wavelength components as

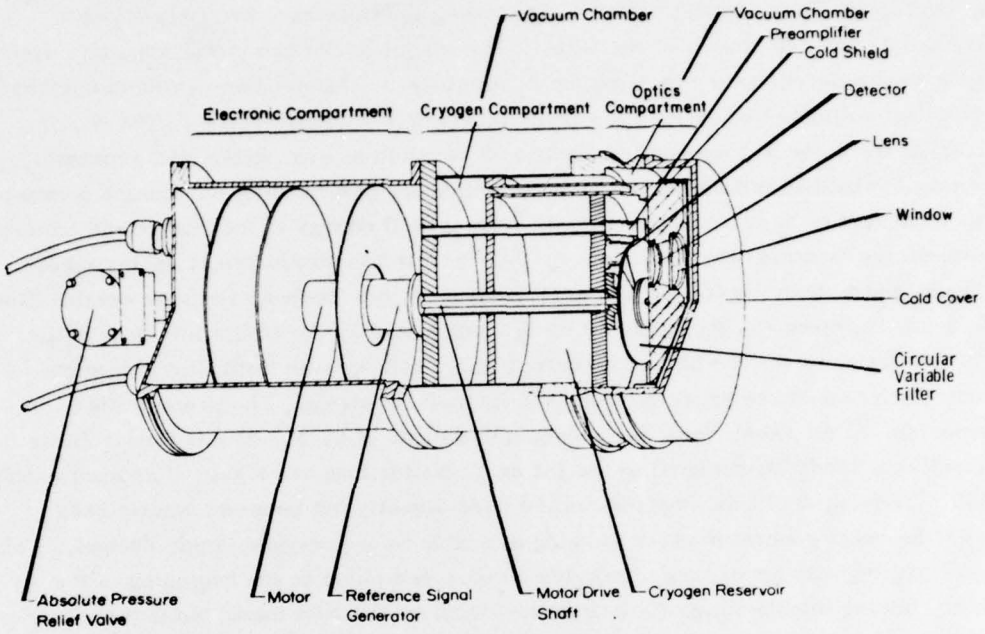

Figure 2. Cutaway View of the CVF Spectrometer

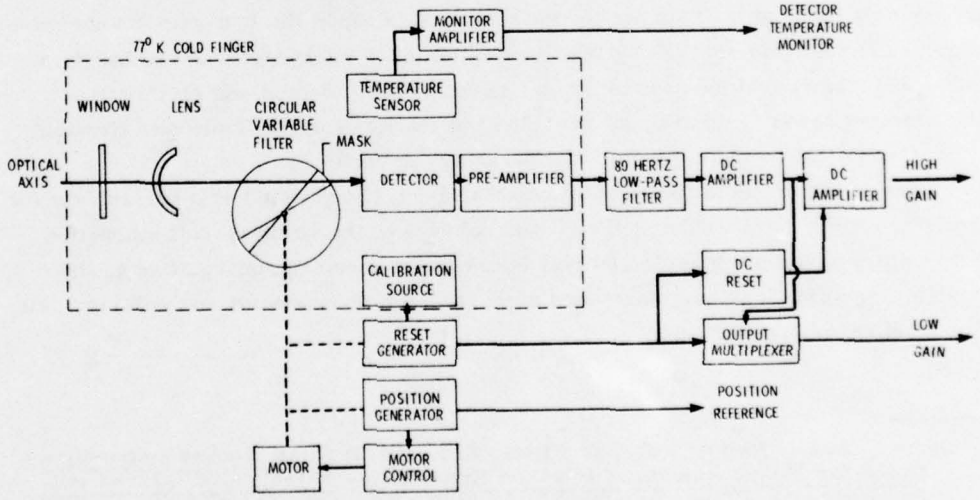

Figure 3. Simplified CVF Spectrometer Block Diagram

a function of filter wheel position. The filter wheel has two metal masks covering the 0° and 180° joints of the filter. The larger of the two metal masks is used as a zero reference for resetting the dc amplifiers, that is, compensating for any dc offset voltages that introduce errors in absolute radiance levels. The motor rotates the filter at a controlled speed of 2 revolutions per second and generates a set of pulses known as the position reference for determining wavelength position as a function of angular displacement. The optical energy is focused on the Indium Antiminide detector where this energy is converted to an electrical analog signal. The signal is then processed by the detector-preamp-feedback resistor combination to a low impedance signal prior to being conditioned by the 80-Hz low-pass filter. This filter removes the higher frequency noise and permits sufficient electrical bandwidth to observe expected radiation intensity changes. The preamplifier, detector, filter wheel, lens and window all operate at 77°K. The low-pass filter supplies a conditioned signal to the 1st dc amplifier that has a gain of approximately 100. The output of this amplifier is not used directly but becomes multiplexed with the reset generator prior to being available as a low-gain output channel. This multiplexing was necessary to provide a reference pulse at the beginning of the scan, during the blanking of the detector signal by the cold mask, so that the beginning of a filter scan can be determined. The filter wavelength location as a function of angular position can now be calibrated as a percent of a full scan using this reference pulse. The signal from the 1st dc amplifier now goes to the 2nd dc amplifier where an additional gain of 10 is realized. The output of the 2nd dc amplifier is directly available as the high-gain channel. In addition to the two signal channels, a position reference channel is available; however, this channel was not used during the flight. This procedure was used because the low-gain channel contained sufficient information for the determination of wavelength needed for data reduction. Temperature monitors were used for the detector and electronics. The cryogen dewar compartment provides the storage for the liquid nitrogen that keeps the optical compartment at its operating temperature.[2]

Support instrumentation on this rocket (NJ-74-1) consisted of a horizon sensor for determining the position of the rocket relative to the earth, a roll magnetometer which gives pitch angle and roll information of the rocket relative to the earth's magnetic field, and an S-band airborne telemetry system for relaying data to ground recording stations.

---

2. Jensen, L.L., Kemp, J.C., and Bell, R.J. (1972) Small Rocket Instrumentation for Measurements of Infrared Emissions – Astrobee D30.205-3 and Astrobee D30.205-4, AFCRL-TR-72-0691, Scientific Report No. 3, AFCRL Contract F19628-70-C-0302, Center for Research in Aeronomy, Utah State University.

The SWIR spectrometer was originally designed to fit an Astrobee D rocket with a shell diameter of 6 inches. The instrument is only 14 inches in length which allowed for a compact payload design. The output of the instrument consists of two linear gain channels with 0- to 5-V outputs and gains of approximately 100 and 1000 for the low-gain and high-gain channels, respectively. The low-gain channel voltage of 0 to 5 V represents a spectral radiance range from 3 MR/μm (mega-rayleighs per micrometer) (Noise Equivalent Spectral Radiance) to 110 MR/μm (Saturation Spectral Radiance), respectively, at 4.3 μm. In order to calibrate the relative position of radiant response to the spectral wavelength of the filter, a technique was used whereby a starting pulse was multiplexed at the beginning of the low-gain channel scan. This occurred during the reference mask where no data exists so that all applicable wavelengths can be referenced to this pulse as a percent of full scan. The spectrometer's optical axis was aligned with the rocket axis to provide a vertical look direction. Table 1 summarizes the instrument characteristics. The minimum detectable signal was determined by using a noise voltage of one half the peak-to-peak value which in this instrument was set at 0.5 V.

Table 1. Characteristics of the NJ-74-1 CVF Spectrometer NS-1B-6B

Parameter	High-Gain Channel
Offset Error	+0.023 V
Background Noise	1 V peak to peak or 0.2 V rms
FOV	$\theta = 3.517^{\circ}$ half angle or $\Omega = 0.0118$ sr
Optical Resolution	4 percent
Wavelength Coverage	
Short Half	1.6 to 2.8 μm
Long Half	2.8 to 5.5 μm
Instrument Weight	6 kg
Detector Type	Indium antimonide
Cryogen	Liquid nitrogen
Minimum Detectable Signal Range	1.5 MR/μm at 2.7 μm (Min) 34 MR/μm at 3.2 μm (Max)

The launch vehicle was a Nike-Javelin two-stage rocket which was launched on 11 April 1974 at 101:08:00:59.985 UT and reached an apogee of 118 km. The launch site was Poker Flats Research Range operated by the University of Alaska and situated approximately 30 miles N.E. of Fairbanks, Alaska. The auroral condition was quiet during the entire rocket flight. The first stage or booster engine was 16.5 in. in diameter, the second stage was 9 in. in diameter, and the payload section was 6 in. in diameter. The payload weight was 280 lb with an overall length of 80 in. The time for the total flight was approximately 330 sec. The spectrometer's optical axis was aligned with the rocket axis to provide a vertical looking direction. The vehicle aspect shows a relatively smooth flight with no major fluctuations in data due to rocket behavior.

2.2 Ground-Based Instrumentation

The scientific ground support stations and equipment are listed in Table 2. A review of the Ft. Yukon magnetometer data and the Ft. Yukon and Ester Dome all-sky camera and meridian scanning photometer data for UT April 11, 1974, associated with the launch of PF-NJ-74-1 at 0800 UT follows:

The early evening magnetic activity was very quiet. However, some 50γ to 100γ wiggles in ΔH took place between 0400 and 0700 UT. The activity actually decreased between 0700 and 0800 UT with smaller amplitude (25γ) wiggles. No obvious bay activity to the east occurred prior to the launch of PF-NJ-74-1 at 0800 UT. At 0830 UT the ΔH trace began a slow decrease which reached -150γ by 1000 UT, followed by a small -350γ negative bay at 1020 UT. The major negative bay (-950γ) of the evening occurred at 1315 UT.

Associated with this night's magnetic activity, the all-sky camera at Ft. Yukon shows the formation of an arc at 50° north zenith angle around 0745 UT. The 5577 A photometer data gives an intensity around 4 kR. At 0751 UT the intensity increases to ~10 kR and by 0755 UT there is obvious zenith activity, though <5 kR. This extends to perhaps 60° south of the Ft. Yukon zenith. A double peak at 60° and 50° north of the zenith forms around 0759 UT. From College the southern edge of the precipitation appears to lie between 10° and 20° north of the College zenith. Intensity there is around 1 kR which may be partially due to horizon-scattered twilight. Conditions remained much the same with the southern edge of activity moving slowly equatorward, reaching the geographic zenith at College by 0858 UT. At 0901 UT, a 20 kR arc formed at the magnetic zenith of Ft. Yukon. The precipitation extended to perhaps 20°S of the College zenith by 0910 UT, when both Ft. Yukon and Ester Dome systems were shut down. The weather at Ft. Yukon was partially overcast.[3]

3. ROCKET FLIGHT SUMMARY

3.1 Rocket Flight Characteristics

The payload was launched by a two-stage spin-stabilized Nike Javelin solid-propellant rocket. The ballistic wind velocity was 29.98 fps at an azimuth of 72.3° true north from Poker Flat Research Range, Alaska with a surface temperature of -16°F.

A scenario of the rocket flight is illustrated in Figure 4. The rocket was launched at an elevation angle of about 84° or 6° from the vertical (zenith angle). Approximately 3 sec after liftoff the first stage motor burned out and was released. The second stage motor burned out at approximately 23 sec and was not released. At this time the rocket attained a spin rate of about 6 rps from the action of the second stage rocket fins.

Above approximately 70 km, with a finned rocket vehicle, the atmospheric drag is small and the vehicle is essentially in free ballistic flight. In addition to the rocket spin (roll) the vehicle exhibited a coning (precession) motion with a period considerably longer than the spin period, typically 15 to 25 sec. For this flight the axis of precession was approximately 156 deg at 58 km and approximately 152 deg at 103 km obtained from the aspect data plotted for ascent and descent in Figure 5. The axis of precession is found by averaging the instantaneous position angle (γ) of the rocket as referenced to the local earth's magnetic field vector. The pitch angle (α) plotted in Figure 5 is defined as $180^{\circ} - \gamma$. The pitch angle α is the angle measured between the rocket axis and the tail of the local magnetic field vector. At approximately 54 km the payload tip was ejected permitting the spectrometer to view the incident infrared radiation. The ejection of the tip usually aggravates the coning motion which continued, having a half angle of approximately 1.5 deg, through apogee and for a time on re-entry while the vehicle decended tail first.

Finally, around 70 km, air drag became effective and the vehicle tipped over and oscillated for a time, then re-entered nose first. Rocket flight characteristics, particularly rocket aspect during measurements, are important in interpreting spectrometer infrared measurements. The reason for this is that obliquely viewed emission regions of space produce increased signals when compared with emitting regions viewed vertically. This phenomenon is commonly referred to as the Van Rhijn effect.[4] Corrections for obliquely measured emissions depend on a number of factors including the viewing angle relative to the vehicle, extinction, instrument field of view, and so forth. In considering the magnetometer data

4. Grieder, W. F. and Whelan, L. A. (1976) Geometric Aspects of Rocket Photometry, AFGL-TR-76-0046, HAES Report No. 41, Space Science Laboratory, Utah State University.

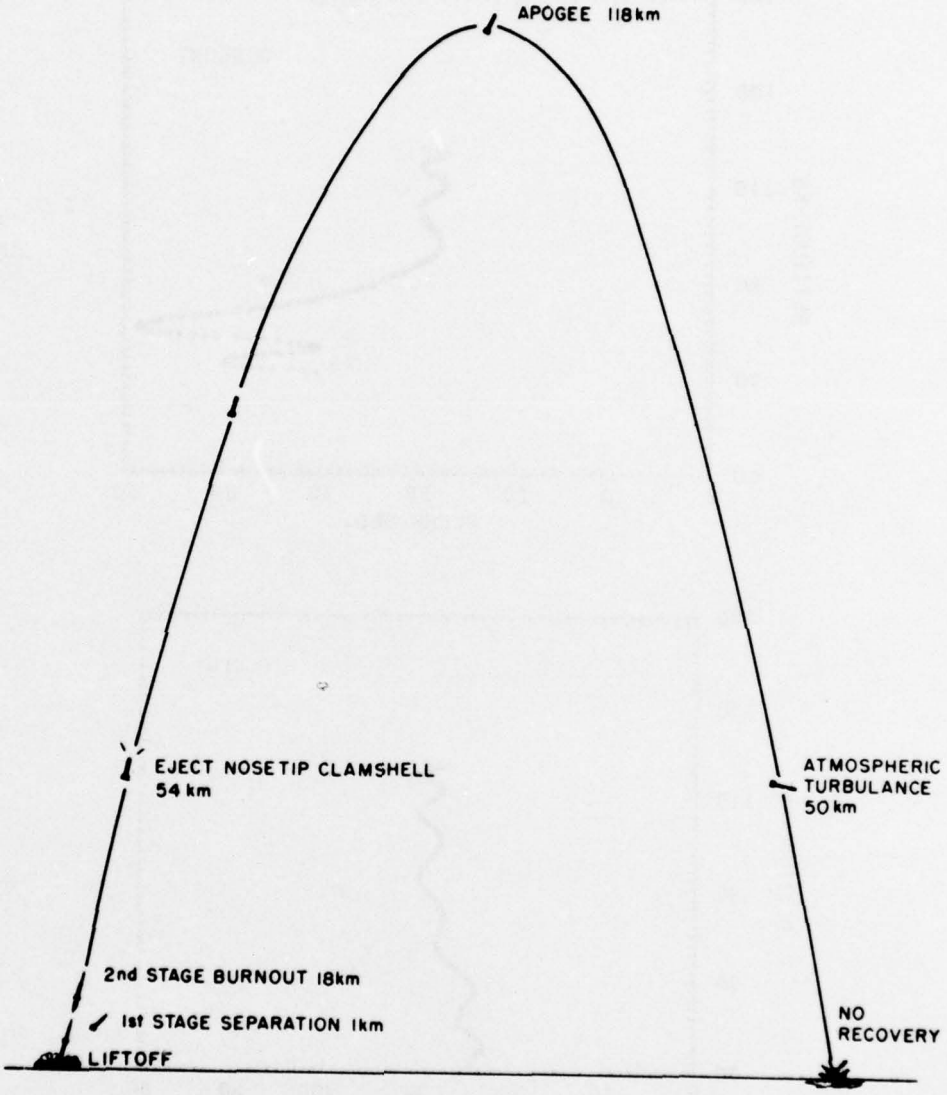

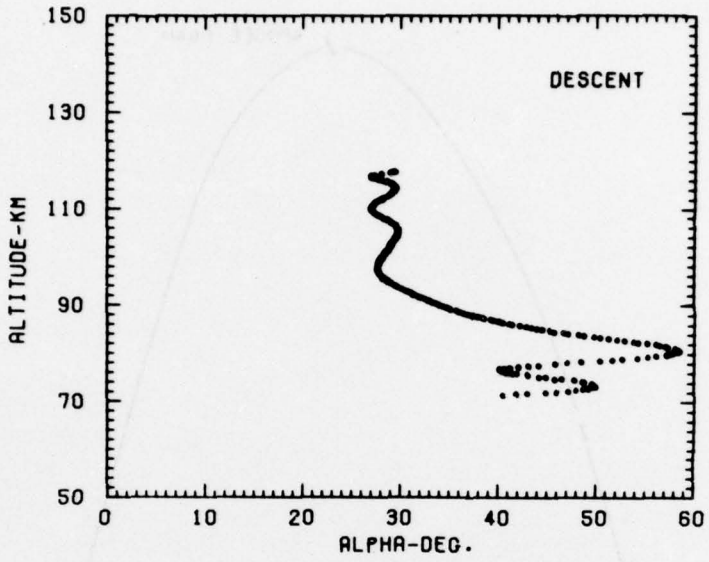

Figure 4. Scenario of a Typical Nike-Javelin Rocket Flight

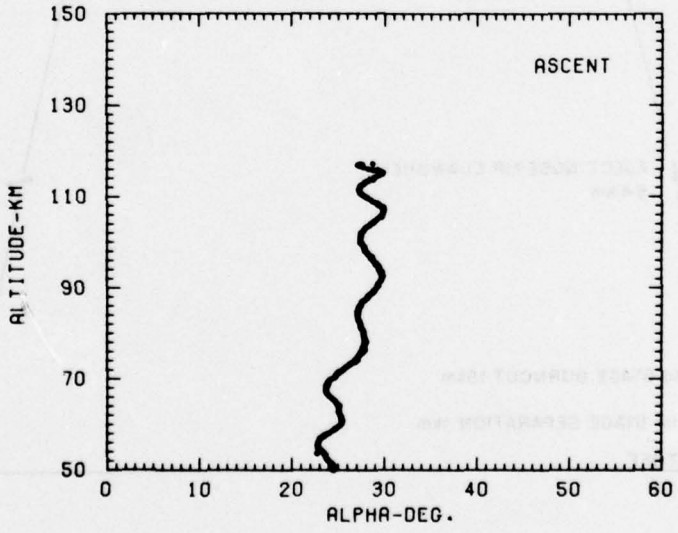

Figure 5. Aspect Plots for Both Ascent and Descent

presented, it is important to understand that the pitch angle as computed represents a cone about the magnetic field vector on which the rocket axis can lie. Any position on this cone will produce the same magnetometer output voltage. For this reason it is essential to introduce additional evidence and/or assumptions to deduce the rocket position on the locus cone.[5] Because this rocket was well behaved, for example, maintained a coning angle less than 3 degrees and a pointing direction no greater than 28.5 degrees, the Van Rhijn correction would not improve the accuracy of the data analysis significantly. However, horizon sensor data is available to make this correction if necessary. No apparent Van Rhijn modulation occurred in the prominent feature of CO_2 since this emission is optically thick. This precludes the use of this data to correct for rocket position.

3.2 Launch Summary

Measurements were made during the time from tip ejection (54 km) to vehicle tip over (~70 km) when the instrument views the earth. The spectrometer measurements are continually modulated throughout the flight by the coning motion; however, in this rocket flight the modulation of data due to coning was very small, for example, less than 2.5 MR at 4.3 μm. The spectrometer must look at a fixed position in space during the period of time that the filter makes one complete revolution for maximum resolution to be realized. This condition can only be approached in real rocket measurements and must always be considered to determine its effect on data.

Other rockets participating as part of the ICECAP 1974 program were A30.413-1 Astrobee D launched 11 April 1974 measuring electron and ion densities; A10.312-3 Paiute Tomahawk launched 18 April 1974 measuring electric fields, ionizations, and particle flux.

4. ROCKET DATA PROCESSING

4.1 Digitization of Data

The data from the rocket flight were transmitted to the ground support receiving and recording equipment by a composite telemetry FM signal. This signal was direct recorded at 60 ips along with a reference frequency to provide for tape speed control. The data tape was discriminated into separate subcarrier analog output voltages and digitized at a rate of 2000 points/sec, correlated with time after launch, and coded in a format compatible with the AFGL CDC 6600 digital computer.

5. Grieder, W.F., Baker, K.D., Stair, A.T., Jr., and Ulwick, J.C. (1976) Rocket Measurement of OH Emission Profiles in the 1.56 and 1.99 μm Bands, AFCRL-TR-76-0057, HAES Report No. 38.

This computer was used for all data processing and plotting. The analog tape data were digitized on a tape deck whose drive motor was synchronized to the reference frequency on one of the TM tape channels. This precluded errors in time due to nonuniform tape speeds. The analog tape data were digitized from 5 sec before launch (T-5 sec) to 305 sec after launch (T + 305 sec). This period of time was selected to cover the entire useful rocket flight data and also 10 scans before motor ignition. The data between T-5 sec and T+30 sec were used to verify that no malfunction of the instrument occurred due to motor impulse or vibration.

4.2 Data Processing

The purpose of the data processing procedures is to establish a relatively consistent method to evaluate rocket data that will be useful to the community. The procedures established for this rocket and for future CVF spectrometers is explained as follows: due to the complexity of the CVF spectrometer data, many factors must be considered when observing an anomaly in the data output so that misleading information can be analyzed correctly.

The CVF spectrometer has a rotating filter with blocking masks over the connecting joints of the two filter halves. One of these masks is used in a dc-reset scheme on the two gain channels. Any radiant energy reaching the detector by scattering, or noise spikes occurring during the reset period, will introduce an error. The background level must be determined prior to data processing so that an absolute calibration can be used to determine signal intensities.

Data scans that do not meet acceptance criteria are not used as part of the data processing. Acceptance criteria include: (a) minimum noise spikes on signal channels, (b) low offset voltages, (c) low drift, (d) absence of internal calibration signal. Scans that meet the acceptance criteria prior to cap removal are used to determine a true background by coadding these scans. The first useful scan after booster motor burnout, designated as Scan No. 1, starts at 30 sec after launch and the final scan number 558 occurs at 305 sec after launch. Spectral position is determined by recognizing the fraction of a full scan that can be determined by a reference pulse at the beginning of each scan at which the spectral feature occurs. This fraction of a full scan at which the spectral line occurs is related to the spectral position by the following equations:

For the short-wavelength half of the filter:

$$\lambda_n = 2.7485\, P_n + 1.4958 \quad , \quad 0 \leq P_n \leq 0.48 \quad ,$$

where

λ_n is the wavelength in micrometers (μm) for the nth point in the scan,

P_n is the fraction of a full scan for the nth point being considered.

The corresponding relation for the long wavelength half of the filter is:

$$\lambda_n = 5.6202\ P_n - 0.009 \quad , \quad 0.48 < P_n \leq 1 \quad ,$$

where λ_n and P_n are defined above.

The beginning of each scan is determined by a start-pulse which is multiplexed with the low-gain channel on IRIG 16. The start of each scan begins at the time when the leading edge of the start pulse reaches 1 V ± 0.5 V. The end of one scan marks the beginning of the next. The total number of digitized points occurring in one scan is used to determine spectral position. Errors in determining spectral position occur due to the following reasons:

(a) A delay in rise time of the beginning of a scan pulse is due to the telemetry IRIG channel filters. A typical delay time would be 1.5 msec and a typical rise time would be 0.5 msec giving a total of 2 msec delay for IRIG channel 14 with a 330 Hz low-pass constant-amplitude filter. However, this delay is common to all signals on a given channel.

(b) The relative error between the low-gain channel and the high-gain channel is approximately 0.6 msec. This error is due to the different bandwidth filters associated with IRIG channel assignments. The discrepancy in wavelength as correlated between the low- and high-gain channels due to a 0.6 msec error could be 0.0072 μm for the long-wavelength half of the filter. This error in spectral position correlated between gain channels is due to the long-wavelength half of the filter scanning 12 μm/sec, for example, this filter scans 3 μm on approximately 250 msec. For the short-wavelength half of the filter this discrepancy could be 0.0036 μm, for example, this filter scans 1.5 μm in approximately 250 msec.

(c) The resolution element of the filter is determined by the following equations:

For the short-wavelength half of the filter, which covers the range of 1.696 to 2.692 μm,

$$\Delta\lambda = 9.23 \times 10^{-3}\lambda + 0.064 \quad .$$

For the long-wavelength half of the filter, which covers the range of 2.995 to 5.45 μm,

$$\Delta\lambda = 0.01\lambda + 0.122 \quad .$$

(d) The deviation from the straight line approximation of the filter's spectral linearity with angular position is typically ±1 percent.

(e) The computer sampling accuracy is approximately ±0.5 msec. This error is due to the fact that the analog-to-digital converter has a resolution of 1 msec.

(f) The wavelength shift due to a point source moving across the field from edge to edge is approximately 0.033 μm. This shift is due to the angle of incident radiation passing through the filter changing as energy moves from edge to edge and thereby causing a different spatial position on the filter to be seen. Moving to a different spatial position on the filter represents a different wavelength.

The absolute brightness in megarayleighs per micrometer (MR/μm) is determined by the following equation after the spectral position has been determined. The zero background discrepancy is less than the noise equivalent spectral radiance of the spectrometer system. The conditions preceding the background measurement at apogee are different from the background measurement with the cover on in that energy had excited the detector shortly before apogee. Because of time constants associated with the detector and circuitry, undesired backgrounds can be observed if signal changes are great enough and the elapsed time between measurements is not sufficient to allow the detector and circuitry to respond in a normal way to the signal being measured.

$$R_{\lambda_n} = GC_{\lambda_n}(V_n - \Delta V_n)^x \quad [\mathrm{MR}/\mu\mathrm{m}] \ ,$$

where

R_{λ_n} = spectral brightness of the nth point in a scan,

C_{λ_n} = inverse responsivity for the nth point in megarayleighs per volt per μm,

V_n = TM volts for the nth point corrected for in-flight calibration,

ΔV_n = reset voltage for the particular scan,

G, x = constants from calibration data.

The two portions of the filter, long- and short-wavelength halves, require separate curves according to the following criteria:

For the short-wavelength half:

Use C_λ for $1.696 \leq \lambda \leq 2.692$.

For the long-wavelength half:

Use C_λ for $2.995 \leq \lambda \leq 5.45$.

The following sequence of events was used to prepare the data contained in this report. The objective of this process is to provide a reliable data base for the using community.

(1) Scans prior to tip off were plotted and reviewed. The best scans were 27 through 56, omitting scan 31. Reasons for omitting scans are:

(a) Excessive drift,

(b) TM drop out,

(c) Calibration source on during scan.

(2) Scans 27 to 30, 32 to 56 were co-added point by point (points 1 through 1225) for both gain channels of TM volts. The standard deviation for both co-added sets (29 points for each set) were computed and plotted).

(3) Zero reset voltages and standard deviations were computed for points 32 through 38 for scans 27 to 30, 32 to 56 and Chauvenet's criterion was used to omit unwanted points. The mean zero resets were listed for each scan.

(4) Mean zero reset voltages for each scan were subtracted from all TM voltage points in scans 27 to 30, 32 to 56 and the scan co-adding process was repeated. The co-added noise spectra were approximately 50 mV in both co-added computations and therefore the need to correct the data was alleviated.

4.3 Measured Altitude Emission Profiles

The altitude emission profiles are determined from the scans shown in Appendix C. The peak values at the wavelength of interest are plotted as a function of altitude. In Figure 1, this altitude profile is plotted for the CO_2 emission.

In Figure 6, an altitude profile is shown for N_2O in a band averaged between 4.55 μm and 4.61 μm. The signal to noise ratio for this measurement is less than one and no trend for signal is observed. In Figure 7 an altitude profile is shown for CO_2 in a band averaged between 4.78 μm and 4.93 μm which begins to show a trend in signal above the minimum detectable signal for altitudes below 70 km. In Figure 8 an altitude profile is shown for NO (v = 1) emission in a band averaged between 5.25 μm and 5.35 μm which shows a constant signal level. The shaded area has been drawn on these plots to aid the eye in reading the data. These measurements are consistent with previously reported data.[6,7] In the preliminary summary of previous ICECAP probes[6] the 5.3 μm emission was observed to be a

layer peaked at 130 to 140 km. The Russian literature[7] reported observing this radiation from a satellite limb look where the layer varied in peak altitude from 140 to 200 km. The wavelengths have been shifted by approximately 0.074 μm to allow the CO_2 peak to occur at 4.269 μm. This was done to be more consistent with later rocket aircraft data measurements.[8] Also evidence has been established that calibrations using fixed filters, such as those used in calibrating this CVF, can produce errors in wavelength of the order of 0.1 μm. This error is due to one's inability to determine the exact center of wavelength for the fixed filter whose response function is nonsymmetrical and irregular. This wavelength shift will help to avoid confusion when observing CVF data since there is strong evidence that this is the correct wavelength.

Other CO_2 emission profiles have been reported.[1,9,10] The low-gain channel IRIG 14 offset can be mostly compensated for by subtracting the zero background signal from the instrument. This offset in voltage for the low-gain channel IRIG 14, shown in Figure 9a, corresponds to a brightness level of approximately 3 MR/μm at 4.3 μm. Figure 10a. shows the high-gain IRIG 16 which has negligible offset.

Another example concerning data analysis is given in Figure 11 where composite scans for the CO_2 peak are plotted on the low-gain channel during ascent. This plot is useful when it is desired to observe a trend in wavelength shift with altitude. It should be remembered that altitude increases from top to bottom in the figure.

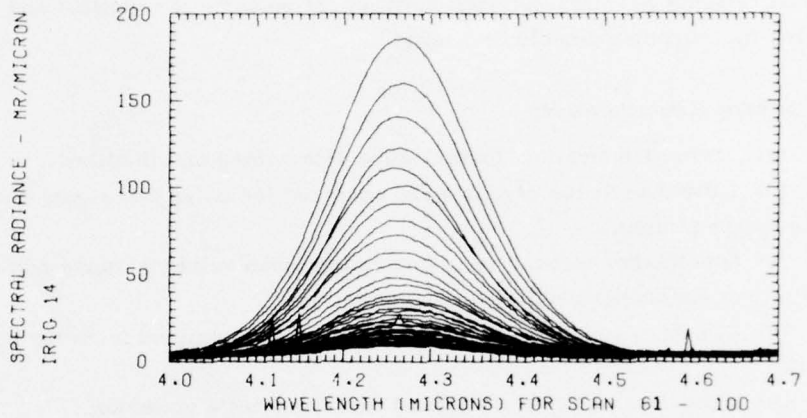

Figure 11. Composite Scans of the 4.3 μm Band for the Low-Gain Channel During Ascent

4.4 Magnetometer Aspect Data Reduction

In reference to Figure 5 and the explanation given in Section 3.1 concerning this figure, the total coning angle during the measuring portion of the flight did not exceed approximately 3 deg. The angle α held fairly constant ranging from approximately 23.5 deg at 50 km to approximately 28.5 deg at 116 km for ascent. The descent curve shows approximately the same coning angle during the measuring portion of the flight but begins to deviate greatly at approximately 90 km where the rocket begins to tip over. The angle between the rocket axis vector and the vertical cannot be found without more information about the rocket, except in the case where the rocket axis vector is known to be in the plane of the true vertical and the earth's magnetic field vector. If the radiation source profile can be predicted accurately enough as a function of altitude, a trial and error matching technique can be used.[5] However, these data cannot be processed using the technique described because CO_2 at 4.3 μm is optically thick. An optically thick medium as a radiating source provides a relatively steady signal as coning motion proceeds. In contrast to this an optically thin medium as a radiating source will produce modulation or fluctuation in the signal as coning motion is experienced.

This is obvious when one considers that obliquely viewed regions have greater optical depth and therefore greater radiating energy as compared with a vertical measurement. Another point of interest concerning optically thin NO^+, whose center wavelength is slightly higher than CO_2 which is an optically thick medium, is that an apparent wavelength shift can occur depending upon which radiating source has the highest excitation as a function of altitude. However, in these measurements NO^+ was not excited by an active auroral condition and its effect on the measurement should be negligible.

4.5 Summary of Data Processing

(a) Scale size and data format were determined and finalized.

(b) Individual scans of data were analyzed for noise and signal content; useful scans were plotted.

(c) Quiet scans were used to determine mean values of noise and standard deviations for background level determinations.

(d) The zero reset sampling criteria were determined from the computer plots.

(e) Acceptance of data was based on Chauvenet's criterion.

The conclusions reached from the above analysis were as follows:

(a) Zero reset voltages were subtracted from each scan to give more accurate absolute radiance levels.

(b) Offset voltages were not subtracted from each scan because:

(1) Offset voltages were approximately the same as the system noise level and therefore do not add in a significant way to the error in reading absolute radiance levels.

(2) Offset voltages appear to be different before and after the cover is removed from the instrument but are less than the noise equivalent radiance of the instrument.

(c) Error bar curves were superimposed on two sample scans shown in Figure 12 to assist in determining useful data. These error bars were determined by measuring the saturation voltage and the noise equivalent voltage of the instrument when converted to radiance as a function of wavelength. A study of the processes previously explained can be made by observing a sequence of plots beginning with Figure 13. This figure depicts individual scans for both low-gain (IRIG 14) and high-gain (IRIG 16) channels. An overlap in wavelength occurs at 2.75 μm due to the common wavelengths at the mating edges of the filter halves. The approximate noise for the low-gain channel is 50 mV peak-to-peak for scan 19 and approximately 250 mV peak-to-peak for the high-gain channel for scan 18.

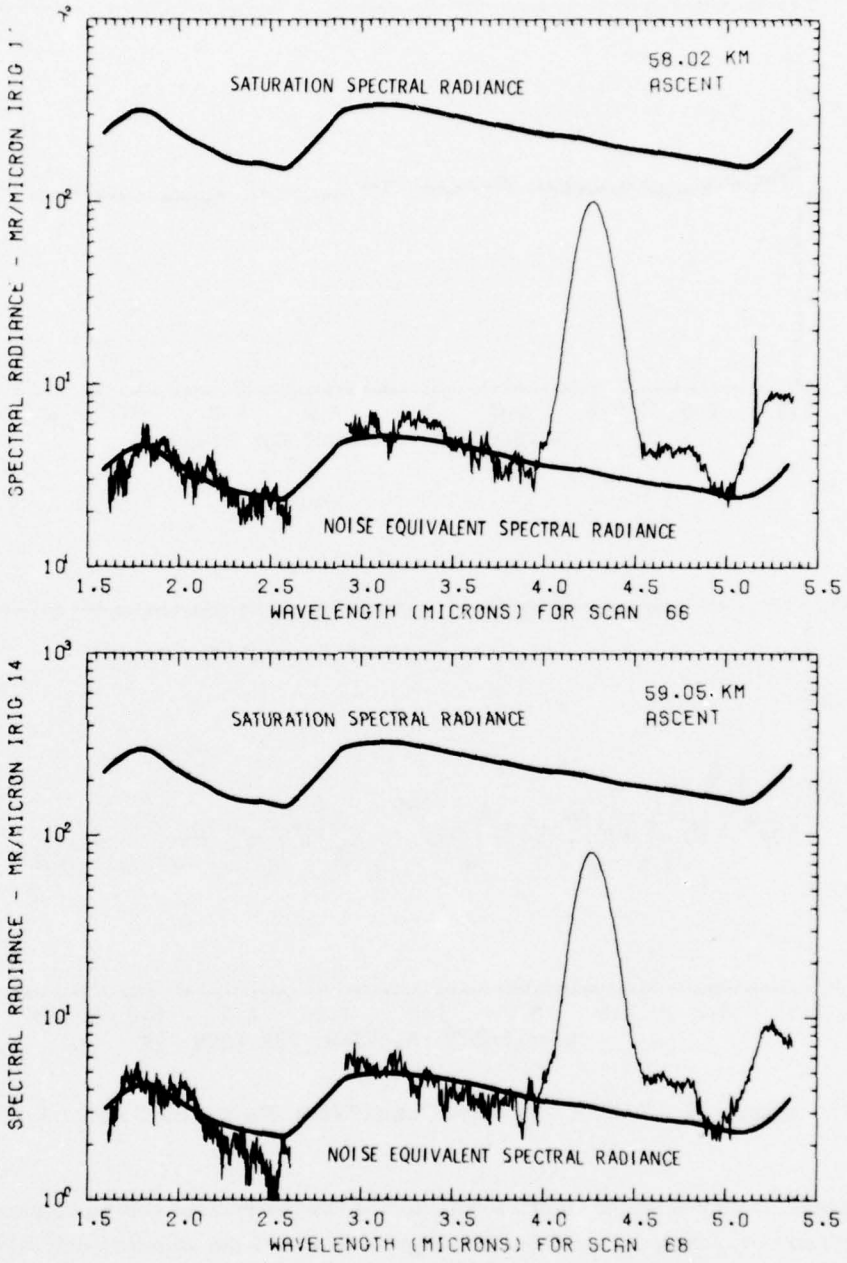

Figure 12. High and Low Spectral Radiance Limits for Data Analysis

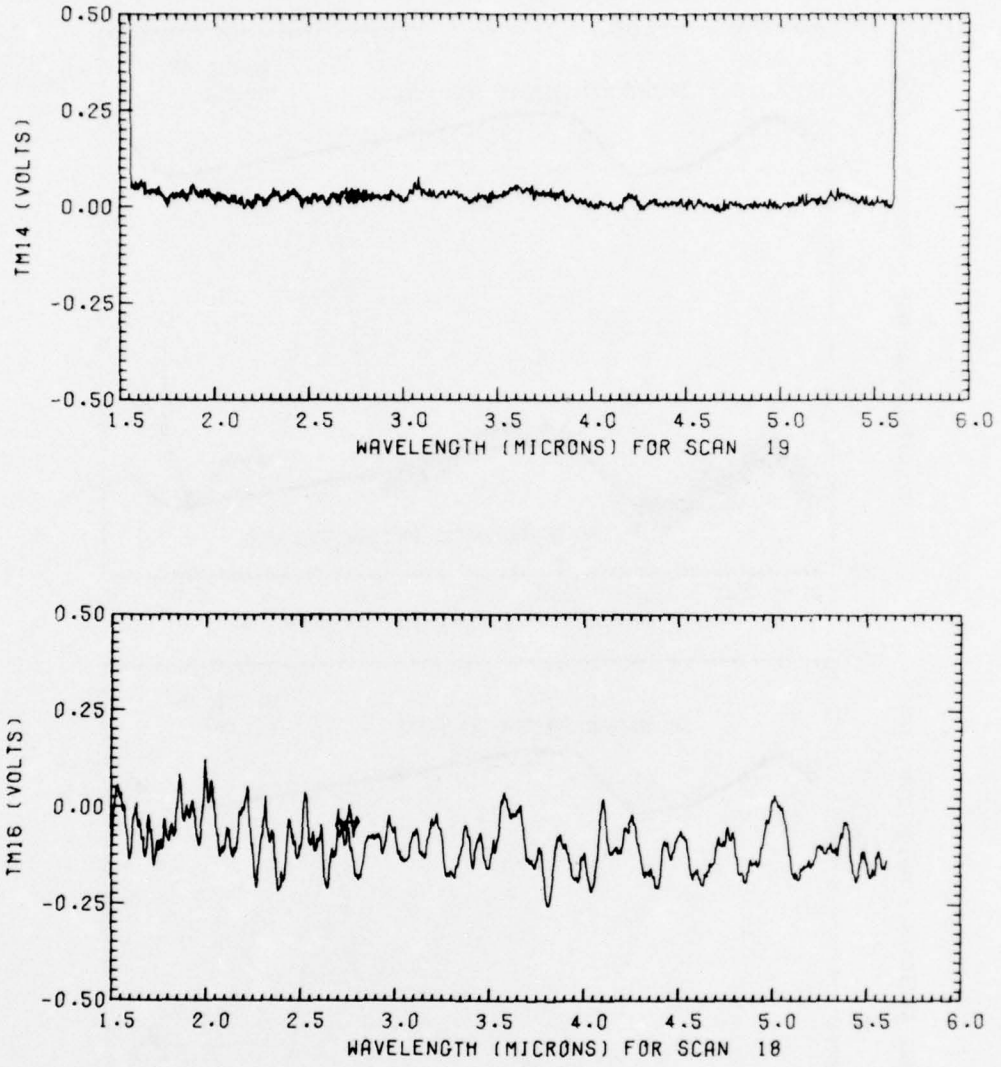

Figure 13. Sample CVF Data Output Wave Form with No Signal

Figure 9a shows the co-added scans before the instrument cap was removed and with no correction for zero reset. Figure 9b shows the standard deviation for this co-added plot. Figure 9c shows the same plot as Figure 9a with the exception that the zero reset portion of the scan occurring at 1.55 μm has been corrected to read zero. This zero reset portion of the scan is the true instrument zero since the detector is looking at a cold mask on the filter during this time period.

Figure 9d shows the standard deviation for the plot shown in Figure 9c. Two noise spikes occur in these scans and the standard deviation plots magnify these perturbations dramatically. Figures 10a, b, c, d follow the same reasoning as described above for Figures 9a, b, c, d except that the high-gain channel is shown. It is clear from these plots that the co-adding process reduces the noise considerably and provides a clear indication on the low-gain channel as to where the zero reset position of the filter occurs.

5. DISCUSSION

5.1 Summary of Data Analysis

Low-level data obtained from each scan depend upon the analyst's ability to distinguish the source response from the system noise. This can be approached by realizing that the system can produce certain types of perturbations that limit the ability to identify spectral features and determine spectral radiance levels. These perturbations include zero offset, drift, instrument noise, and system noise. The zero offset and long term drift are determined by co-adding techniques. The instrument noise can be observed during calibration since the calibration equipment noise is negligible. The system noise can be determined during a complete system cold-cap (minimum radiation) test. This can be accomplished because all noise producing equipment such as TM, and so forth, is included during this measurement. The data analysis can proceed after confidence in each scan has been obtained and limits for background noise and saturation levels have been applied.

6. CONCLUSIONS

The following list shows the conclusions reached as a result of preliminary data reduction and analysis described in this report.

(1) The instrument performed within the design tolerances.

(2) The offset voltage, which would produce an error in absolute spectral radiance, did not exceed 0.0 75 V. Since the noise equivalent voltage is 0.5 V no correction was made for this effect.

(3) The observed wavelength for CO_2 was 4.34 μm at 60 km ascent. However, the CO_2 emission in the 4.3 μm band should peak around 4.26 μm when convolved with the CVF spectral resolution.[11] Further evidence that the CO_2 emission occurs closer to 4.26 μm is present in later rocket flights.[6]

(4) Procedures and techniques used in calibrating these instruments have been modified and improved since this measurement was made.

(5) The descent data for the CO_2 emission were not presented because of high background, erratic and noisy signals.

(6) The altitude profile in Figure 1 shows a very distinct knee in the curve between 86 and 90 km. The level of this knee ranges from approximately 2.5 MR at 90 km to 3 MR at 86 km. This feature is currently being interpreted as being due to vibrationally excited hydroxyl (the chemiluminescent airglow) collisionally transferring vibrational energy to N_2 and subsequently to the ν_3 fundamental of CO_2.[12]

(7) Before reading any individual scan one should observe the noise equivalent spectral radiance curve given in Figure 12 so that background or noise signals are not assumed to be real data.

(8) The measurements of this rocket flight were made during a quiet auroral condition. This is the first and only measurement at the present time for a quiet auroral condition on the wavelength region at 1.5 to 6 μm.
