20. ABSTRACT (Continue on reverse side if necessary and identify by block number) The effects of single overload-underload interaction on constant amplitude crack growth in 2219-T851 aluminum alloy are characterized in terms of delay cycles, affected zone sizes and overload shut-off ratios. Data are presented showing the effects of overload-underload/underload-overload sequences, overload magnitude, underload magnitude, and the constant amplitude maximum and minimum. The effects of hold periods in both tension and compression are also experimentally investigated. Delay cycle data are correlated with predictions from three different crack growth retardation models; namely		

20. ABSTRACT (Cont'd)

the generalized Wheeler model, the generalized Willenborg model and the Grumman closure model. For each model, predictions are made using an assumed plastic zone radius and diameter for both plane stress and plane strain conditions and model comparisons are made. Correlations of measured affected zone sizes with the four different assumed plastic zone sizes are also presented. Sensitivities of the generalized Wheeler and generalized Willenborg models to overload shut-off ratio and threshold stress intensity factor are determined. Prediction sensitivity to three different crack growth equations for the 2219-T851 aluminum alloy is also evaluated. Recommendations for future work in development of crack growth retardation models are presented.

FOREWORD

Reported herein are results of work performed by the Lockheed-Georgia Company on Contract No. F33615-75-C-3111, "Underload Effects on Spectrum Crack Growth". The effort was sponsored by the Air Force Flight Dynamics Laboratory as part of the "Advanced Metallic Structures - Advanced Development Program" (AMS-ADP), Project No. 486U. Mr. Robert Engle of AFFDL/FBE was the Air Force Project Engineer.

The Lockheed Project Engineer was W. M. McGee of the Structures and Materials Laboratory. Analytical work was performed by Dr. T. M. Hsu. The experimental evaluations were accomplished by F. L. Amend who was assisted by R. I. Prescott and L. T. Reynolds. This is Volume II of the final technical report and contains tabulations of basic data generated during the experimental evaluations performed over the period of July 1975 - October 1976.

SUMMARY

An experimental and analytical investigation was performed under Contract No. F33615-75-C-3111 to characterize the effects of underloads on crack growth and to evaluate current crack growth retardation models for predicting underload effects. This is Volume II of the final technical report and contains tabulations of basic data collected during the experimental portion of the program. Data tabulations are presented for approximately 200 different variables evaluated on specimens from a single heat of 2219-T851 aluminum alloy plate. The 200 variables represented combinations of different load classes and stress intensity factor parameters. Load classes evaluated were tension-tension, tension-zero, zero-tension, tension-compression and compression-tension. Stress intensity factor parameters varied for each load class were the overload stress intensity factor ratio, constant amplitude stress intensity factor ratio and the underload stress intensity factor ratio. The maximum of the constant amplitude stress intensity factor was also a variable. Data tabulations are also presented for limited evaluations on hold times in tension and compression.

Volume I contains analytical predictions and data correlations for the same variables evaluated experimentally. Predictions were made using three current crack growth retardation models in generalized form; namely the Wheeler model, Willenborg model and closure model. The models were evaluated to determine prediction sensitivity for variances in overload shut-off ratio, stress intensity factor threshold and overload affected zone size formulations. Also evaluated, was prediction sensitivity associated with different crack growth rate equations for the 2219-T851 aluminum alloy.

SECTION I INTRODUCTION

Analytical methodology to predict subcritical crack growth in aerospace structures subjected to complex loading is an essential element in the overall fracture control program currently being applied on fracture critical structures. Current analytical methods for complex loading are not precise; however, considerable effort has, and is, being directed toward a better understanding of the crack growth process. From such efforts will evolve improved analytical modeling of fatigue crack behavior. Within the current state of technology, an unconservative or conservative crack growth prediction is possible depending upon the analysis methodology selected for a particular load profile. Consequently, current methods must be judiciously applied and substantiated by adequate testing. Eventually, unconservatism must be eliminated for reasons of safety and structural life, and over-conservatism must be eliminated since it integrates throughout the entire design process to adversely effect total performance.

It is generally agreed that linear analysis produces acceptable crack growth predictions for constant amplitude loading provided an adequate data base is available, a valid stress intensity factor solution is available, and environmental variations are excluded. The introduction of a high load, however, retards subsequent crack growth to the extent that use of linear analysis without considering load interaction effects is precluded. Considerable data are available characterizing this retardation effect, and several retardation models have been developed for predicting the overload effects on subsequent crack growth rate. Limited data are available which show that this retardation effect is reduced when the high load is followed by a compressive load or underload. The current retardation models account for the beneficial effects produced by overload conditions, but most models do not consider a reduction in these beneficial effects when underloads are included. Further characterization of the underload effect and its interaction with overloads was necessary to identify controlling parameters which will guide future development of analytical methods to more accurately predict crack growth under complex loading.

This program represents an experimental and analytical investigation to characterize crack growth behavior associated with underloads and their interaction with overloads. The experimental effort encompassed approximately 200 variables which represented combinations of load profile classes and stress intensity

factor parameters. All experimental evaluations were performed on specimens from a single heat of 2219-T851 aluminum alloy plate. Analytical predictions were made for the same variables evaluated experimentally. Predictions were made using three current retardation models in generalized form, and these predictions were correlated with the experimental data. Sensitivities of the models to such parameters as overload shut-off ratio, stress intensity factor threshold and overload affected zone size formulations were evaluated.

SECTION II EXPERIMENTAL PROGRAM

General - Volume I contains complete details of the experimental evaluations; however, essential elements are briefly covered in the following sections to provide a general understanding of the program and data tabulations. For complete details, Volume I must also be consulted.

Load Classifications and Stress Intensity Factor Parameters

Seven different load classes were evaluated as illustrated in Figure 1. Note that three different sequences were contained in the tension-tension class. These were illustrated in terms of stress intensity factor, K , since testing was performed under quasi-constant K conditions as later described. Definitions of the stress intensity factor parameters evaluated are contained in Figure 2. The basic program for K_2 constant at $10 \text{ KSI} \sqrt{\text{In.}}$ is shown in Figure 3 and represents combinations of load classes and stress intensity factor parameters. Parameters evaluated for $K_2 = 7.78 \text{ KSI} \sqrt{\text{In.}}$ and $14 \text{ KSI} \sqrt{\text{In.}}$ are shown in Figures 4 and 5, respectively. Conditions evaluated to determine hold time effects are defined in Figure 6.

Material and Specimens - All experimental evaluations were performed on specimens machined from 2219-T851 aluminum alloy plates having a nominal thickness of 5/8-inch. All test specimens were the center crack configuration shown in Figure 7. The test section of each specimen was polished to enhance crack tip detection, and one surface was prepared with a grill against which to reference subsequent crack length measurements. Pitch of the grill was approximately 0.010 inch, and exact value was determined for each specimen using a toolmaker's microscope.

Testing Procedures - All testing was performed in ambient temperature desiccated air. Where compressive loading was required, Teflon lined lateral support bars were employed to prevent specimen buckling. Two identical electro-hydraulic servo controlled test systems manufactured by MTS Systems Corporation were employed. The test systems were programmed and controlled by digital computers. Load form was sinusoidal at a frequency of 12 cycles per second for the constant amplitude cycles; however, a much slower rate was used for the overload and underload cycles.

Each test system computer was programmed to accept desired stress intensity values as input, compute corresponding loads using the stress intensity factor equation

for a finite width center cracked plate, and then apply these loads to the specimen. Periodically during test, crack length measurements were made by microscopically observing the crack tip against the grill. The computer was supplied these measurements, and loads were automatically reduced in accordance with the stress intensity factor equation. In this manner testing was accomplished under quasi-constant K conditions, and crack length data were updated at intervals necessary to maintain desired K values within one percent.

In evaluating each of the previously defined variables, constant amplitude cycling was initially performed using the appropriate R and K_2 values. This was continued while collecting data until it was assured that a constant growth rate had been reached. The desired overload-underload cycle was then applied followed by the previously applied constant amplitude condition. During this constant amplitude cycling, crack length and cycle data were periodically recorded until it was assured that the previous constant amplitude growth rate had been reached. From these data, the number of delay cycles, N_D , produced by the overload-underload cycle and the associated affected zone size, a^* , were determined. These retardation parameters are defined in Figure 8. Except for cases producing a large number of delay cycles and hold time evaluations, at least three data runs were usually made. For those data runs, crack length measurements were made at the same cycle increments, established based on a preliminary run, which allowed data averaging.

In performing the experimental evaluations, the overload ratio, S, was increased by 0.5 increments until shut-off was reached. Additional tests were then performed at intermediate values of S to zero-in on the overload shut-off ratio to within 0.1. In determining overload shut-off ratio, cycling was performed until it was assured that crack growth rate was less than 10^{-9} inch per cycle which corresponds to threshold growth rate from basic da/dN data.

Data Tabulations - In addition to controlling the tests, the computers were also used to store, reduce and output tabular data. Data tabulations in this report are copies of the computer output. Each data tabulation is comprised of three parts; incremental data for each run, average crack length referenced to the midpoint of the cycle increment and average crack length referenced to the cycle increment at time of measurement. Typical data representative of these three parts are shown in Figures 9, 10 and 11, respectively. Notes of explana-

tion are also included in these figures. Where more than one run was made, the tabulated incremental data represent all measurement increments. In most cases more incremental data than tabulated were collected for cases where only one run was made. More incremental data were collected for those cases to insure that the desired quasi-constant K conditions were maintained; however, the computer program allowed combining data increments to prevent extremely long data tabulations. As the overload shut off ratio was approached, both crack tips did not always recover at the same rate which produced an eccentric crack. When this occurred, testing was terminated before the difference in far field correction factors for the symmetric crack and eccentric crack invalidated quasi-constant K conditions. The resulting data were subsequently reduced to reflect growth of only one crack tip. Where this was done, it was noted on the data tabulation.

The data tabulations are organized by load class as follows:

LOAD CLASS	TABLES
Tension-Tension, $K_2=10$	1-29
Tension-Tension, $K_2=7.78$ and $K_2=14$	30-41
Tension-Zero, $K_2=10$	42-63
Tension-Zero, $K_2=7.78$ and $K_2=14$	64-78
Zero-Tension, $K_2=10$	79-87
Compression-Tension, $K_2=10$	88-102
Compression-Tension, $K_2=7.78$ and $K_2=14$	103-113
Tension-Compression, $K_2=10$	114-151
Tension-Compression, $K_2=7.78$ and $K_2=14$	152-178
Tension-Compression, $K_2=10$ and $K_5=-7.5$	179-195
Tension-Tension, Hold Time	196-220
Tension-Compression, Hold Time	221-237

Within the tabulations for each load class, data are organized with respect to increasing overload ratio, S. All values of K are in $\text{KSI}\sqrt{\text{In.}}$.

Data Summary and Limitations - Where delay rather than shut-off was obtained, the data tabulations were used to determine the number of delay cycles, N_D , and overload affected zone size, a^* . Average data referenced to the midpoints of measurement increments, illustrated in Figure 10, were used in these determinations.

For the data shown in Figure 10, the crack was considered to have reached constant rate at increment 14. This increment corresponds to 56,000 delay cycles and an affected zone size of 0.0144 inch. Data obtained in this manner are contained in Figures 12 through 23 for the various load classes and stress intensity factor parameters evaluated.

Based on fractographic evaluations, stable tear occurred during the overload cycle for cases where K_I exceeded $30 \text{ KSI} \sqrt{\text{In.}}$. Data for those cases contain the stable tear crack extension which should be considered in their use. This data limitation applies only to tension-compression evaluations in Figures 19 and 20.

Test performed to zero-in on overload shut-off ratio. $S = 2.4$
 considered to be shut-off ratio for this case.

Average data not presented since first run produced approximately 160,000 delay cycles, the second run produced in excess of 300,000, and the third run produced shut-off. Consequently, S=2.5 was considered to be very near shut-off for this case.
