| 20. ABSTRACT (Continue on reverse side if necessary and identify by block number)<br>The SAMCEP code (BRL CR 330) is used to perform sensitivity studies to determine the effects of moisture content in the air and ground and different ground compositions upon the predicted tactical nuclear environments produced by a nuclear burst. Neutron and secondary gamma fluences, energy deposition rates and Compton electron currents are given for various combinations of 0% - 6% water vapor content of the atmosphere; Nevada Test Site (NTS), typical German dry and German wet soils; and different weapon sources and burst heights. |                                                                                                       |                                             |

## 1. INTRODUCTION

A series of time-dependent air-over-ground tactical nuclear environment calculations has been performed to assess the effects of moisture content and material composition in the air and ground upon the predicted results. The correlated Monte Carlo code SAMCEP<sup>1</sup> was used to characterize the detailed environments. This code system has been under development for BRL over the past several years by the Mathematical Applications Group, Inc. (MAGI). The basic capabilities of SAMCEP are to predict, in a statistically significant way, the effects of perturbations in the nuclear properties of a transporting medium, upon the neutron and secondary gamma ray fluence and flux. More recently its capabilities have been expanded to include the effects of given perturbations upon neutron energy deposition, gamma-ray ionization and Compton currents for EMP drivers. These quantities or related functionals are needed to derive requirements for lethality<sup>2</sup> and hardening of tactical Army systems.<sup>3</sup>

As a result of the enhanced capabilities of SAMCEP, the Harry Diamond Laboratories<sup>4</sup> requested that sensitivity studies be conducted to determine the effects of moisture content in the air and ground and the effects of the differences in soil composition between the (Nevada Test Site) NTS and West Germany upon the predicted tactical nuclear environments produced by a nuclear burst. At the same time, the HDL employed the MAGI to perform a series of calculations to determine the energy deposition and Compton currents, in standard air and NTS soil, due to neutron and secondary photon interactions from low-altitude nuclear bursts.<sup>5</sup> These calculations were made using the latest version of SAM-CE.<sup>6</sup> In the SAM-CE calculations, three point-isotropic sources of primary neutron radiation were considered:

- a. degraded fission weapon<sup>7</sup> at 50-m and 100-m height of burst (HOB)
- b. 14-MeV source at a 100-m HOB.

The energy deposition rates and Compton electron sources were determined as a function of time in 74 radial and altitude (r,z) bins surrounding the burst points. The atmosphere was taken to be homogeneous at an assumed density of  $1.11 \times 10^{-3} \text{ g/cm}^3$ . Results were obtained for penetrations in air ranging out to 2.4 km which corresponds to a depth of 266  $\text{g/cm}^2$  at this density.

The scope of work within the AH-75 program did not allow us to perform sensitivity-effects studies for all combinations of HOB and sources that were requested. As a result, one source height-of-burst at 100 metres with a degraded fission spectrum was considered for the perturbation investigations of the transport in moist and dry air with the soil composition that of the NTS. Also a 1-metre HOB calculation was performed with the same source spectrum to investigate the sensitivity of radiation transport in an air/ground geometry to the moisture content in West German soil. A by-product of the above calculations allows a comparison of the radiation transport over NTS and West German soils.

The differential details of the quantities calculated include the energy dependence of the neutron fluence as a function of distance from the burst point at all directions in the atmosphere. Energy deposition rates for both neutrons and secondary photons are calculated for times out to 10 msec in local time. Local time is determined in reference to the arrival of an uncollided photon from the source.

## 2. COMPUTATIONAL METHODS

The SAMCEP correlated stochastic code has been installed on the BMDATC (ARC) CDC 7600 computer in Huntsville, AL. The installation of the code was achieved via the CDC update utility routines which also facilitate implementation of any subsequent new developments in the code.

SAMCEP is a Monte Carlo neutron and secondary gamma-ray transport code which is designed to calculate differences in fluences and flux functionals, such as dose, as a function of perturbations in the basic nuclear and materials input data. The code is an extension of the SAM-CE Monte Carlo procedure. The mathematical basis for this extension is that several Monte Carlo problems are run simultaneously and, through the use of correlated sampling, differences among the results of these problems are determined. The statistics of the differences

<sup>7</sup>L. Huser and W. Woolson, "Version 3 of Air Transport of Radiation," DNA 3819F, p. 27, July 1975.

are on the order of the statistics of the problems themselves and they are achieved with very little time in excess of the execution time for a single problem solution.

Recently, the SAMCEP code has had a major increase in its capabilities:

- 0 Secondary gamma-ray capability
  - o Klein-Nishina scattering algorithms
  - o Algorithms for computing and storing nonelastic interactions
  - o Banding of gamma-ray cross sections
  - o Perturbation of gamma-ray production data
    - o yield
    - o angular distributions
    - o energy
- 0 Neutron slowing-down in air
  - o Generation of a good representation of the secondary gamma-ray source distribution from neutron capture
- 0 Extension of the Bounded Flux-at-a-point estimation (BFAP)
  - o Efficient BFAP at interface between dissimilar media
- 0 A priori angle biasing
  - o A posteriori angle biasing algorithm has been changed to a more effective a priori biasing technique

### 3. DESCRIPTION OF THE CALCULATIONS

Several series of Monte Carlo calculations have been performed with the improved version of SAMCEP to determine the neutron and secondary gamma-ray fluences, energy deposition rates due to the neutron and secondary gamma-ray interactions, and Compton electron currents for EMP drivers. The neutron and gamma-ray fluences are generated as a function of position and energy integrated over all times. Energy deposition and EMP drivers are predicted as a function of space, energy and time. Sensitivity investigations have been studied to determine the differences in the above environments as a function of the perturbations made in the moisture contents in the air and ground and in the soil composition of NTS and West Germany.

### 3.1 Sources Considered

The sources of neutrons which are considered in this study are the "S-device" fission spectrum at 14 shakes<sup>8</sup> (see Figure 1), a degraded fission spectrum and a 14-MeV (22.4 pJ) neutron source. The energy groups specified for the S-device were made compatible with those acceptable to the SAMCEP code. Only the results of the calculations for the degraded fission source will be reported in this document. An extensive effort on the 14-MeV source has been reported by ORNL<sup>9</sup> and MAGI.<sup>5</sup> The S-device fission spectrum at 14 shakes is very similar to a Pu fission spectrum. The average energy of the S-device is a little higher than the average energy of the Pu spectrum.

### 3.2 Air/Ground Geometry

The atmosphere was divided into a cylindrical grid structure for the purpose of tallying the quantities of interest as a function of position. Figure 2 shows the grid structure in the (r,z) plane. Ground level is the abscissa. Distances are indicated in the vertical and horizontal direction in mean-free-paths (mfp) referenced to 14-MeV neutrons. Also mfp in gm/cm<sup>2</sup> are indicated. In order to investigate, in more detail, the behavior of the interesting quantities at the air/ground interface, regions 2, 4 and 10 are further subdivided by a finer mesh. Table 1 shows the finer mesh structure. The mfp for a 14-MeV neutron is approximately 150 metres in normal density air.

### 3.3 Unperturbed Base Cross Sections and Response Functions

The following data given in Table 2 is the neutron and secondary gamma-ray basic cross section information for the transport processes. The ENDF/B files listed are the latest DNA cross sections as distributed by the Radiation Shielding Information Center, ORNL, Oak Ridge, TN, or by the National Neutron Cross Section Center at Brookhaven. The average range data for the Compton electrons were taken from the work in Reference 5.

The environmental conditions assumed for the unperturbed or base problem are dry atmosphere at 0.328 km (1000 ft.) altitude (NTS altitude) with a density of  $1.11 \times 10^{-3}$  gm/cm<sup>3</sup>. The composition of the referenced atmosphere is listed in Table 3. Argon is included only for the transport of photons and the concentrations are changed accordingly.

### 3.4 Perturbations in the Environmental Conditions

This sensitivity investigation examines the effects of environmental conditions upon the predicted radiation transport from a nuclear burst. Two perturbations are considered interesting from a tactical Army engagement standpoint. The first perturbation which is considered is the variation of the moisture content in the atmosphere above a ground composition similar to that of the NTS. The second case describes the effects of the moisture content in a soil composition similar to that of the Federal Republic of Germany. For the second study a dry atmosphere above the ground will be assumed. Compositions for the perturbed environments are listed in Table 5. In all the calculations stated above the basic nuclear cross section data are not changed. Only the sensitivity of the nuclear environments to the quantity and type of material constituents in an air-over-ground geometry is calculated.

### 3.5 Output Quantities Calculated

The primary neutron and secondary gamma-ray fluences are obtained in three spatial locations along the ground and at a 45° angle with the ground in the energy bin structure shown in Table 6. Total fluences were produced from an integration over the total time interval from 0 to 10 msec (local time).

TABLE 6. Energy Bin Structure for SAMCEP Sensitivity Calculations

are calculated and reported in Reference 5. The four components of the secondary gamma sources are as follows:

1. Photons generated by the interaction of "high energy" neutrons ( $E > 0.11$  MeV) in the air

2. Photons generated by the interaction of high energy neutrons in the ground

3. Photons generated by the interaction of "low energy" neutrons ( $E < 0.11$  MeV) in the air

4. Photons generated by the interaction of low energy neutrons in the ground.

The units of the fluences are neutrons or photons per eV per  $\text{cm}^2$  per source neutron. The units of energy deposition rates are

$$(\text{eV}/\text{cm}^3 \cdot \text{sec} \cdot \text{source neutron})$$

and the units of both radial and polar currents are

$$(\text{electrons}/\text{cm}^2 \cdot \text{sec} \cdot \text{source neutron}).$$

#### 4. PRESENTATION AND DISCUSSION OF RESULTS

##### 4.1 General

The problems which are addressed involve difficult Monte Carlo importance sampling strategies and much help was gleaned from the previous work of Reference 5. Answers are needed with low statistical uncertainties, over the entire domain out to 2.4 km and for a long temporal range. Some of the techniques used to ensure adequate solutions include the following:

a. A special tracking procedure for neutrons below the inelastic threshold and a special thermal diffusion model.

b. Energy importance sampling to generate a sufficient number of high energy neutrons for the (degraded fission) source.

c. Energy importance sampling to discriminate against those low energy inelastic neutron collisions which would be unlikely to generate secondary gamma radiation.

d. Spatial importance sampling to generate a sufficient number of neutron high energy interactions at shallow penetrations (since the gamma rays which they generate dominate the temporal ranges).

e. Spatial importance sampling to obtain adequate solutions at the deep penetrations.

f. Spatial importance sampling to "push" a sufficient number of neutron events towards the ground and towards the special subdivided volumes shown in Table 1.

g. Directional importance sampling to discriminate against ground-generated gamma radiation initially headed deeper into the ground.

#### 4.2 100-Metre Height-of-Burst (HOB) Study

##### 4.2.1 100-Metre HOB Study for the Perturbation in the Atmosphere Over the NTS

The SAMCEP code is used to calculate the sensitivity of the transport of neutron and secondary gamma-rays through an atmosphere which is perturbed by moisture. The particular case discussed in this section is for the degraded fission source at a 100-metre HOB above the NTS. In order to bracket the sensitivity of the transport of the neutrons and secondary gamma to this perturbation, the moisture content of the air is varied from 0% (dry) to 6% by volume. Some typical results will be presented in the succeeding paragraphs to illustrate the trends of the data.

Table 8 displays the total neutron fluence as a function of distance from the source in spatial regions located on a 45° angle with respect to the ground. The normal falloff in fluence is seen as a function of distance from the source. However, the fluence falls off more rapidly for the atmosphere with the higher water content, as expected, because the hydrogen which is present thermalizes the neutrons more quickly, thereby reducing the fluence.

TABLE 8. Total Neutron Fluence Vs. Distance for 45° Angle of Elevation Over NTS

| <u>Region</u> | <u>Neutron Fluence (Neut./cm<sup>2</sup>•Source Neut)</u> |                    |                    |

| 1             | 2.356E-09                                                 | 2.259E-09          | 2.087E-09          |
| 6             | 3.012E-10                                                 | 2.570E-10          | 2.010E-10          |
| 17            | 5.571E-11                                                 | 4.480E-11          | 2.850E-11          |
| 22            | 1.209E-11                                                 | 8.670E-11          | 4.870E-12          |
| 31            | 1.649E-12                                                 | 1.061E-12          | 5.239E-13          |
| 40            | 1.175E-13                                                 | 6.495E-14          | 2.872E-14          |
| 48            | 1.061E-14                                                 | 5.343E-15          | 2.281E-15          |

Tables 9-15 show the dependence of the neutron fluence spectrum upon energy and distance from the source for the energy structure chosen in Table 6. Again the effects of moisture content in the atmosphere are apparent. Since region 48 is at approximately 14 mfp from the source for a 14-MeV neutron, the number of mfp at this point for neutrons whose average energy is around 1.0 MeV is much higher. Therefore, the statistics for the quantities listed in Table 15 are quite large for this depth of penetration.

In general, differences in the effects of water content in the atmosphere upon the the transport of the energy dependent neutrons vary by a factor of 2 or more at the lower energies and on the order of 25 percent at the higher energies.

Tables 16-22 show the same type of data along the air/ground interface. These regions are represented by numbers 1, 2 (subdiv. 65), 3, 4 (subdiv. 68), 9, 10 (subdiv. 71), 11 and 12.

The spectral neutron fluence has been folded with several dose response functions, which are tabulated in Table 23, in order to give an indication of how the dose varies with distance from the source. The units of the dose response are given in terms of a unit source strength of neutrons. Table 24 shows the Rad-Si dose as a function of ground range for detectors immediately above the ground (scoring region 0-25m altitude). Table 25 gives the Auxier-Snyder tissue dose response for the same positions along the ground. Tables 26 and 27 exhibit the Rad-Si and tissue dose distributions for the regions which are located at a 45° angle of elevation out to distances of approximately 2 km. A comparison between the results shown in Table 27 and some recent infinite air calculations<sup>10</sup> performed by Science Applications, Inc., shows excellent agreement with the tissue dose in regions 17 and 40.

A discussion is now presented on the results of the neutron energy deposition in each of the scoring regions cited above for the 100-metre HOB case. The neutron energy deposition is needed to infer the total ionization and ionization rate produced by the neutrons directly as opposed to the ionization produced by subsequent gamma rays. Only the energy deposition and deposition rates will be presented in this report since the trends produced by the perturbations in the Compton currents are quite similar and published elsewhere<sup>5</sup>.

Table 28 displays the time-integrated neutron energy deposition in the spatial regions located at a 45° angle of elevation for the 100-metre HOB source. The perturbation of the atmosphere considered for the energy deposition calculation is a 6% variation in the water content by volume. The change is equivalent to approximately 3.8% variation in the water content by weight. The appropriate numbers used

| 40     | 6.74 - 13                                            | 5.89 - 13 (6)       | 3.54 - 13                |
| 48     | 4.58 - 14                                            | 6.03 - 14 (20)      | 3.14 - 14                |

\* Relative error is indicated in the parentheses. The moist air results have relative error comparable to the dry air results.

The trend in the data of Table 28 indicates that the hydrogen content in the atmosphere induces a larger energy deposition than the dry air for the portion of the transport which is close to the source. The energy deposited is approximately the same around region 17 (450m) for both dry and moist air with the energy deposition subsequently lower for moist air as the range increases. The results from SAM-CE show excellent agreement.

Table 29 gives the neutron energy deposition for the regions immediately above the ground and the trends are quite similar to those of the previous data. Table 30 shows the energy deposition rates in Region 1 as a function of the local time bins given in Table 7. The SAMCEP moist air results show that at very early times many high energy neutrons have collided with hydrogen and they are rapidly depositing energy in the region close to the source. At later times, the deposition rate slows because the neutrons have lost most of their energy. Table 31 exhibits the time dependence of the deposition for Region 31, farther out from the source and along the 45° angle-of-elevation line.

TABLE 29. Neutron Energy Deposition as a Function of Distance Along the Ground From the Source.

| Region        | Energy Deposition ( $\text{eV}/\text{cm}^3 \cdot \text{Source Neut.}$ ) |                     |                          |

Besides the neutrons, the photons are a major contributor to the ionization phenomenon and the energy deposition. As a result of a special interest to the EMP community, the direction of the project was changed to investigate the sensitivity of the above two phenomena to the perturbations cited earlier. It was also interesting to tally, separately, the contributions to the photon energy deposition which came from low and high energy neutron interactions in the air and ground respectively. These four components were computed for all the regions shown in Figure 2; however, only samples of the voluminous amount of data are presented. Table 32 displays the contribution in regions along the  $45^\circ$  elevation line which is derived from the low energy neutrons ( $<0.111$  MeV) in the ground. Again SAMCEP is in good agreement with the SAM-CE results. The moisture content in the air produces, in all regions, results which are approximately 30% lower than the dry air results. Table 33 shows the low-energy-air component's contribution to the total energy deposition in the regions along the  $45^\circ$  elevation. An analysis of the data in the two tables immediately above shows that, for the moist air, fewer neutrons reach the ground; however, for those that do, the conversion to photons via absorption is quite high (ground constituents vs. air composition). Also the presence of hydrogen in the atmosphere causes the neutrons to slow down early in the transport cycle. This effect is reflected in Table 33 since the regions close to the source show a larger contribution for wet than for dry air and this trend reverses as one moves away from the source.

Note that the number of neutrons prevented from reaching the ground by the moist air represents only a small fraction of the total neutron population. Therefore, the low-energy-air component is affected very little by the presence of the water. This result is demonstrated in the data of Table 33.

Table 34 is the high-energy-ground component of the total energy deposition for the 45° elevation. Since the high-energy-ground component involves neutrons which have not suffered many collisions, the results for both the dry and moist air should be about the same.

TABLE 34. Contribution of High Energy Neutrons in the Ground to the Photon Energy Deposition Along the 45° Line

| Region | Energy Deposition (eV/cm <sup>3</sup> ·Source Neut.) |                     |                          |
|--------|------------------------------------------------------|---------------------|--------------------------|

| 48     | 0.22 - 14                                            | 0.22 - 14 (16)      | 0.17 - 14                |

The remaining component for the energy deposition is the energy deposited by photons which are born from high energy neutrons interacting with the air. These photons are generated primarily by the neutron inelastic scattering events with nitrogen and oxygen. Since the inelastic thresholds for these elements are well above the average neutron energy of the degraded source spectrum, one would not expect this component to be very sensitive to the water content in the atmosphere. The results shown in Table 35 affirm this conclusion in that the transport through wet and dry air is essentially the same except at extremely deep penetrations.

TABLE 35. Contribution of the High Energy Neutrons in the Atmosphere to the Photon Energy Deposition Along the 45° Line

As seen in Table 35, the results from SAM-CE differ from those of SAMCEP for dry air. This difference can be explained by the way in which SAM-CE and SAMCEP represent the degraded fission source spectrum. Although SAM-CE and SAMCEP have the same input source spectrum, they treat the numerical representation of it slightly differently. The former assumes a decaying exponential between the increasing energy values, whereas the latter assumes a piecewise constant value across an energy bin. It turns out that the high energy component in the air is sensitive to the difference in representation because the inelastic scattering thresholds are above the average energy of the source and the cross sections rise very rapidly with increasing energy. Because of the two different representations, the average energy of the spectrum in SAMCEP exceeds the average energy of the spectrum as represented by SAM-CE by approximately 10%. This difference could account for some of the disagreement between the SAM-CE and SAMCEP results.

#### 4.2.2. Neutron Transport Over Dry NTS and West German Soils.

A brief investigation has been completed to assess the differences in the neutron transport in an air-over-ground environment for which different constituents of the ground are considered. In the discussion to follow, neutron fluences will be presented as a function of soil type and moisture content of the soil for the degraded fission source at a 100-metre HOB. Results for a dry NTS soil and a wet and dry West German terrain will be compared. The dry air composition is given in Table 3; NTS and West German dry soils are given in Table 4; and West German wet soil is stated in Table 5. The neutron fluence and dose are given in a manner similar to that of Section 4.2.1.

Tables 36 and 37 show the results for Regions 1 and 6 for the 45° angle of elevation. As can be seen in the data, the results are essentially the same for these two regions and deviate even less as the distance along the 45° line increases. This trend is as expected since one would not expect the perturbations in the ground to affect the transport high into the atmosphere. The same is not true along the ground as Tables 38-44 substantiate. The general trend of the data shows that at the higher energy levels, differences in the fluence at all ranges are not significant, whereas in the lower energy bin, at intermediate ranges, variations of approximately 25% occur. The following tables tabulate the Rad-Si and Auxier-Snyder tissue dose responses. In general the differences among NTS dry, German dry and German wet soils are 25% or less.

The total neutron energy deposition ( $\text{eV/cm}^3 \cdot \text{source neutron}$ ) for the 100-metre HOB case has also been calculated and the results are reported in Tables 46 and 47. The perturbations again consider the transport over NTS, German dry and German wet soil. The atmosphere has no moisture content for this case. Results are presented for the air regions directly over the ground and those regions at a 45° angle of elevation. If one compares Table 46 with Table 29, it is immediately evident that the moisture content in the air causes a larger energy deposition for the regions along the ground that are close to the source. For a ground range of approximately 750 metres, the energy depositions become approximately equal and, at the longer ranges, the moisture content in the soil gives about a factor of 2 larger deposition. As expected, the data in Table 47 shows that the composition of the ground has little effect on the transport and deposition of neutrons for short distances away from the air/ground interface and at higher altitudes.

The results for the subsequent secondary photon energy deposition show that, for regions in the air, the moisture content in the ground enhances the deposition by about 30 to 50 percent for ranges out to 10 mfp. These results are shown in Tables 48 and 49.

#### 4.3 One-Metre Height-of-Burst Study

SAMCEP calculations, similar to those described above, have been made for a one-metre HOB source over typical German soil. Simultaneous perturbation computations are treated in which the base, or unperturbed, calculation is dry air and German dry soil. Comparison calculations are made for dry NTS and German wet soils. The compositions of interest are those listed in Tables 3, 4 and 5.

Tables 50 and 51 show the neutron energy deposition in regions along the air/ground interface and along the 45° elevation angle, respectively.

| 12              | 8.15 - 14                                                         | 8.47 - 14 (20)    | 7.50 - 14         |
| 13              | 1.45 - 14                                                         | 1.72 - 14 (36)    | 1.27 - 14         |

From Table 50 we see that the results are essentially unchanged by soil composition although there is an indication that the energy deposition for German dry soil (least hydrogen in the ground) is slightly higher than for the other two cases and that the energy deposition for the German wet soil case (most hydrogen in the soil) is slightly lower than for the other two cases. Table 51 (along the interface) shows the trend even more clearly. These differences were actually shown by the SAMCEP printout (with uncertainties in the differences) to be statistically real. Nevertheless, the hydrogen content of the soil clearly does not significantly affect the neutron energy deposition in air.

## 5. CONCLUSION

A number of coding developments have been performed to effect a major upgrading of the SAMCEP system for the quantitative evaluation of cross section uncertainties on radiation transport. The principal development of this modernization of the system has been the implementation of a secondary-gamma capability. Thus, sensitivity studies, heretofore limited to evaluating effects of neutron cross section uncertainties on neutron transport, can now be extended to include subsequent effects upon gamma transport of uncertainties in neutron as well as gamma production data.

Using the neutron-gamma SAMCEP system, a series of problems have been solved. An important conclusion to be drawn from the results of these calculations is that the SAMCEP system is yielding correct results, as indicated by comparison and agreement with independently obtained solutions, using the SAM-CE system. Moreover, comparable statistics were obtained 3 to 4 times more efficiently using SAMCEP than would have been possible by performing independent and uncorrelated analyses.
