Renewal model of reliability for series systems - revisited

Abstract. This report consists of two parts; the first (pp 1-15) is a reproduction of pp 457 - 471 of the Proceedings of the 23rd Conference on the design of experiments in army research development and testing; the second is a recalculation of tables and curves of the asymptotic reliability of a series system with a number of gamma components, n=64, 256, ∞ .

20. ABSTRACT (Continued)

distribution. These reasons are investigated, especially the latter one. In many cases, equipment do not last long enough to reach the steady state alluded to in (2). For the special case where the failure law of (n=64,256,∞) identical components is given by the gamma distribution (α = 2 (2) 12) the distribution of the time to next system failure has been recalculated and tabled over a range in which the system failure law differs markedly from exponential.

The exponential is wrong
But works like a song.
Beware the Weibull:
It's incorrigiible.—Anon.

All models are wrong.
Some work.—G. E. P. Box

ABSTRACT. The fact that failures follow the exponential distribution is almost universally accepted in reliability analysis. Two reasons are given for this assumption: (1) It is commonly assumed that electronic components do not wear out but are subject to random „shocks" which may cause failure. If these shocks form a Poisson process the underlying failure distribution *is* exponential. (2) Sufficiently complex equipment run for a sufficiently *long* time (failed components being replaced by good ones) will follow the exponential distribution. These reasons are investigated, especially the latter one. In many cases, equipment do not last *long enough* to reach the steady state alluded to in (2).

1. INTRODUCTION. The exponential distribution is used, almost exclusively, for the time between failures in reliability analysis. Even when it cannot be assumed that the failure distribution of a component is exponential, the exponential distribution is used for the time between failures of systems. The rationale for this is the belief that there is a theorem which states that for *large* systems the time between failures *is* exponentially distributed. Use of the exponential distribution simplifies the analysis considerably: it is well known that systems, whose failure law follows the exponential distribution, do not age; the exponential failure law is the only continuous distribution with this property. Since the analysis using any other failure law complicates the solution considerably, engineers are loth to give up use of the exponential. If retaining the exponential leads to incorrect conclusions, one might say that the reliability engineer is „being seduced by an easy solution" or is „cursed by the exponential distribution". The purpose of this paper is to state, somewhat colloquially but a little more precisely, the theorem

*Preparation of this paper was partially supported by the Office of Naval Research under Contract No. N00014-77-C-0601/NR042-377.

underlying the correct use of the exponential failure law for systems whose components fail according to another law, and to show the dangers when this theorem is not used correctly.

This paper is concerned with the *superimposed renewal process*, illustrated in Figure 1 for the case of $n = 5$ components connected in series. When any component fails, the system fails. We assume that a failed component is instantly replaced by a new one. The ×'s indicate times of failure for each component and the bottom line indicates the failures of the renewal process or system. One version of the exponential limit theorem [4] states that if one has a renewal process consisting of n components, with identical non-exponential failure laws, connected in series; then, for n greater than some n^* and t greater than some t^*, the times between failures of the system are indeed exponentially distributed. Intuitively the theorem states that for a sufficiently complex system, after some time t^* the components have been replaced at „random" times, and there is a random mix of ages of components. Thus the succeeding times of failure will occur at random—one of the postulates of a Poisson process, which implies that times between failures follow the exponential law.

We have investigated how large n^* and t^* must be for the limit theorem to yield a good approximation when the underlying component failure law is lognormal, gamma, or Weibull. For all those laws it appears that the dependence on n is not so crucial as the dependence on t; it is believed, however, that reliability engineers frequently ignore the dependence on t.

Actually the exponential limit theorem is more general than given above. Under certain conditions, the components need not all have the same failure distribution: in this case t^* would have to be larger yet, and the results given here would be even stronger.

2. *RENEWAL DENSITY AND SYSTEM HAZARD.* Although the mathematical details, which appear elsewhere [1, 2, 3], will not be repeated here, we will give some definitions, outline the techniques used, and present some cases to illustrate the results. Calculations are based on

$$h(t) = \text{renewal density of a component}$$

$$= f(t) + f(t)*f(t) + [f(t)]^{*3} + \ldots + [f(t)]^{*n} + \ldots,$$

where $[f(t)]^{*n}$ denotes the n-fold convolution of $f(t)$, i.e. the density of the distribution of the time to the nth failure of the component, measured from the initial time; and $f(t)$ is the failure density of a component. Thus $h(t)$ is the density of *all* failures for a specific component and $h(t)dt$ is the probability that, in the interval $(t, t+dt)$, the component either fails for the first time or fails for the second time if it was replaced prior to t or fails for the third time if it failed twice and was replaced prior to t, etc. It can be shown that $h(t) \to 1/\mu$ as $t \to \infty$, where μ is the mean time to failure of a component. Note that the renewal function

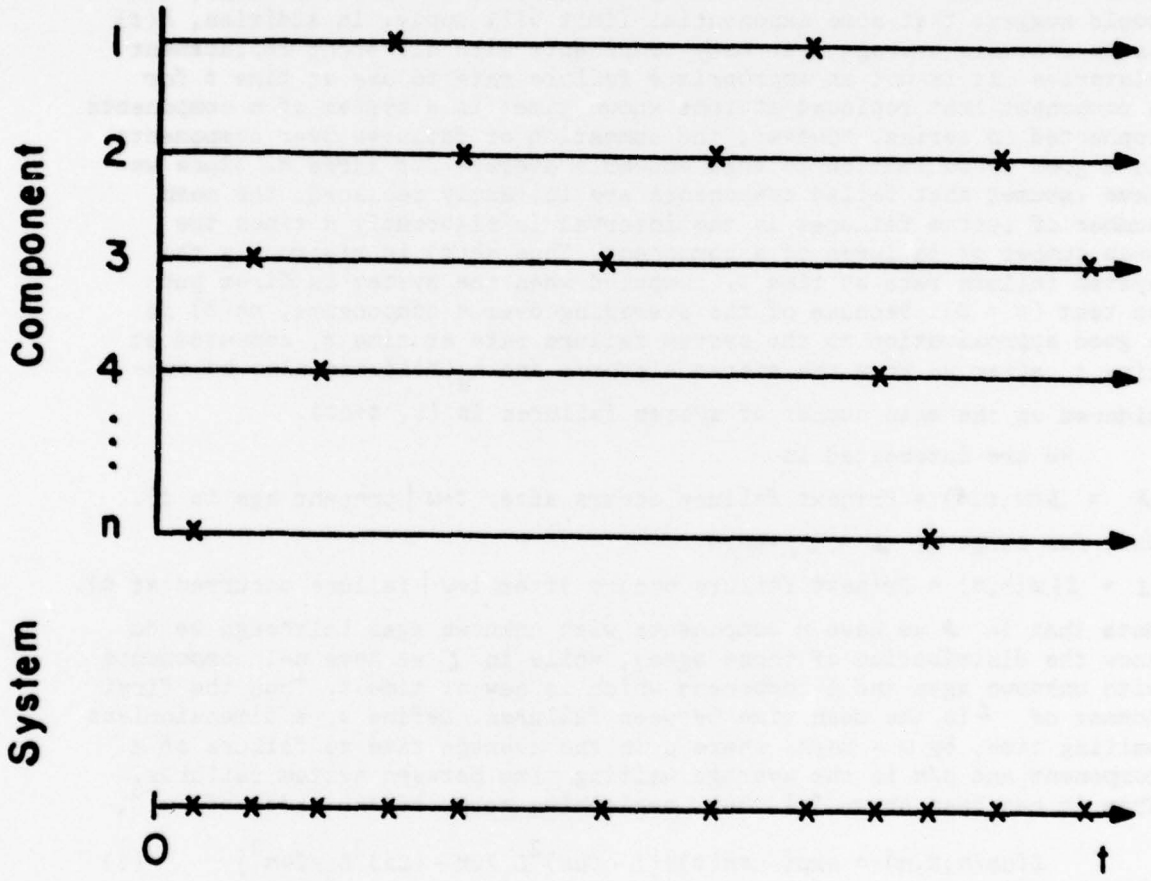

FIGURE 1. Failure times in a superimposed renewal process

$$H(t) = \int_0^t h(\tau)d\tau = \text{Expected number of failures up to time } t,$$

and that $H(t) \sim t/\mu$ - constant, where the constant reflects the fact that, for small t, $h(t)$ is typically less than $1/\mu$.

Let $h_s(t)$ be the system hazard so that $h_s(t)\Delta t$ is the probability that the system fails in the interval $(t, t+\Delta t)$, given that it was operating at time t. For $\Delta t << t$ the probability of more than one failure in the interval is negligible and $h(t)$ will be reasonably constant in the interval. These of course are the postulates of a Poisson process, and would suggest that some exponential limit will apply. In addition, $h(t)$ is an ensemble average over many components with different replacement histories. It is not an appropriate failure rate to use at time t for a component last replaced at some known time; in a system of n components connected in series, however, the summation of failures over components is a good approximation to this ensemble average for large n. Since we have assumed that failed components are instantly replaced, the mean number of system failures in the interval is rigorously n times the mean number of failures of a component. Thus $nh(t)$ is rigorously the system failure rate at time t, computed when the system is first put on test ($t = 0$). Because of the averaging over n components, $nh(t)$ is a good approximation to the system failure rate at time t, computed at time t, after we know the system history; and $h_s(t)\Delta t$ can also be considered as the mean number of system failures in $(t, t+\Delta t)$.

We are interested in

$$\mathcal{P} = \mathcal{P}(\omega;t,n) = \Pr\{\text{next failure occurs after } t+\omega \mid \text{present age is } t\}.$$

But, for large n, $\mathcal{P} \sim \mathcal{L}$, where

$$\mathcal{L} = \mathcal{L}(\omega;t,n) = \Pr\{\text{next failure occurs after } t+\omega \mid \text{failure occurred at } t\}.$$

Note that in $\mathcal{P}$ we have n components with unknown ages (although we do know the distribution of those ages), while in $\mathcal{L}$ we have $n-1$ components with unknown ages and 1 component which is new at time t. Thus the first moment of $\mathcal{L}$ is the mean time between failures. Define s, a dimensionless waiting time, by $\omega = \mu s/n$, where μ is the average time to failure of a component and μ/n is the average waiting time between system failures. Then it has been shown [3] that, neglecting terms of the order of n^{-3},

$$\mathcal{L}(\mu s/n;t,n) = \exp\{-\mu s h(t)\}\{1 - (\mu s)^2 L_1/2n - (\mu s)^3 L_2/24n^2\}, \qquad (1)$$

where

$$L_1 = L_1\{\mu s,\ h(t),\ h'(t)\} \text{ and } L_2 = L_2\{\mu s,\ h(t),\ h'(t),\ h''(t)\};$$

i.e. the „correction" terms depend on μs and the renewal density and its derivatives. This dependence is reasonable. For large ω (earlier in this section, when relating the system hazard to the Poisson process, ω was denoted Δt) the system hazard $h_s(t+\theta\omega)$, $0 < \theta < 1$, is not a constant; so that $h_s(t) \neq h_s(t+\omega)$. The mean number of failures in time ω is given by

$$\int_0^1 h_s(t+\theta\omega)\,\omega\,d\theta\ .$$

Using a Taylor expansion around t for the integrand will involve the derivatives of h.

Now, for n infinite, (1) becomes

$$\lim_{n\to\infty} \mathfrak{L}(\mu s/n;t,n) = \exp\{-\mu s h(t)\}, \tag{2}$$

and the waiting time is characterized by a non-homogeneous Poisson process. If, furthermore, $n \to \infty$, then $h(t) \to 1/\mu$ and we have

$$\lim_{t\to\infty}\lim_{n\to\infty} \mathfrak{L}(\mu s/n;t,n) = e^{-s}, \tag{3}$$

the limit theorem referred to in Section 1.

We shall present results based on (1) and (2) when the underlying failure distribution is gamma or Weibull. For the gamma we have

$$f(x) = x^{\alpha-1}\exp(-x/\theta)/\{\theta^{\alpha}\Gamma(\alpha)\},\ x > 0,\ \theta > 0,\ \alpha > 0; \tag{4}$$

$$\mu = \theta\alpha; \tag{5}$$

for the Weibull,

$$f(x) = px^{-1}(x/\theta)^{p}\exp\{-(x/\theta)^{p}\},\ x > 0,\ \theta > 0,\ p > 0; \tag{6}$$

$$\mu = \theta\Gamma(1+p^{-1}). \tag{7}$$

3. EXAMPLES. $\mathfrak{L}(\omega;t,n)$ is plotted as a function of t in Figures 2-9 for gamma and Weibull components. The smooth curve represents $n = \infty$, + represents $n = 64$ and × represents $n = 256$. Figures 2, 4, 5 appeared in [1]; Figures 3, 6, 7, in [3]; Figures 8, 9 were used in the oral presentation of [5] but did not appear in the Proceedings and have not been published previously.

In interpreting the gamma plots, Figures 2-7, several successive transformations from real time to coded time must be made. Start with T, the age of the system, and W, the waiting time, both in clock hours; so that we are concerned with failures in the interval $(T,T+W)$. Then transform: *(a)* Eliminate θ by computing $t = T/\theta$ and $\omega = W/\theta$. *(b)* The non-dimensional waiting time

$$s = nW/\mu = nW/(\theta\alpha) = n\omega/\alpha.$$

(c) The curves are indexed by e^{-s}, the double limit for n and T infinite, which is given equally spaced values from .05 to .95; thus

$$W = -\mu n^{-1}\log e^{-s}.$$

(d) Instead of t,

$$t/\alpha = T/\mu$$

was used in order to relate the plots to systems composed of elements having unit mean life regardless of α. To have used t would involve

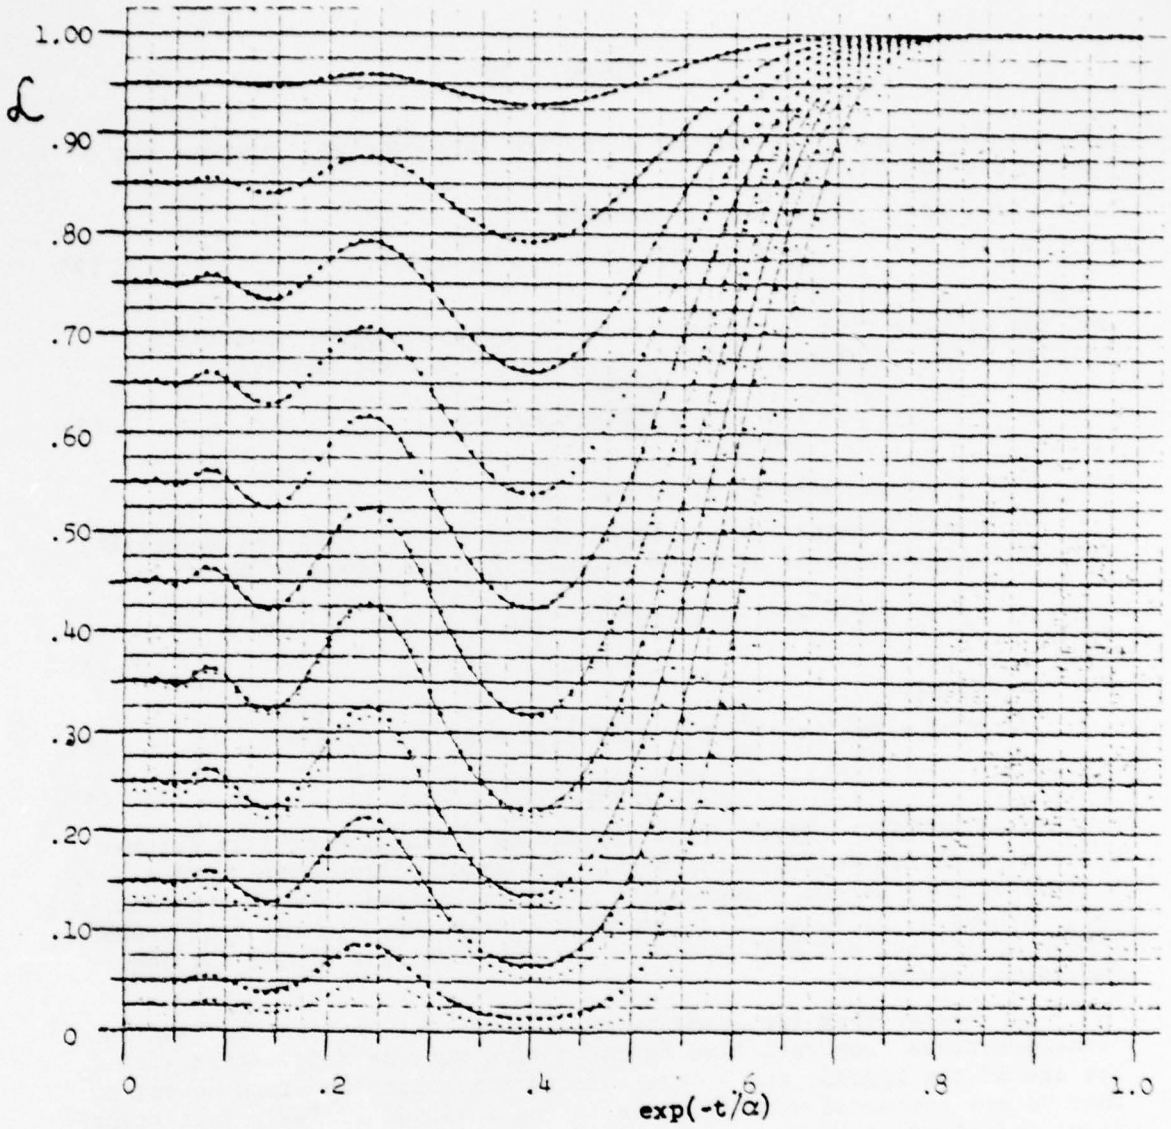

FIGURE 2. $\mathfrak{L}(\alpha s/n;\ t,\ n)$ for n gamma components: $\alpha = 12$

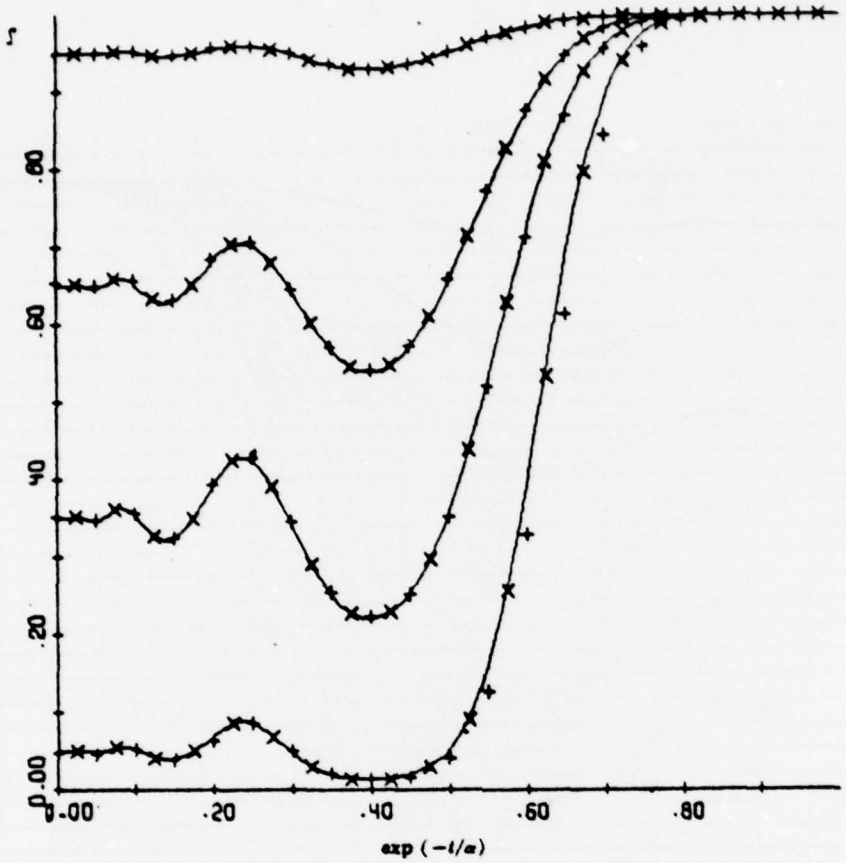

FIGURE 3. $f(\alpha s/n;\ t,\ n)$ for n gamma components: $\alpha = 12$

making plots for systems whose elements had different mean lives for different values of α and would make comparison of the results for different α more difficult, since both shape and mean life would be changing. *(e)* Finally, $\exp(-t/\alpha)$, rather than t/α, was taken as the argument, to „compress" the abscissa in the curves. This final normalization means that the gamma plots must be read from right to left: $t = 0$ and ∞ correspond to abscissas of 1 and 0 respectively. (The Weibull plots, Figures 8 and 9, read from left to right.)

The asymptotic probability e^{-s} ranges from 0.05 to 0.95 by steps of 0.10 in Figures 2, 4, 5 and by steps of 0.30 in Figures 3, 6, 7, 8, 9. Thus the top curve in Figure 2 corresponds to $s = \log(.95) \approx .05$; $\alpha = 12$, $w = \alpha s/n \approx .6/n$. Because w depends on both α and s, each curve on any figure represents a different w; the same w, moreover, corresponds to different W as θ is varied.

To illustrate these somewhat confusing transformations that take W into s, consider a system with $n = 300$ components, $\alpha = 2$, and $\theta = 5000$ hours, so that $\mu = 10{,}000$ hours; and let the contemplated waiting time

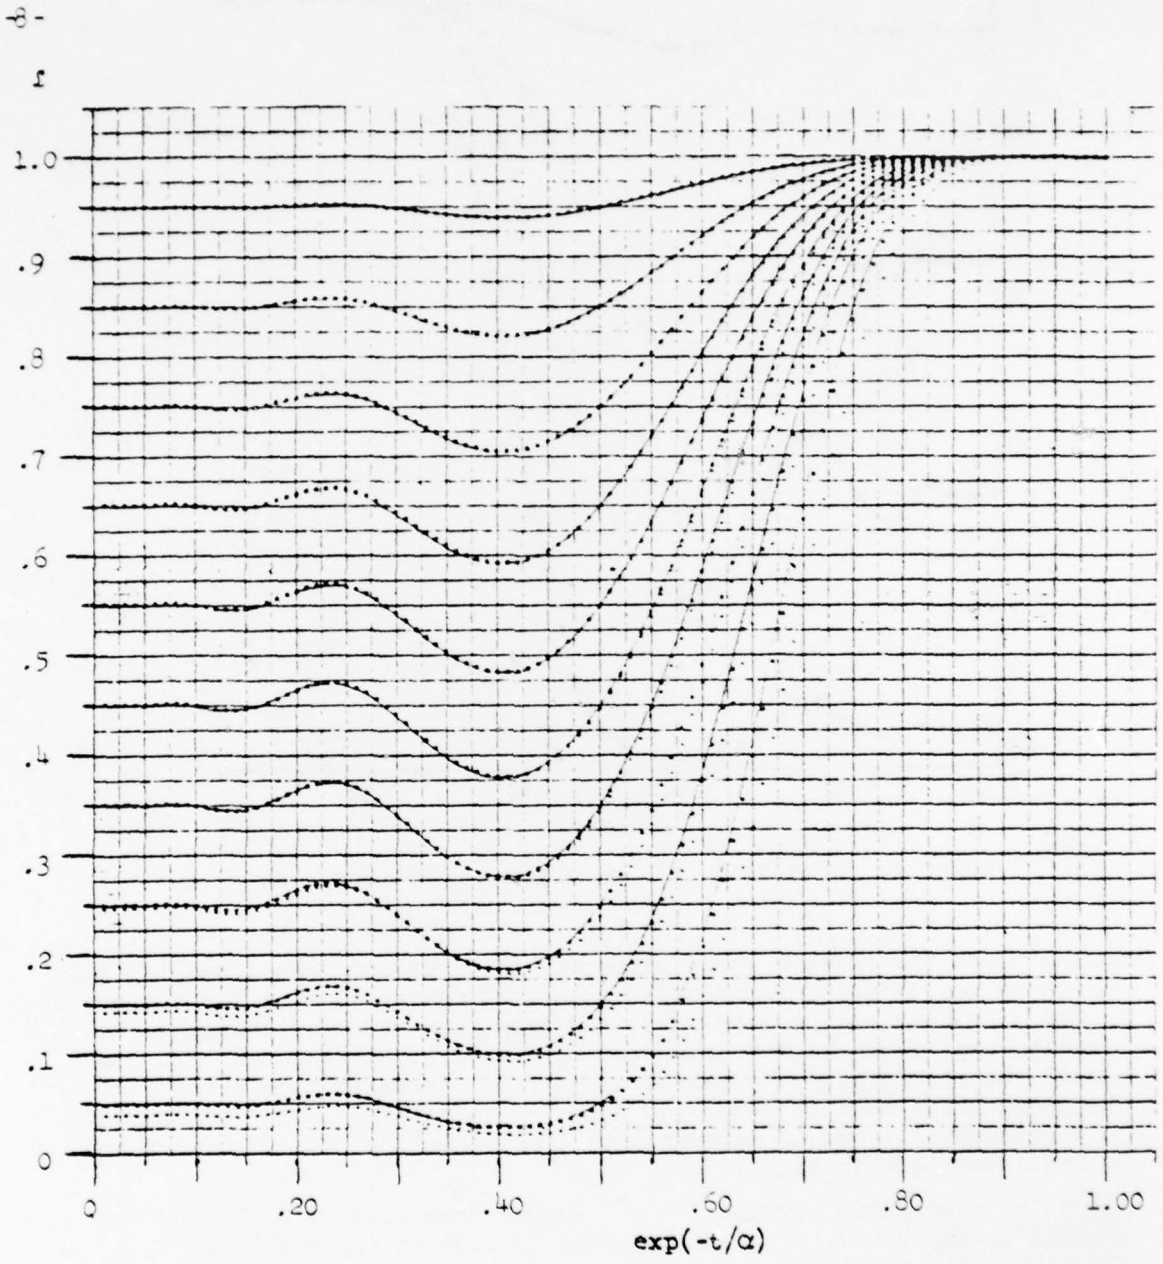

FIGURE 4. $\mathfrak{L}(\alpha s/n;\ t,\ n)$ for n gamma components: $\alpha = 8$

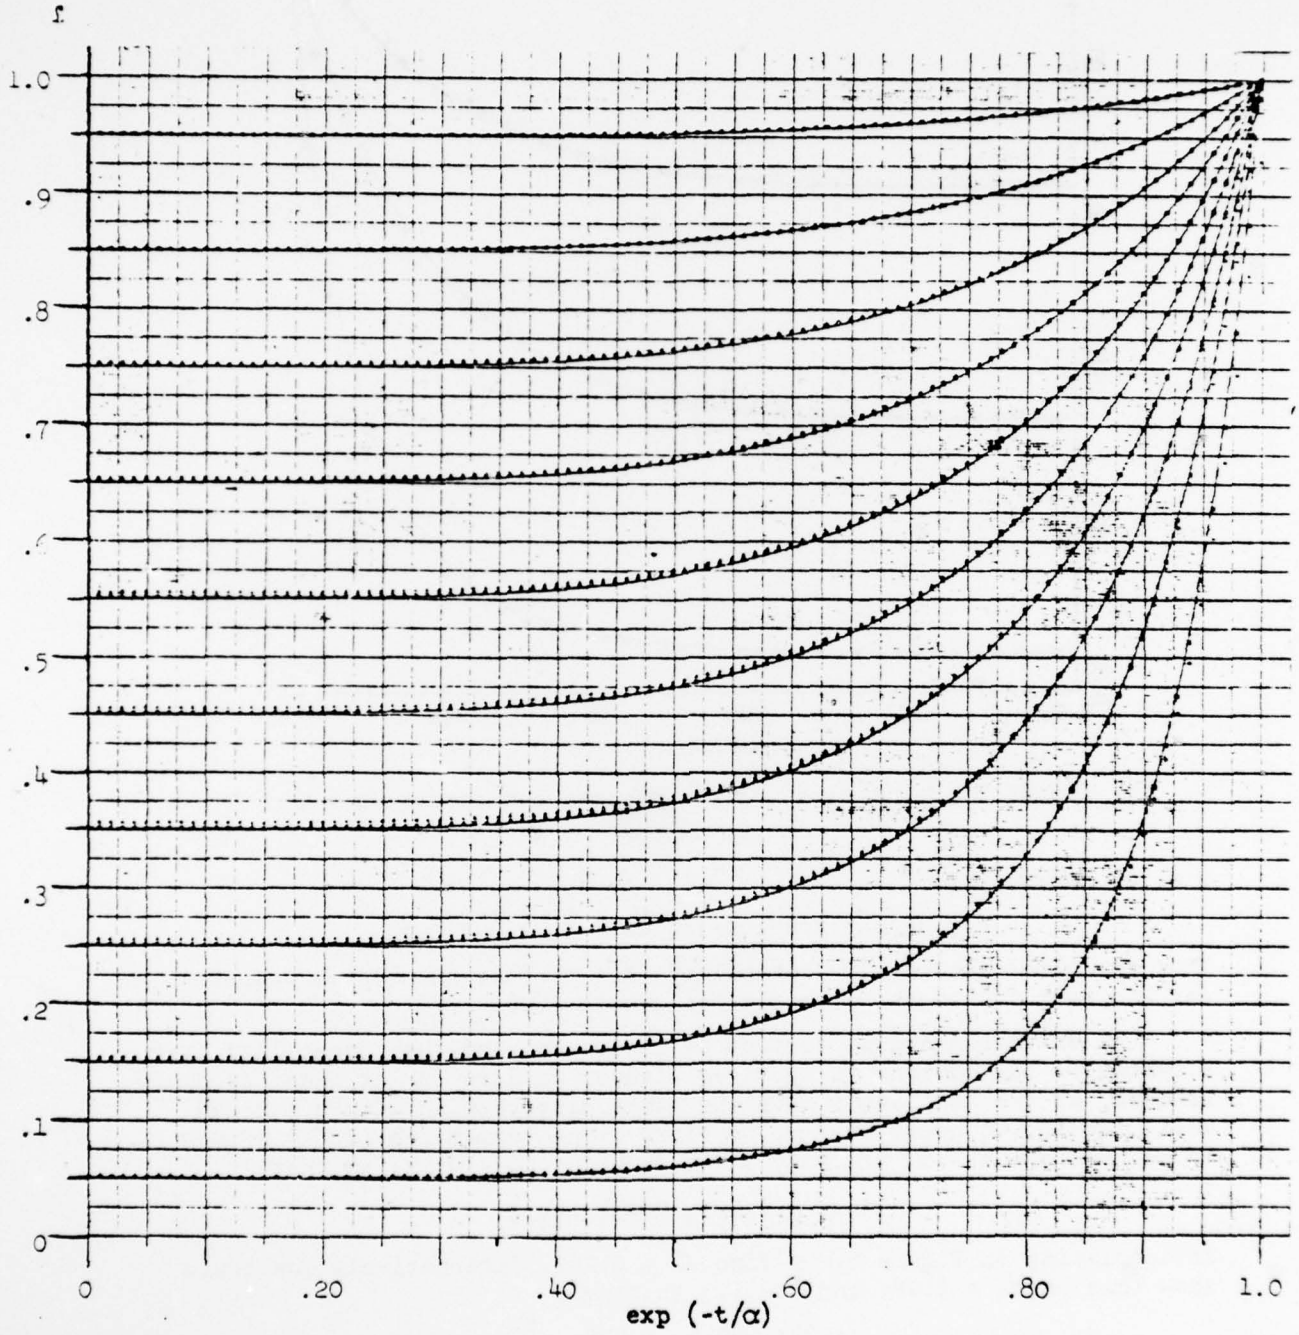

FIGURE 5. $\mathfrak{L}(\alpha s/n;\ t,\ n)$ for n gamma components: $\alpha = 2$

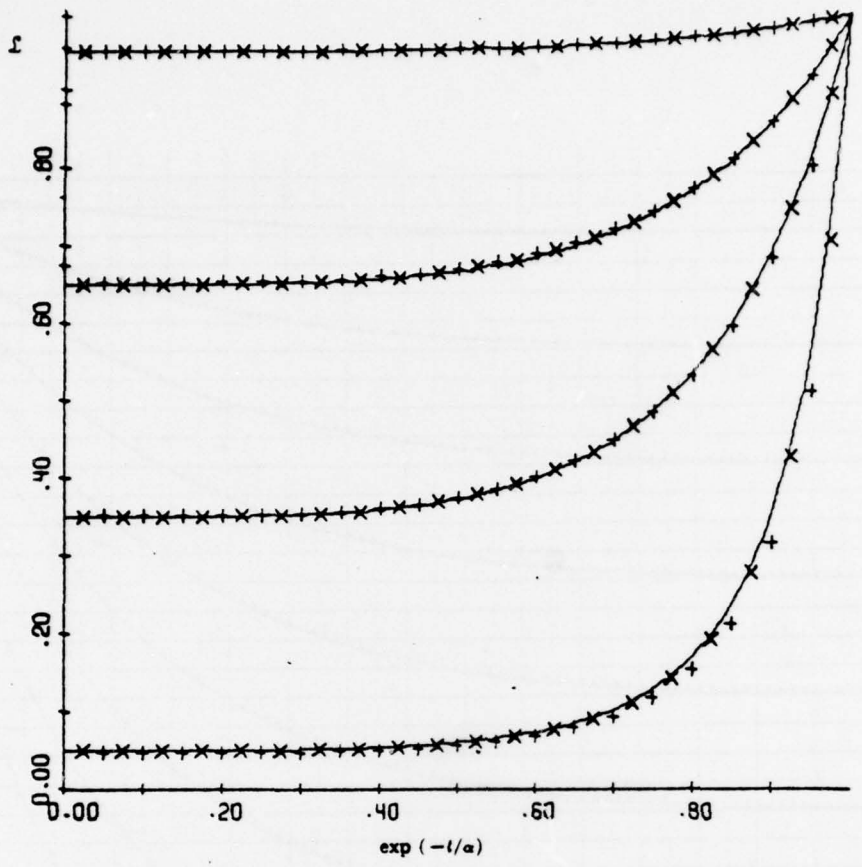

FIGURE 6. $\mathfrak{L}(\alpha s/n;\ t,\ n)$ for n gamma components: $\alpha = 2$

w = 100 hours. Then

$$s = nW/\mu = 300\times100/10{,}000 = 3,\ e^{-s} = 0.05.$$

Thus the time-equilibrium probability ($t = \infty$) that the system operates for at least 100 hours without a failure is 0.05.

As another example, suppose we desire to find the probability that a system of 100 components survives without failure for at least 24 hours when all of the components have the gamma distribution with $\alpha = 2$ and mean life 10,000 hours (θ = 5,000 hours). The system age is T = 10,000 hours. We have $t = 2$, $t/\alpha = 1$, $s = 100\times24/10{,}000 = 0.24$; so that

$$e^{-s} = 0.787,\ e^{-t/\alpha} = 0.368.$$

Interpolating in Figure 5, we find $\mathfrak{L} \doteq 0.792$. Alternatively one could show that $\mu h(t) = 0.984$ and use (2) to obtain

$$\mathfrak{L} = e^{-.24\times.984} = e^{-.236} = 0.790.$$

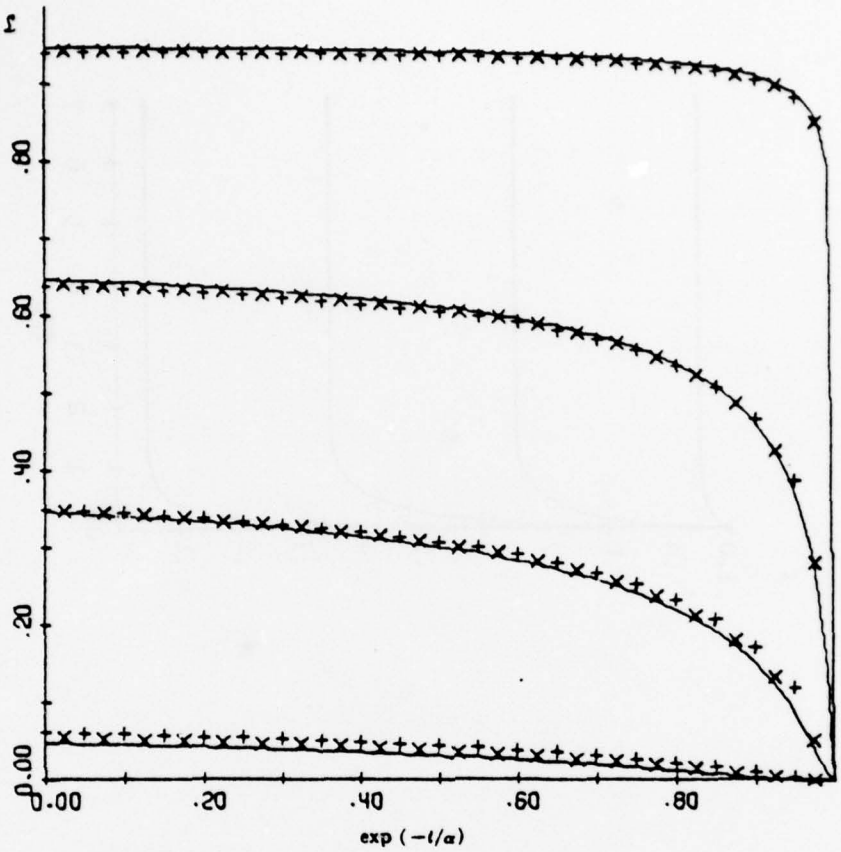

FIGURE 7. $\mathfrak{L}(\alpha s/n;\ t,\ n)$ for n gamma components: $\alpha = \frac{1}{2}$

It may be worth noting that when the time scale is changed (as from T to t), the same scale factor appears in the denominator in μ and in the numerator in h, so that the product $\mu h(t)$ is invariant.

Suppose the system, with size and age as above, consisted of gamma-distributed components with $\alpha = 4$ and mean life of $\mu = 10{,}000$ hours, so that $\theta = 2500$ hours; and we desire the survival probability for 24 hours as before. Then $t = 4$, $t/\alpha = 1$, $s = 0.24$, and the equilibrium probability is 0.787 as before. It can be shown that $\mu h(t) = 1.028$; and a calculation including terms in negative powers of n yielded $\mathfrak{L} = 0.782$.

At $T/\mu = t/\alpha = 1$, as in the last two examples, the time-dependent correction is only moderate; the next example will consider a system less well aged. Suppose the system consists of 100 components with $\alpha = 2$, $\mu = 10{,}000$ hours ($\theta = 5{,}000$ hours); $W = 24$ hours, and the system is $T = 2200$ hours old. Then $t = 2200/5000 = 0.44$, $t/\alpha = 0.22$, and $\exp(-t/\alpha) = 0.8$. Also, $s = 100 \times 24/10{,}000 = 0.24 = -\log(.787)$. Interpolation in Figure 5 at an abscissa of 0.8 yields $\mu h = .5904$ and

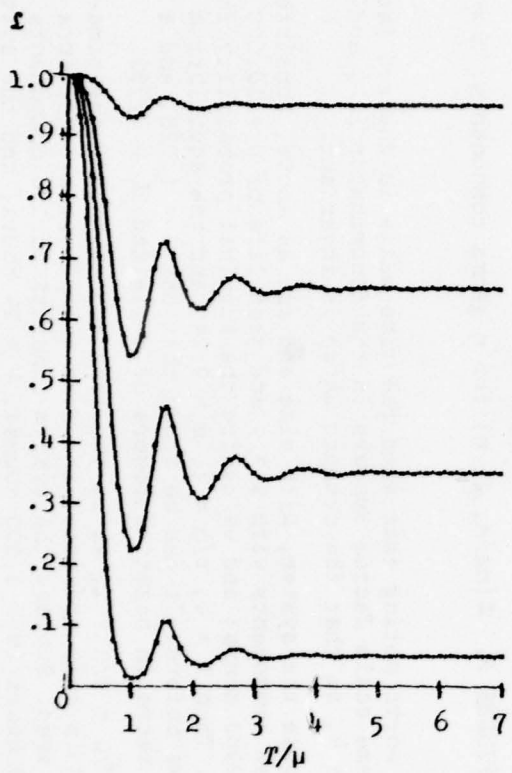

FIGURE 8. $p = 4.0$

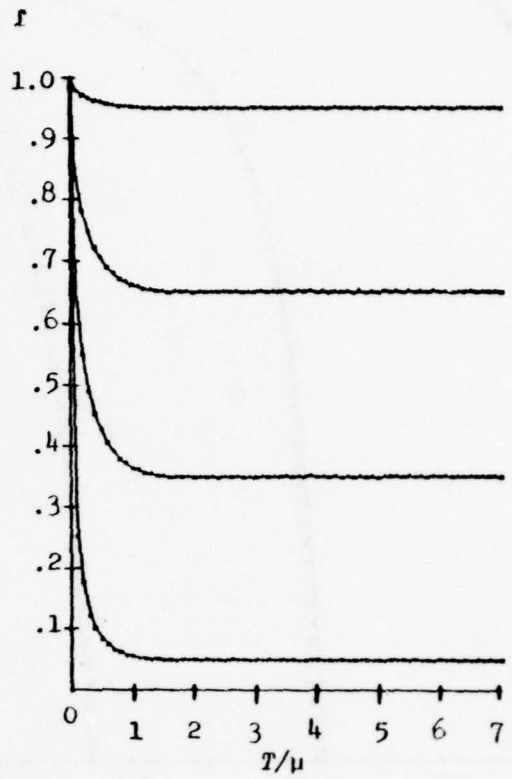

FIGURE 9. $p = 1.5$

$f\ (\mu s/n;\ T/\mu,\ n)$ for n Weibull components

$$\mathcal{L} = e^{-.24\times.5904} = e^{-.141} = 0.868.$$

This is a somewhat larger survival probability than the time-equilibrium prediction would give. The difference is more striking if we consider the probability of surviving 240 hours so that $s = 2.4$;

$$e^{-s} = 0.091 \text{ and } \mathcal{L} = e^{-\mu s h(t)} = e^{-1.4} = 0.247,$$

which is considerably larger than the equilibrium value, 0.091. The errors in ignoring system age are seen to be far greater for large waiting times than for small ones.

Several global conclusions can be drawn from these curves. The most important is that the effects of finite t are more important than the effects of finite n. This may be seen from the wide fluctuations of $\mathcal{L}$ as t varies and the closeness* of ×'s and +'s to the smooth curve for $t = \infty$. The approach of $\mathcal{L}$ to its limiting value for $\alpha = \frac{1}{2}$, as displayed in Figure 7, is monotonic increasing; this is because gamma components have decreasing hazard rates when $\alpha < 1$. Although we do not present the curve here, the same phenomenon has been seen for Weibull components with $p < 1$. As α (or p) gets larger there is a range of shape parameter for which the approach is monotonic decreasing, as shown in Figures 6, 7, 9. For still larger α or p the curve oscillates before damping in its approach to the equilibrium value; the larger α, the more oscillations are visible.

These oscillations were not expected, but they are genuine. Since hindsight is often 20/20, we now give an intuitive justification for the phenomenon. If the mean of the failure distribution of a component is large relative to its standard deviation (if the component has a small coefficient of variation) failures concentrated near the component mean life μ reduce the reliability, causing a relative minimum. After replacing the failed components, the reliability is increased, causing a maximum. But after an additional time μ the second generation of components will fail, causing a second maximum, etc. Thus we *expect* peaks to occur at values of T that are multiples of μ. The peaks get wider and shallower as T increases, until failures are essentially „random" and the exponential limit takes effect. This situation is illustrated in Figure 10. The upper set of curves represents $f(t)$ and its convolutions (time to second failure, time to third failure, etc.). The distribution of kth failures peaks at $t = k\mu$; its standard deviation is of the order of $\mu\sqrt{k}$ times the coefficient of variation of f. Thus the peaks do get wider and shallower as T increases. Another heuristic argument is illustrated by the lower curve in Figure 10, representing $h(t)$, the sum of the curves in the

*A comparison of the two curves for $\alpha = 2$, Figures 2 and 3, indicates that the approach for $n \to \infty$ is faster in Figure 3 than in Figure 2. Both curves represent computer plots. We had intended to include only Figure 3, but, having discovered the discrepancy, found it advisable to include both. Clearly one of the computer programs used was in error. The program is being rewritten; a correct tabulation and plot will be furnished on request.

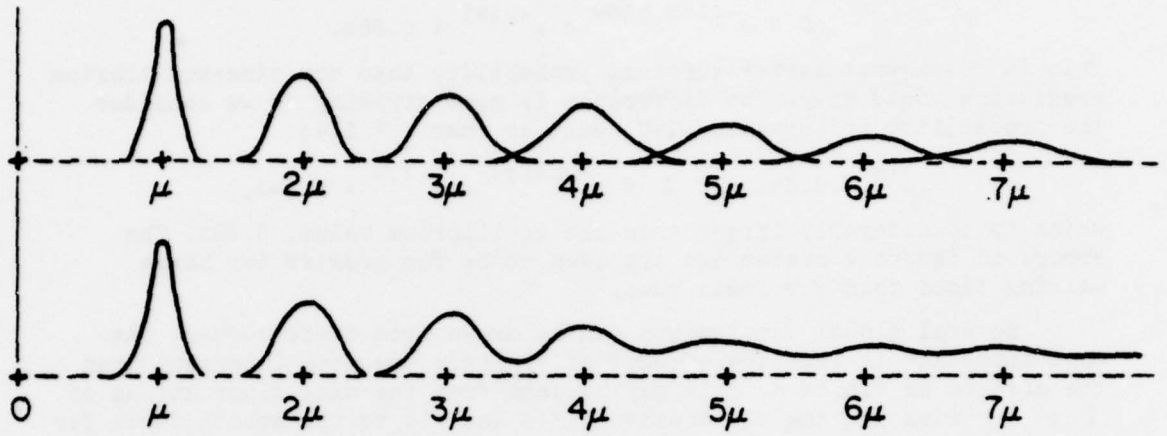

FIGURE 10. Schematic representation of $f^{*n}(t)$ (above) and $h(t)$ (below)

upper figure: it oscillates and then stabilizes to a constant value. But one observes from (1) that $\mathcal{L}$ is essentially a monotonic function of $h(t)$ (L_1 and L_2 affect the size of the oscillation, but have little effect on its location) and one observes from (2) that the asymptotic $\mathcal{L}$ for $n \to \infty$ *is* a monotonic function of $h(t)$, with sense reversed: the peaks of $h(t)$ are mirrored into the troughs of $\mathcal{L}(t)$. It is well known that the coefficient of variation of the gamma and Weibull distributions decreases as α and p, respectively, increase.

The oscillations increase the value of T/μ needed before one can be sure that the deviation of $\mathcal{L}$ from its limit is less than some specified value. For example, consider the curve of

$$e^{-\mu s h(t)} \quad \text{for } e^{-s} = 0.35$$

when $f(t)$ is a gamma density. Table 1 is obtained by finding on these curves the time beyond which the value of $\mathcal{L}$ never deviates from 0.35 by more than 1% (i.e. 0.0035). Note that such a time as $T = 3.1\mu$ can be very large for highly reliable components. For example, if $\alpha = 12$, and $\theta = 1$ month, and $n = 256$, then on the average the system has 256 failures per year or one failure every 1.4 days. Yet the steady-state exponential limit is reached after 3.1 years! If $\alpha = 12$, and $\theta = 1$ year, and $n = 256$, then the system fails every 17 days; and the steady state is reached after 37 years! Do many systems last this long? if not, one should not be analyzing their reliability by means of the exponential assumption.

Table 2 illustrates how the mean life $\mu = \alpha\theta$ (for gamma components) enters the calculations. The first two lines were read from Figure 2. If $\theta = 15$ hours and $n = 256$, the MTBF of a component is 180 hours and there is a system failure every 42 minutes. If $\theta = 15$ years and $n = 256$, the MTBF of the system is 257 days; the last line of Table 2 indicates that steady state has not arrived after 165 years.

TABLE 1. Time for oscillations to die down as function of scale parameter

PART II. RECALACULATION OF TIME TO NEXT FAILURE FOR GAMMA COMPONENTS

As indicated by the footnote on Page 13 there was an anomaly between two of the computer plots [1, 3] for gamma components. For this reason it was decided to recalculate $\mathcal{L}$ for n=64,256 and ∞ , $\alpha = 2(2)12$ yielding Tables 3 - 8 in the appendix. The curves for α=2 and 12 were then plotted by hand against $\exp(-t/\alpha)$ and appear as Figures 12 and 14, indicating that the computer plots in Figures 3 and 6 were correct. In addition these curves were also plotted with abscissa t and appear below as Figures 11 and 13.

In redoing these calculations other properties of the asymptotic approximation, which were unnoticed previously, appeared. For this reason it is deemed useful to review the approximation in order to point out these properties.

It was shown [6;p.45] that the general expansion for $\mathcal{L}(\mu s/n;t,n)$, the distribution of waiting time to the next failure, when the last failure occurred at time t is given by (1) with

$$L_1 = R_0(t)+2[(f(0)-h(t)]/\mu s \tag{8}$$

$$L_2 = 4R_1(t)-12R_0(t)(2f(0)-h(t)+(1/\mu s))-3\mu s R_0^2(t)$$
$$-(12/\mu s)(f^2(0)-4f(0)h(t)+h^2(t)-f'(0)) \tag{9}$$

and

$$\mathcal{L}\left(\frac{\alpha s}{n};t,n\right) = \exp(-\alpha s h(t)) \left\{1 - \frac{(\alpha s)^2}{2n}\left[R_0(t) - 2(h(t)/\alpha s)\right]\right. \tag{18}$$

$$\left. - \frac{(\alpha s)^3}{24n^2}\left[4R_1(t) - 12R_0(t)((1/\alpha s) - h(t)) - 3\alpha s R_0^2(t) - 12(h^2(t)/\alpha s)\right]\right\}$$

where

$$R_0(t) = h^2(t) + h'(t) \tag{19}$$

$$R_1(t) = h''(t) + 3h(t)h'(t) + 2h^3(t) \tag{20}$$

For gamma densities with integral shape parameter α, the renewal density $h_\alpha(t)$ is given by

$$h_\alpha(t) = \frac{1}{\alpha} + \frac{1}{\alpha}\sum_{j=1}^{\alpha-1} \omega^j e^{-t(1-\omega^j)} \tag{21}$$

and

$$\omega = e^{\frac{2\pi i}{\alpha}}, \quad \omega^j = e^{\frac{2\pi i j}{\alpha}}, \quad i = \sqrt{-1}\ . \tag{22}$$

Of course ω^j are the non-unity αth root of unity.

Equation (21) represents a neat mathematical expression for the renewal densities, but is not convenient for calculating. The renewal density and its differential were calculated [6; p7] by

$$h_\alpha(t) = e^{-t} S_1 \tag{23}$$

$$h'_\alpha(t) = e^{-t}(S_1 - S_2) \tag{24}$$

$$h''_\alpha(t) = e^{-t}(S_1 - 2S_2 + S_3), \tag{25}$$

where

$$S_j = \sum_{n=1}^{\infty} \frac{t^{n\alpha-j}}{\Gamma(n\alpha-j+1)} . \tag{26}$$

and $[\Gamma(m)]=0$ wherever m is zero or a negative integer.

Using these procedures, $\mathcal{L}(w;t,n)$, the probability distribution of w, the waiting time for the next failure when there has been a failure at time t, has been recalculated for gamma component failure distributions for $\alpha = 2(2)12$. These tables appear in the appendix to this report where $\mathcal{L}$ is tabulated against both t and $u = \exp(-t/\alpha)$. The headings L, x, + represent $\mathcal{L}$ for $n=\infty$, 256, 64, respectively.

It should be noted that the S' given by (26) are suitable for computing the renewal density, h for any value of α. When α is an integer or half-integer the successive terms of these series are readily calculated by recurrence. However, for arbitrary α this recurrence procedure fails. It is then necessary to calculate each gamma function independently and then sum. Unfortunately this leads to serious overflow problems for moderate t. Since the calculation of $\mathcal{L}$ for integer and half-integer α did describe the curves adequately [1], the arbitrary α - case was not pursued.

Two facts emerge from these tables that were not apparent in the previously published curves (two of which are republished here). The last column in Table 3 ($\alpha = 2$) indicate that $\mathcal{L} \neq 1$ for finite n. This can be seen by examining (13) - (16). For $\alpha = 2$, we have

$$\mathcal{L}\left(\frac{2s}{n}\ ;\ t,n\right) = [\exp(-2sh(t)][k(s,t,n)]$$

and

$$h(0) = 0, \quad R_0(0)=1, \quad R_1(0)= -2,$$

so that

$$\mathcal{L}\left(\frac{2s}{n}\ ;\ 0,n\right) = k(s,0,n)$$

$$= 1 - \frac{2s^2}{n} + \frac{s^2}{3n^2}(8+6s) \ ,$$

which is <u>not</u> equal to 1, unless $n = \infty$. For large values of e^{-s} the difference from unity is not large. But for $e^{-s} = .05$ we have $\mathcal{L}(\cdot;0,256) = .93$ and $\mathcal{L}(\cdot;0,64) = .78$. The reason for this is that the expansion used for $\mathcal{L}$ is not valid for very small t. We believe the expansion is good for $t > n^{-1/(2\alpha)}$ or $t > n^{-\frac{1}{4}}$ for $\alpha = 2$. We have indicated the abscissas $t = n^{-1/(2\alpha)}$ and $\exp(-t/\alpha)$ for these values of t by dashed arrows in Figures 11-14. These values are

α	n	t	$e^{-t/\alpha}$
2	64	.35	.84
2	256	.25	.88
12	64	.84	.93
12	256	.79	.94

The solid arrows correspond to $t = n^{-\frac{1}{2}}$ (.0625 and .125 for n = 256 and 64). They are given for comparison purposes only.

The second overlooked fact that is apparent in the tables is that the finite curves cross each other. That is, the curves for n=256 is not always closer than the n=64 curve to the n=∞ curve. For example Table 3 shows that for $\alpha = 2$ and s = 1.3863 the three curves have the same value, 0.2957 at t=1.0553. However at t=1.1242 the 256 -curve is closer than the 64-curve to the ∞curve; but at t=0.9886 the 256-curve is closer than the 64-curve. Tables 7 and 8 indicate that for small value of e^{-s} the finite curves cross each other several times.

The reason this phenomenon was overlooked is that the n = ∞ curve was plotted, but only selected values were plotted for n=64 and 256. It was always <u>assumed</u> that the 256-curve would be closer to the n=∞ curve. Actually a similar procedure was used here to get Figures 11-14. The n=64(+) values were plotted for u=.05(·10).95 and the n=256 (x) values were plotted for u = .10(·10)1.00.

The explanation of the phenomenon is given by the sign of the term

$$R_0(t) - \frac{2\,h(t)}{\alpha s} \qquad (27)$$

in (14) and (18), since this will determine whether the finite n term (for given t) is above or below the n=∞ term. If $\alpha = 2$, (27) becomes

$$\frac{1}{2}\left(\frac{1}{2}-\frac{1}{s}\right) + \frac{1}{2}\left(1+\frac{1}{s}\right)e^{-2t} + \frac{1}{4}e^{-4t}, \qquad (28)$$

which is for s=1

$$\tfrac{1}{2}(-\tfrac{1}{2}+2e^{-2t}+\tfrac{1}{2}e^{-4t}).$$

This is positive for small t and becomes negative as t increases. Thus, for small t, the finite n term will be smaller than the infinite n term and for large t, the finite n term will be larger. For any fixed t, the finite system reliability could be above or below the infinite size case depending on the term (27). It should be noted that s plays a role and crossover will occur at different t-values for different s values. Expression (28) is always positive for $s \geq 2$, when there is no crossover and the 256-curve is always close to the ∞-curve. This is, of course, borne out in Table 3.
