I. SUMMARY

This report presents the results of prototype manufacturing, rig testing, application, and engine testing of a small advanced technology turbocharger. The turbocharger features variable turbine nozzles, ball bearings supported rotor system, self contained lube system and a broad operating range compressor. The purpose of the work was to show the potential benefits of the subject turbocharger in enhancing specific fuel consumption, emissions, and transient response of a diesel engine. The work was accomplished through laboratory testing of hardware and subsequent mathematical duty cycle simulation using the acquired data.

The proposed turbocharger was manufactured and successfully run on a turbocharger test rig. Compressor maps were generated for several compressor trims with vaned and vaneless diffusers. A turbocharger was successfully run for 53 hours on a John Deere, 239 cubic inch, four cylinder, diesel engine. Fuel consumption and emissions data were obtained for this engine as well as the "as received" turbocharged engine and the engine with no turbocharger.

Best specific fuel consumption was equal to or better than the "as received" turbocharged engine. In general, the fuel consumption was improved at all conditions except medium speed, medium to high

load where the original turbocharger was apparently optimized. Emissions were responsive to turbine nozzle position. Closed nozzles (producing higher turbocharger speeds and intake manifold pressures) produced greater NO_2 and less CO, hydrocarbons and smoke than the baseline "as received" turbocharged engine. Open nozzles produced the opposite results. Transient testing was inconclusive.

Test data showed that the compressor was not well matched to the engine. Further, the exhaust temperatures were much lower than the initially assumed (1190°F max. versus 1600°F) design point. The turbocharger was therefore rather poorly matched to the engine.

Data reduction also showed that more heat was being transferred from the turbine to the compressor than was anticipated. This resulted in reduced intake manifold densities (than theoretically possible with no heat transfer) and therefore, reduced air mass flow.

The extremes of nozzle travel (generally ± 10 degrees) did not seem to produce the extremes of potential improvement.

The general conclusion reached is that, in spite of the poor aerodynamic match and the adverse heat transfer condition, an

advanced turbocharger with variable area turbine nozzles, a broad operating range compressor and very low loss anti-friction bearings can produce lower specific fuel consumption, can "flatten" the sfc versus engine speed (at constant horsepower) characteristics and can be an effective control variable for emissions. A fully developed turbocharger, appropriately matched, will give the engine designer a new tool, heretofore not available, for matching a diesel powerplant to a specific requirement while optimizing fuel consumption and emissions. A more exhaustive effort, utilizing a better matched turbocharger, is required to better define the potentials.

II. PREFACE

This work was authorized by contract DAAK70-78-C0031 administered by the Electromechanical Division of the Mobility Equipment Research and Development Command, Ft. Belvoir, Virginia. The Contracting Officer was John A. Gabby. The Contracting Officers' Technical Representative was Paul Arnold. Robert Ware contributed valuable reviews and suggestions. The effort was funded through the U. S. Army Advanced Concepts Team, whose Executive Director is Dr. Charles Church, as a result of an unsolicited proposal. Dr. Church provided considerable overall guidance to the effort.

Dr. Koneru Tataiah of Southwest Research Institute, San Antonio, Texas managed and supervised the engine test portion of the effort as well as formulated and programmed the mathematical model. This work was conducted in the Department of Engine and Vehicle Research, Charles Wood, Director. Mr. Wood contributed much in guidance and specific suggestions.

It should be noted here that Southwest Research Institute wrote a final report on their efforts and it is attached as Appendix "D". For those areas that were predominately Southwest Research Institute work, the objectives and basic results will be presented with reference to their report for the particulars.

III. INTRODUCTION

A. Purpose

The purpose of this effort was to demonstrate the technical feasibility of using an advanced design turbocharger (featuring variable area turbine nozzles (VATN), a ball bearing supported rotor system, a self contained lubrication system and a broad operating range compressor) to improve specific fuel consumption, emissions, and transient response of a diesel engine.

B. Background

1. summary of turbocharger design -

Aerodyne recognized the need for an improvement in the state-of-the-art of small turbochargers, particularly in the following areas:

- * mechanical efficiency
- * control
- * bearing life
- * operating range

A design concept evolved that held promise for improvements in the targeted areas. The turbocharger design concept features variable area turbine nozzles (VATN), ball bearing supported rotor system, a self contained lubrication system and a broad operating range compressor.

The broad operating range compressor, used in conjunction with the VATN, allows exceptionally broad ranges of efficiently controlled operation with respect to engine speed and boost pressure. The VATN also provides additional turbine power output for improved, transient response. Additionally, the low friction ball bearings provide dramatic improvements in mechanical efficiency - reducing the steady state turbine power requirement as well as enhancing transient response. The ball bearings provide a relatively "stiff" rotor system which allows reduced blade tip running clearances - thereby improving compressor and turbine efficiency.

Additionally, the rotor system is overhung placing the bearings in the cool environment of the compressor inlet. This allows a self contained, wick fed lubrication system with the following benefits:

- * no seals are required - any excess oil (which is minimal) is simply passed through the engine
- * any shaft orientation can be run (including vertical)
- * engine oil and associated plumbing is not required - contaminated engine oil or the lack of engine oil is the primary cause of bearing and seal failures in present turbochargers

- * the bearing system is considerably less complex than journal/thrust bearing systems

A detailed design of a specific turbocharger was completed for a spark ignition engine. The design point was chosen for what Aerodyne judged to be future typical automotive requirements. The aerodynamic design point of the turbocharger was: a corrected flow of 200 CFM ($Q/\sqrt{\frac{T_1}{519}}$) at a compressor pressure ratio of 2.3 (R_c) (vaned diffuser) and a turbine inlet temperature of 2060°R at a fuel/air ratio of .067 with compressor inlet loss of 1 inch of mercury and a turbine discharge loss of 6 inches of mercury.

A cross-section of this turbocharger is shown in Figure 1.

2. simulated rotor test rig

In order to verify the rotor/bearing/lube system design approach a simulated rotor rig was constructed and run. The details of this effort are presented in Appendix "A".

FIGURE 1 - TURBOCHARGER

C. Program Breakdown and Scope of Work

This report covers the program outlined below as well as the conclusions drawn from the results and the recommendations.

The program was broken down into the following major areas:

1. manufacture turbochargers
2. conduct bench tests to characterize the turbocharger's operation
3. develop a mathematical model to predict fuel consumption and emissions for small turbocharged diesel engines for a selected automotive driving cycle
4. select a commercially available test engine and apply the turbocharger to it
5. conduct engine tests to define operating characteristics at various VATN settings
6. predict fuel consumption and emissions, using the developed mathematical model and actual engine test data

IV. INVESTIGATION

A. Manufacture Turbochargers

The objectives of this effort was to make provision for the materials, tooling, processing, and assembly necessary for the manufacture of turbochargers.

A brief description of the turbocharger follows:

The rotor consists of an overhung back-to-back compressor/turbine arrangement with the bearings located in the relatively cool compressor inlet. The bearing is a full complement instrument ball bearing with the inner raceway being an integral part of the shaft. Slinger ramps are provided, adjacent to the inner raceways, on which wicks contact the shaft. These wicks, which are immersed in a reservoir of oil, continually "write" a film of oil on the slinger ramps during shaft rotation. The oil reservoir is integrally cast with the compressor housing. Centrifugal force then causes the oil to be "slung" from the sharp intersection of the slinger ramp with raceway onto the balls and outer raceway. Thus, a miniscule flow of very clean oil is provided to the bearings during operation. At rest no flow exists. A compression spring preloads the bearings. The compressor wheel is captured

axially and driven by an interference fit sleeve with driving lugs that engage the compressor wheel. No seals are required or used in the bearing system design.

A constant velocity scroll with a single discharge is used to collect and deliver compressor air. A similar type scroll is used for the turbine to prepare the gases for the turbine nozzles.

The VATN actuating mechanism is located in the air space between the compressor and turbine and consists of:

- * stamped sheet metal levers with a "D" shaped indexing hole for mounting on the turbine nozzle vane trunnions and engagement means for locating in the coordinating ring. One of the levers extends radially outward, having provision for attaching a rod leading to an actuator.
- * the VATN bearing, which is a large bore ball bearing with the outer race being the coordinating ring with slots for engagement of the levers.

An asbestos heat shield is provided between the turbine backwall and the VATN mechanism. The heat shield and air space provide the heat transfer barrier between the turbine and compressor.

The four major structural members are clamped axially by a single 'V' clamp and are piloted such that thermal expansion causes increased radial interference.

Turbochargers were successfully manufactured. Casting tooling was procured that produced very high quality castings. Purchased parts were of good quality and were functionally acceptable. Tooling and fixturing were fabricated in-house for machining, balancing, and assembly. Outside sources were developed for those tasks requiring very specialized equipment or skills. Figures 2 through 11 are photographs of the resulting parts.

There are 24 items, consisting of piece parts and sub assemblies, which make up the turbocharger. They are shown in Figure 12.

B. Bench Testing

The bench testing consisted of conducting oil/wick/wick-shaft interface tests and running of complete turbochargers.

1. Oil/wick/wick-shaft interface tests

The purpose of these tests was to determine the oil flow rate of the lubrication system (comparing results with the result found on the rotor rig test ran earlier) and to evaluate the flow characteristics of two different candidate oils as well as the selected wick material.

The flow rate found after 231.5 hours of single rotor rig test was .0069 cubic inches of oil (Mobil DTE medium) per hour for the two wicks. In this case the shaft was run vertically with no opportunity for recirculation of the oil.

For the present test a test rig, simulating the slinger ramps on the turbocharger shaft, was utilized. The surface speed of the slingers

represented a rotational speed of 130,000 RPM of the turbocharger rotor. Twelve ramps were incorporated on the test rig rotor. Provision for 12 wicks and 12 graduated cylinders was made. A photograph of this rig is shown on Figure 13.

For these tests the original spindle oil (Mobil DTE medium) and a turbine oil (Humble Turbo Oil #2380-MIL-L-23699B) were used.

Two test conditions were run - the first allowed the oil that was ejected from the ramp to collect around the wick and therefore had an opportunity to recirculate. The second condition shielded and drained the wick so there was no opportunity for recirculation of the oil.

The average of the results are as follows (flow for two wicks):

RECIRCULATION ALLOWED	NO RECIRCULATION ALLOWED
<u>Mobil DTE medium</u> .00135 in ³ /hour <u>Humble Turbo Oil # 2380</u> .00128 in ³ /hour	<u>Mobil DTE medium</u> .00739 in ³ /hour <u>Humble Turbo Oil # 2380</u> .00669 in ³ /hour

FIGURE 13 - OIL WICK TEST RIG

After preliminary running of the rig to establish pulley ratios, rotor speed and overall operating characteristics, the wicks, (first soaked in the appropriate oil) were placed in the rig and adjusted for the appropriate contact. The graduated cylinders were filled with the selected oil and mounted in the rig. Readings were taken on all cylinders and the test was run continuously for 138.5 hours. Following this test five wicks were replaced and the rig set up to eliminate the possibility of recirculation. This test was run continuously for 136 hours.

2. Complete turbocharger testing

The purpose of this testing was twofold:

- * Mechanical - Determine the basic integrity of the turbocharger components and develop the bearing system to the point that the engine testing could be attempted with some degree of confidence.
- * Aerodynamic - Generate compressor maps and verify turbine performance and its ability to control power output through the VATN.

The results of turbocharger testing were:

- * Mechanical - The basic integrity of the turbocharger components, as designed, was shown to be adequate. There were no failures of component due to steady or vibratory stresses (other than bearing failures). The rotor has been run (cold) to a speed of 205,000 RPM. Lubrication of the bearings proved to be adequate. The bearing geometry had to be accurate and balance requirements were very important (as expected).
- * Aerodynamic - Data was obtained to construct complete compressor maps of the "as designed" compressor as well as "high flow" and "low flow" trims of the basic compressor. These compressors utilized a vaned diffuser. Additionally, a vaneless version of the "high flow" compressor was tested and a compressor map constructed. These maps are shown on Figures 14, 15, 16, and 17.

FIGURE 14

FIGURE 15

FIGURE 16

FIGURE 17

Turbine testing was accomplished to the point of verifying design goal efficiencies and demonstrating the ability of the VATN to control power output and therefore rotor speed.

In order to conduct the mechanical and aerodynamic tests a complete facility, including a data acquisition system, had to be designed and built. An outline of the features of this facility are presented in Appendix C.

C. Develop Mathematical Models

The objective of this effort was to develop mathematical modeling techniques whereby the effects of turbocharging on diesel engine characteristics could be predicted - both from a theoretical standpoint and using actual test data from an empirical standpoint. A further objective was to utilize these predicted characteristics to evaluate the effects of engine displacement and drive ratios on fuel economy and emissions for a typical duty cycle.

A computerized mathematical model was developed to theoretically compute the fuel used over the 13 Mode Federal Diesel Emission Cycle for diesel engines. Another computerized mathematical model was developed to calculate the fuel used over the Federal Urban and Highway Driving Cycles using empirical relations developed from the turbocharged engine test data. The model is based on empirical formulae derived from experimental data of various engines by C. F. Taylor (Reference 1 of Appendix D). The duty cycle is divided into many short "steady state" conditions and the fuel consumed at each condition calculated. Total fuel consumption is the summation of all conditions.

This work was conducted by Southwest Research Institute and the details of the effort are included in their report which is attached as Appendix D.

D. Select Engine

The objective of this effort was to select a commercially available four stroke diesel engine that would have a swept volume rate (displacement X RPM) that would closely approximate the pressure flow characteristics of the proposed turbocharger compressor. Secondary considerations such as availability, being previously turbocharged, etc. were included.

A John Deere, 4 cylinder, direct injected, turbocharged engine was selected. It's displacement is 239 cubic inches and maximum speed is 2500 RPM.

This work was conducted, in large part, by Southwest Research Institute and the details of the effort are included in their report which is attached as Appendix D.

E. Engine Performance Tests

The objective here was to conduct engine performance tests, collecting fuel consumption, CO, NO₂, HC and smoke emissions

data for the baseline turbocharged engine, the engine with no turbocharger and with the Aerodyne turbocharger at various VATN settings. Additionally, transient response characteristics were to be evaluated.

After a "break-in" period a matrix (speed-load) of engine data was obtained for the turbocharged engine "as-received" and without the turbocharger. Then, with the Aerodyne turbocharger installed, the same speed-load matrix testing was accomplished for three different turbine nozzle settings at each speed-load point. Transient tests were conducted. A total of 53 hours of testing was accomplished with the Aerodyne turbocharger. Figures 18, 19, and 20 graphically summarize the results of the performance testing.

This work was conducted by Southwest Research Institute and all of the reduced test data and the details of the effort are included in their report which is attached as Appendix D.

F. Predict Fuel Consumption

The objective was to show the potential improvements available through turbocharging with an advanced technology turbocharger in a typical automotive duty cycle. Two

FIGURE 18 - SPECIFIC FUEL CONSUMPTION VS RPM & BHP

EMISSIONS AND FUEL ECONOMY OVER 13-MODE
FEDERAL DIESEL EMISSION CYCLE

FIGURE 19

BAR PLOTS OF SMOKE TEST RESULTS

FIGURE 20

primary sources of improvement would be utilized.

- (1) At any given engine operating point (load/speed), optimize the VATN setting to produce minimum fuel consumption.
- (2) Through final drive ratio changes, cause the engine to operate at various BMEP levels. This will cause variations in internal engine friction as well as basic overall thermodynamic efficiency. As the engine is forced to run slower and slower, performance would be made up through higher levels of turbocharging.

This effort was conducted via the previously developed computerized mathematical model for the Federal Urban and Highway Driving Cycle using empirical relations derived from the engine test data. The results of this analysis are shown in Figure 21, which is a plot of fuel consumption versus final drive ratio (expressed as engine speed/vehicle velocity) at optimum turbine nozzle position.

This work was conducted by Southwest Research Institute. The results of the analysis and the details of the effort are included in their report which is attached as Appendix D.

FIGURE 21-MODEL ESTIMATION OF FUEL ECONOMY
FOR VARIOUS N/V RATIOS

V. DISCUSSION

A. Manufacture Turbochargers

The assembly of the Aerodyne turbocharger is simple and quick (particularly compared to normal turbochargers). While the VATN adds to the complexity and assembly time, this is outweighed by the simplicity of the bearing system and lack of a bearing housing, thrust plates and washers, piston rings and "O" rings. In-house studies indicate that little or no cost difference exists between this design and a typical wastegated turbocharger.

The Aerodyne turbocharger weighs about 10.5 pounds compared to 16-17 pounds for similar flow size commercially available turbochargers. At this point, all parts in the turbocharger can be produced on a prototype basis. The turbocharger was designed with producibility as a keystone design objective. All indications are that all parts can be mass produced readily.

B. Bench Tests

The wick testing supported the basic lubrication system design approach. Adequate consistency was demonstrated. Allowing the oil to recirculate reduced the consumption by a factor of perhaps five and may prove to be a means

of minimizing oil consumption.

Mechanically, the turbocharger proved to be sound. Quite often turbomachinery is beset with vibratory stress problems leading to fatigue failures. To date no such problems have been found. The demonstration of 205,000 RPM (about 80 percent overspeed) produced a permanent set of about .004 inch in the compressor wheel but showed the basic integrity of the rotating components. The turbocharger was once operated for about three hours at 110,000 RPM at the lowest attainable flow (about 32 CFM) with no detrimental effects.

The compressor maps produced with the basic compressor hardware are unique. While backward curved blading is known to produce a less pronounced surge, the familiar compressor map surge line still exists and operation to the left of this line is not practical. The characteristics of this compressor hardware are such that the surge line is very difficult to define and, more importantly, operation to its' left, on the map, produces no ill effects. The air produced in this region of the map is very usable by an engine (as practically demonstrated on the John Deere engine). What this allows is the turbocharging of an engine at any speed so long as the turbine can produce the required power.

The compressor efficiencies demonstrated in these tests (for the "as designed" and for flow trim modified compressors) are as good or better than published data for similar flow compressors. The design flow compressor achieved a peak efficiency of 76 percent. The vaneless configuration achieved about equal peak efficiency with published data but showed a much broader operating range.

As a means of providing comparative data, a compressor map was constructed for the turbocharger received with the test engine. The data was obtained on Aerodyne's test rig using the same instrumentation as on all other tests. This compressor map is shown on Figure 22.

Sufficient turbine performance data was obtained to show that the design goal peak efficiency of 75 percent was met and that the VATN produced radical changes in power output while maintaining good efficiency. Evaluation of the turbocharger, with VATN, on an engine, from bench test data was beyond the scope of this effort.

"First order" estimates of turbine performance were made from the data taken at both Southwest Research Institute and Aerodyne. The results of these estimates are shown

COMPRESSOR MAP - TURBOCHARGER
RECEIVED ON JOHN DEERE ENGINE

FIGURE 22

on Figure 23. The SWRI results were calculated as follows:

Using measured compressor pressure ratio and corrected airflow in conjunction with the compressor efficiency from the map generated at Aerodyne for this compressor, the required work was calculated. Measured turbine inlet temperature, turbine inlet pressure and turbine exit static pressure were then used to calculate ideal turbine work, corrected turbine flow and V' (isentropic jet velocity). Turbocharger speed was deduced from the compressor map since many of the speed readings seemed suspect.

A similar method was used to calculate turbine efficiency from the results of three different compressor component tests. Figure 23 shows that the Aerodyne data was all at conditions greater than the optimum U/V' (U =turbine rotor tip speed) and all the SWRI data was taken at U/V' values less than optimum (classically, this curve normally shows a peak efficiency in the range of .65 to .70 values for U/V'). Therefore, the maximum efficiency of the turbine was not observed. It is felt that, from the data plotted in Figure 23, the maximum total-to-static efficiency might be in the 77 to 78 percent range. This would reflect

- X

 +
 •

Closed Nozzles
 Nominal Nozzles
 Open Nozzles
 Nozzle Position Undefined (Aerodyne Compressor Mapping)

} (SWRI Engine Tests)

FIGURE 23 - MEASURED TURBINE EFFICIENCY

peak total-to-total efficiency of about 80 percent.

C. Engine Performance Tests

The turbocharger design was complete before the contract was begun and the engine was selected to match the anticipated flow characteristics. The aerodynamic design point was: a corrected compressor flow of 200 CFM at a compressor pressure ratio of 2.3 and a turbine inlet temperature of 2060°R at a fuel/air ratio of .067 with compressor inlet loss of 1 inch of mercury and a turbine discharge loss of 6 inches of mercury.

The engine testing produced compressor pressure ratios that were generally much lower than design point and the maximum turbine inlet temperature encountered was only 1650°R . Secondary differences were that the design point losses were not reached in the engine testing. Therefore, while complete turbine maps are not available, it must be assumed that the turbine was operating far from peak efficiency. Review of the actual engine pressure/flow characteristics plotted on the actual compressor map (see Figure 24) reveal that the compressor flow potential was greater than optimum. The maximum engine speed line (2500RPM)

should have been further to the right such that the 2000 RPM line was in the peak efficiency area of the compressor map.

Also, since the turbine data did not show a peak in turbine efficiency (see earlier discussion of turbine efficiency versus U/V'), it can be concluded that the turbine and compressor aerodynamic matching can be improved thereby producing higher turbine efficiencies.

The back-to-back compressor/turbine arrangement, of necessity, brings the turbine and compressor flowpaths in close proximity to each other, thereby producing the opportunity for transfer of heat from the turbine to the compressor. For turbocharging a diesel engine this is an adverse condition since the added heat in the compressor flow results in a density decrease (opposite the desired result). The turbocharger, as designed, incorporates an air gap and an asbestos heat shield as a barrier to heat flow. However, there is a rather direct metallic path for heat flow at the outer diameter of the turbocharger where the piloting and clamping of the compressor and turbine stationary parts takes place. Compressor discharge temperature data on

the test engine did not match the theoretical temperature that would be calculated from the compressor map - showing that heat transfer was taking place. This heat transfer was of such a magnitude that a significantly adverse effect on airflow resulted (see Figure 24). An analysis of the engine performance penalties resulting from the heat transfer is beyond the scope of this effort. A number of ways exist to modify the heat transfer characteristics, including; slots, additional barriers and material changes.

The "as designed turbocharger was capable of plus or minus 11 degrees of turbine nozzle vane travel. Some of the initial testing was conducted at plus and minus 8 degrees as well as nominal. Later testing was at plus and minus 10 degrees (and nominal). The engine test data reveal that the potential improvements (or penalties for that matter) had not yet been reached, under most operating conditions, at even the 10 degree extreme of motion. In other words, additional turbine nozzle travel would have produced an additional incremental decrease (or increase - according to operating condition and direction of movement) in specific fuel consumption and emissions.

— — — — — THEORETICAL
..... ACTUAL

THEORETICAL AND ACTUAL AIRFLOW
PLOTTED ON COMPRESSOR MAP

FIGURE 24

Taking the above into account (poor compressor and turbine match, excessive heat transfer and the potential for utilizing even more turbine nozzle travel) and the fact that this was not a fully developed turbocharger - the specific fuel consumption results were very encouraging. The specific fuel consumption was improved over nearly the entire load/speed range of the engine (except medium speed/medium to high load where fuel consumption was about equaled) compared with the "as received" engine. Emissions, which are primarily sensitive to fuel/air ratio at a given speed/load condition, could be made better or worse through nozzle position changes. It is estimated that an additional four percent improvement in sfc can be achieved through a rematch of compressor and turbine. Reducing the heat transfer and providing additional nozzle travel should produce an additional two to three percent improvement at the extreme operating conditions.

D. Predict Fuel Consumption

The analysis shows clearly that very significant improvements in fuel consumption are available through turbocharging - particularly via drive ratio changes (causing the engine to run slower and at higher BMEP). Performance is made up through turbocharging. A strong secondary influence that

is available using an advanced turbocharger, such as the present one, is through the optimization of fuel/air ratio, manifold pressures and the like by means of the VATN. Unfortunately, the model did not predict the degree of turbocharging required to maintain performance as drive ratios were changed. However an advanced turbocharger can more readily achieve this goal because of its ability to produce boost at very low engine speeds. Additionally, in light of the discussion in the previous section, adequate opportunity exists for even further improvements in fuel consumption via turbocharger performance improvements.

VI. CONCLUSIONS

A. Manufacture Turbochargers

1. Turbochargers of this design were built using present day manufacturing techniques and were successfully operated.
2. The manufacturing techniques used lend themselves to mass production techniques and studies show that cost would be comparable to present technology turbochargers.
3. The Aerodyne turbocharger is inherently lighter in weight than present technology turbochargers owing largely to the lack of a separate bearing housing.

B. Bench Tests

1. The bearing system allows stable rotor operation throughout the operating range of the turbocharger. Compressor blade tip clearance of .005 inch and turbine blade tip clearance of .008 can be run with no interference.
2. The lubrication system provides adequate lubrication for the bearings with enough oil in the present turbocharger reservoir for at least 680 hours of high speed operation.
3. Compressor efficiencies equal or exceed present equivalent flow turbocharger compressors, but, with a broader operating range. No defined surge

exists and operation to the left of stall is practical.

4. Turbine efficiencies met design goals.
5. The VATN produced large changes in power output, but effects could not be evaluated at this stage of testing.
6. There are no inherent detrimental vibration or stress problems with any component or assembly of the turbocharger.

C. Mathematical Models

1. The present model gives a good representation of the relative effects on fuel consumption of turbocharging and final drive ratio changes.
2. The model does not address emissions.
3. The model does not predict maximum turbocharging levels required to meet minimum performance requirements.

D. Engine Performance Tests

1. An advanced turbocharger with VATN can produce significant improvements in specific fuel consumption including a "flattening" effect on specific fuel consumption versus load at a constant engine speed or specific fuel consumption versus speed for a

constant power level.

2. The aerodynamic match of both the compressor and turbine of the present turbocharger was poor.
3. The heat transfer from turbine to compressor was excessive.
4. Plus and minus 10 degrees of VATN vane excursions was not adequate to show the extremes of potential improvement.
5. A VATN system can significantly affect emissions via A/F ratio control.
6. An extremely broad range of pressures and air flows can be run with this type turbocharger.

E. Predict Fuel Consumption

1. Turbocharging can be used to effect dramatic improvements in fuel economy for a diesel engine in an automotive application.
2. An advanced turbocharger with VATN can produce very significant secondary improvements in fuel economy.
3. Fuel economy improvements are almost proportional to drive ratio changes. Performance must be regained through a greater degree of turbocharging.

F. General Conclusions

An advanced technology turbocharger can be developed that will be considerably more effective than present technology turbochargers for improving fuel consumption and optimizing emissions for automotive diesel engines. The turbocharger would weigh about 65 percent of present wastegate turbochargers. It would not be dependent on engine oil for lubrication. The cost is approximately equal to present wastegate turbochargers.

VII. RECOMMENDATIONS

The following areas need to be investigated to fully demonstrate the concept and its potential as well as answer any questions concerning mechanical integrity.

- A. Conduct analytical studies and a design effort to define a heat transfer barrier system that will minimize the transfer of heat from the turbine to the compressor.
- B. Conduct analytical studies and design efforts to aerodynamically rematch (using present hardware) the turbocharger to the John Deere diesel engine. This would include provision for additional turbine nozzle travel.
- C. Build a turbocharger with the defined components from A and B above, apply the turbocharger to the John Deere engine and re-run all fuel consumption and emissions tests.
- D. Extend the mathematical model to include emissions prediction.
- E. Define and carry out a program to define the balancing tolerance of the individual rotating components as well as the assembled rotor.

F. Define and carry out a program that will result in a definition of the tolerance range for the major variables within the bearing system.

G. Develop a program aimed at utilizing the VATN to minimize adverse transient response effects of a turbocharged engine. This would include:

- * A mathematical model to simulate the engine/turbocharger system that would show the effects of the VATN, bearing losses, intake and exhaust volumes, intake and exhaust temperatures and rotor inertia.
- * Verification of analytical modeling techniques via dynamometer testing.
- * Definition of an optimum engine/turbocharger system, including turbine nozzle and fueling scheduling.
- * Manufacture and testing of the defined engine/turbo-charger system.

APPENDIX A

SIMULATED ROTOR TESTING

The simulated rotor test rig is shown on Figure A1. The rotor was machined from solid stock with the inner raceways being identical to the turbocharger as designed. Shaft diameters were the same as on the turbocharger. The two disks were located at the calculated centers of gravity of the compressor wheel and turbine wheel, and were of the same calculated masses and moments of inertia.

This rotor was housed in a bore identical to the turbocharger design with the same outer races and preload spring. It was driven by a small turbine on the end opposite the bearings.

The rotor was operated up to 125,000 RPM for a total of 1,000,000,000 revolutions (231.5 hours at average speed of 72651 RPM). A plot of the speed history is shown on Figure A2.

APPENDIX C

TEST FACILITY

Hot gas, to drive the turbine, is provided by Cummins NH 250 diesel engine illustrated in Figure C1. A G-Power water brake dynamometer is utilized to load the engine and to control the exhaust temperature. The exhaust is discharged from the exhaust manifold into a 80 gallon tank to minimize pulsation as shown in Figure C2. From this tank the gases are directed through a six inch diameter pipe to a transition duct. This transition duct forms the passage from six inches diameter to the size and shape of the turbine inlet and provides for turbine inlet condition instrumentation and mounting of the turbocharger. The engine is in one room and the turbocharger is mounted in an adjacent room. A duct is provided at the turbine discharge to direct the gases from the turbocharger to a much larger vent duct, that is evacuated with a blower, leading to the roof. The turbine discharge duct incorporates manually operated butterfly valves (to control backpressure for Reynolds Number investigations) and provisions for turbine discharge condition instrumentation. The vent duct draws air from the test room (as well as turbine discharge gases) allowing fresh air from another vent to enter the room. A Meriam "laminar flow meter" is used to measure engine

FIGURE C1 - CUMMINS NH250 DIESEL ENGINE

FIGURE C2 - EXHAUST PLENUM 80 GALLON TANK

airflow (and therefore turbine airflow).

The compressor inlet ducting consists of a Meriam "laminar flow meter" followed by an eight inch diameter plenum (settling station) followed by a bellmouth entrance to the turbocharger and is shown in Figure C3. Compressor inlet condition instrumentation is incorporated in the plenum. The compressor exit ducting is illustrated in Figure C4 and consists of a short section of square tubing (with one end matching the compressor discharge size and shape) branching into three square tubes of different sizes. Each of these tubes contains a manually operated butterfly valve for controlling the pressure/airflow characteristics of the compressor.

A manually operated spur gear and lever system controls the position of the VATN.

The instrumentation used to measure overall performance is as follows:

- * One Meriam model 50 MC2-4F laminar flowmeter including three thermocouples and two static pressure taps, to measure diesel engine airflow.
- * Two static taps in the 80 gallon plenum to measure turbine inlet total pressure.

FIGURE C3 - COMPRESSOR INLET DUCTING

FIGURE C4 - COMPRESSOR EXIT DUCTING

- * Four total thermocouples at the turbine inlet to measure turbine inlet total temperature.
- * Nine total temperature thermocouples at the turbine exit to measure turbine discharge total temperature.
- * One Meriam model 50 MC2-4F laminar flowmeter, including three thermocouples and two static pressure taps to measure compressor airflow.
- * Four static pressure taps in the compressor inlet plenum to measure compressor inlet total pressure.
- * Four thermocouples in the compressor inlet plenum to measure compressor inlet total temperature.
- * Nine total pressure probes in the compressor discharge duct to measure compressor discharge total pressure.
- * Four static pressure taps in the compressor discharge duct to measure compressor discharge static pressure.
- * Nine total temperature thermocouples in the compressor discharge duct to measure compressor discharge total temperature.

A Hewlett-Packard 3052-A data acquisition system in conjunction with a 96 channel scanivalve is used to acquire the raw data and subsequently to perform calculations on the acquired data. The entire data acquisition system consists of:

HP 9825A desktop computer

HP 3495A scanner

HP 3455A highspped digital voltmeter

HP 5301A counter

HP 9871A printer

Scanivalve-MSS2-48C9 multiple scanivale system

Calibration is conducted via the data acquisition system. All thermocouples were manufactured from the same lot of thermocouple wire for which calibration data was obtained (from 0° F through 600° F) from the supplier. This calibration data is programmed in the computer to correct the standard Hewlett-Packard subroutine for calculating temperature from thermocouple voltage. Additionally, a thermocouple calibration check program was written and is used prior to and following each test. This procedure entails obtaining a listing of all thermocouple calculated temperatures with the thermocouples immersed in both ice water and boiling water. Similarly, a compressor discharge total pressure probe check program was written and is used prior to and following each test. For this check the pressure rake is removed and placed in a special fixture. After a rapid increase in pressure (applied with a variator) each probe is "looked at" via the scanivalve and a listing of the pressure is obtained. The objective here is to ensure that all probes are responsive to pressure changes and no plugging exists. The pressure

transducers (a low pressure 0-10 psi and a high pressure 0-100 psi) are calibrated via the data acquisition system, mercury manometers and a barometer. Manometer and barometer corrections for ambient temperature (both mercury and scale expansion) and latitude are included in the computer calibrations. Three reference pressures establish the slope of the pressure versus voltage line (ambient pressure and two manometer settings). Before these are established a zero voltage output is carefully set for ambient pressure. The accuracy of this system is well within:

- * pressure readings accurate to less than .001 psi
- * pressure sensitivity less than .0003 psi
- * temperature reading accurate to less than .25^oF
- * temperature sensitivity less than .1^oF

A program was written to monitor compressor performance (based on a small sampling of data), acquire data from all instrumentation when the desired stability had been achieved, and to calculate and print overall performance characteristics (including corrected and actual conditions). The data is collected in approximately 11 seconds and the results are printed in about 25 seconds from the initiation point.

A schematic of the test facility is shown on Figure C5.

SUMMARY

The objective of this program was to evaluate the performance characteristics of a variable nozzle area turbocharger developed by Aerodyne Dallas. This turbocharger was tested on a small diesel engine (John Deere Model 4239T) in a test cell at Southwest Research Institute. This engine was originally equipped with a conventional turbocharger manufactured by AiResearch. The baseline tests were performed with this conventional turbocharger under several steady state conditions. The tests with the variable nozzle area turbocharger included steady state as well as transient operation. The emphasis was placed on power output, fuel economy and exhaust emissions.

The regulated exhaust emissions were determined over the Federal 13-mode Diesel Emission cycle. The measurements of smoke in percent opacity were made at eight different steady state conditions.

A mathematical model was developed in order to predict the fuel economy benefits of a variable nozzle area turbocharger in vehicular applications.

As expected, the turbocharger increased the maximum power output and significantly improved the fuel economy at full load conditions. However, at low speeds, the variable nozzle turbocharger did not consistently produce relatively high boost pressures; but the fuel economy with this turbocharger was significantly higher than that with the conventional turbocharger. This lack of consistency was probably due to difficulty in reproducing the same nozzle position under repeated conditions. The higher fuel economy (or lower BSFC) might be a result of the lower backpressure produced by the turbocharger.

The transient response of the engine did not significantly vary with changes in the nozzle area. However, the nozzles had enough control over the peak boost pressures so as to eliminate the need for a "waste gate" in the exhaust system.

As to the emissions, both turbochargers decreased hydrocarbons

and carbon monoxide and increased oxides of nitrogen. Also, smoke was reduced over the entire range of the engine. The variable nozzle turbocharger operating at one of its extreme ends (+ 10° nozzle position), was somewhat better in improving the fuel economy of the engine. This was attributed to the higher air-fuel ratios it maintained.

In general, the compressor efficiency of the variable area turbocharger was lower than that of the conventional turbocharger, indicating that this first generation turbocharger has room for further design improvements.

20. ABSTRACT (Continue on reverse side if necessary and identify by block number) An advanced technology turbocharger featuring variable turbine nozzles, a broad operating range compressor, a ball bearing rotor system and a self contained lubrication system was manufactured, bench tested and applied to a 239 cid diesel engine. Fuel consumption and emissions data were collected during steady state engine performance testing. Compared to the "as received" turbocharged baseline engine the fuel consumption was improved at all conditions except medium speed/medium to high loads. Emissions were responsive to turbine nozzle position. Closed nozzles,

producing higher turbocharger speeds and intake manifold pressures, produced greater NO₂ and less CO, hydrocarbons and smoke than the baseline engine. Open nozzles produced the opposite results.

Analysis of the data reveal several areas for potential improvement. Both the compressor and turbine can be better matched to the engine as well as to each other. The transfer of heat from the turbine to the compressor can be reduced and additional nozzle travel can be utilized for further gains.

The general conclusion reached is that a fully developed advanced technology turbocharger can produce lower sfc, can flatten constant horsepower sfc versus engine speed characteristics and can be an effective control variable for emissions.

I. INTRODUCTION

The advantages of a turbocharger (TC) to an internal combustion engine are well known. It increases the maximum mean effective pressure and resultant maximum power output. It improves the specific fuel consumption by raising the mechanical efficiency under full load conditions. The fuel economy under part-load conditions can also be improved with a turbocharger by increasing the mean effective pressure and decreasing the engine speed without decreasing the desired power output. In spite of these benefits, the present-day turbocharger has limited pressure boost capabilities under low speed conditions. To overcome this difficulty, a turbine nozzle can be designed to improve the low speed pressure boost characteristics. If this route is taken a "waste gate", which wastes the exhaust and its energy, has to be provided at higher speeds and loads. In other words, one nozzle design is not adequate for optimum performance throughout the engine range. Therefore, a variable area nozzle was conceived to eliminate these problems. This type of TC can produce higher boost pressures at low speeds by changing the nozzle area and does not require a waste gate at high speeds. Aerodyne Dallas, as the prime contractor, developed such a turbocharger for use on small internal combustion engines. Southwest Research Institute, as a subcontractor, tested this turbocharger on an engine and determined its influence on fuel economy and emissions in a diesel engine under various loads and speeds. Also, the transient response with two different nozzle areas (positions) were examined. The results of this study are presented in this report.

The scope of this program was limited to testing the engine and turbocharger system in a test cell. In order to make predictions with respect to fuel economy in vehicular applications, some mathematical models were developed in this study and their results are also discussed here.

In the beginning of this program a diesel engine had to be

selected to match the variable area nozzle turbocharger which was being developed by Aerodyne Dallas. An engine equipped with a conventional turbocharger was chosen with the intention of comparing the performance of this conventional TC with that of the test TC. The procedure followed for choosing this engine is described in Appendix A.

II. BASELINE TESTS

Before any testing was commenced, the engine was subjected to a systematic break-in. This consisted of operating the engine initially on a stepwise schedule from idle to full load and speed, and later running it at only steady conditions of rated load and speed. During the break-in, the operating variables were recorded at four hour intervals. In order to determine whether the break-in process was complete or not, the BSFC and high idle fuel consumption were plotted with respect to time, and this plot is shown in Figure 1. Although there is some scatter of results on these plots, it appeared that both BSFC and high idle fuel consumption reached a plateau at about 100 hours time after which the break-in was discontinued.

The baseline tests were performed under steady-state conditions with and without the production turbocharger at 1000, 1500, 2000, and 2500 rpm. The maximum load at each of these speeds was determined either by the upper limit of the fuel pump rack travel or by a chosen minimum air-fuel ratio of 20. The part loads at any one speed were set at 75, 50, and 25% of the full (maximum) load. The engine was operated at each of these speed-load combinations until the conditions were stabilized and various measurements were made to determine the performance characteristics of both the engine and the turbocharger. The recorded data and computed results of these tests are shown in Appendix B. The properties of the fuel supplied to the engine are also included in this appendix.

Also the conventional emission tests were performed with and without the production turbocharger and these will be discussed in a following section on emissions tests.

Performance Characteristics

The important results of these baseline tests were extracted from tables in Appendix B and are shown in Figures 2 through 5. The variation of power output and fuel economy is depicted in Figures 2 and

FIGURE 1 - VARIATION OF HIGH IDLE FUEL CONSUMPTION AND BSFC
WITH RESPECT TO BREAK-IN TIME

3. These two figures indicate that at higher speeds, the turbocharger increased the power output of the engine quite significantly (almost 100%) and lowered the brake specific fuel consumption. The decrease in brake specific fuel consumption is mainly due to improvement in mechanical efficiency which is defined by

$$\eta_m = \frac{Bhp}{Bhp + Fhp}$$

where Bhp = brake horsepower

Fhp = friction horsepower

Under turbocharged conditions, the friction horsepower also increases, but not at fast as brake horsepower. If the friction horsepower increases as a lower rate than brake horsepower, the mechanical efficiency increases and thereby reduces the fuel consumption.

Another factor which also contributed to the lower specific fuel consumption was the decrease in fuel-air ratio with the turbocharger in operation. This decrease in fuel-air ratio improves the indicated thermal efficiency. At the engine conditions of interest, the increase in fuel economy is on the order of 2-5%. However, at lower speeds and lower loads, the turbocharger increased the brake specific fuel consumption, although the power output is slightly higher. This is probably due to relatively high exhaust backpressures at low load conditions. The slow rise in the maximum power output curve around 1500 rpm with the turbocharger is due to the limit set on air-fuel ratio (20).

As expected, the volumetric efficiency of the engine (Figure 4) decreased with increasing speed. However, the turbocharger reversed this trend above 1500 rpm.

Figure 5 indicates that the compressor isentropic efficiency and the pressure boost increased with speed and load, and the compressor efficiency was very low at low speed (1000 rpm) and low load (30 psi BMEP). These results and Figure 2 clearly indicate the limitations of the fixed geometry turbocharger.

FIGURE 5 - COMPRESSOR ISENTROPIC EFFICIENCY AND PRESSURE BOOST AT VARIOUS LOADS AND SPEEDS.

III. TESTS WITH VARIABLE NOZZLE

Turbocharger

The primary objective of these tests was to evaluate the performance characteristics of the Aerodyne turbocharger. This turbocharger was expected to yield higher boost pressures at low speeds, improve transient response, and produce more efficient control of peak boost pressures. In order to examine these features, a number of tests were conducted under steady state and transient conditions with different turbine nozzle positions (or areas). The steady state tests were further classified into maximum power output (full load) and part load tests. The maximum power output tests are discussed here first.

1. Maximum Power Output

The tests in this series were run between 750 and 2500 rpm with fuel rack position at maximum fuel delivery and turbine nozzle position at 0 and +10 degrees. The latter position set the nozzle area to a minimum. Altogether, a total of 12 tests were run, and the results are shown in Appendix C. The performance of the system was measured by the power output, brake specific fuel consumption, exhaust to intake pressure ratio, boost pressure, air flow rate, and air-fuel ratio. The foregoing variables, BMEP and turbine speed, are graphically shown in Figures 6 and 7.

The boost pressure, air flow rate, air-fuel ratio and turbine speed varied with nozzle position and were generally higher with +10 degrees setting at all speeds. However, in the cases of maximum power output, exhaust to intake pressure ratio and brake specific fuel consumption, the results were mixed. The power output and specific fuel consumption were better only at low speed with +10° setting. Also, the specific fuel consumption with both settings increased rapidly below 1000 rpm.

At higher speeds (above 1700 rpm) the decrease in

FIGURE 6 - MAXIMUM POWER OUTPUT, BMEP, BSFC, PRESSURE BOOST AND EXHAUST - INTAKE PRESSURE RATIOS AT VARIOUS SPEEDS - FUEL RATE THE SAME FOR EACH NOZZLE LEVER POSITION AT A GIVEN SPEED

FIGURE 7 - AIR RATE, AIR-FUEL RATIO, AND TURBOCHARGER ROTOR SPEEDS AT MAXIMUM POWER OUTPUT CONDITIONS - FUEL RATE THE SAME FOR EACH NOZZLE POSITION AT A GIVEN SPEED

power output and fuel economy with +10° setting was probably due to two factors: 1) increase in exhaust to intake pressure ratio (Figure 6), which affects the frictional power loss, and 2) the constancy of the amount of fuel supplied to the engine in both nozzle positions.

2. Part Load Tests

Next, tests were performed under essentially the same load and speed conditions at which the baseline tests with the conventional turbocharger were conducted. These load-speed combinations are given below:

<u>Speed</u> <u>RPM</u>	<u>Beam Load</u> <u>Lb.</u>	<u>Torque</u> <u>Lb-ft</u>
1000	31.0	40.7
1000	61.0	88.0
1000	93.0	122.0
1000	124.0	162.8
1500	26.5	34.8
1500	53.0	69.6
1500	79.5	104.4
1500	106.0	139.2
2000	35.0	50.0
2000	70.5	92.6
2000	105.0	137.9
2000	140.0	183.8
2500	37.0	48.6
2500	73.5	96.5
2500	111.0	145.7
2500	148.0	194.3

3. Influence of Nozzle Position

The effect of nozzle position for each load-speed combination is graphically shown in a figure following each table. Shown in these figures (D-1 through D-16) are BSFC, air-fuel ratio,

rate of fuel flow, air flow, compressor pressure boost, exhaust-intake pressure ratio, turbocharger rotor speed, and compressor isentropic efficiency. The results obtained in baseline tests with the AiResearch turbocharger are also indicated in these figures as bars originating from the ordinates. The isentropic efficiency was calculated using the following definition taken from Reference 1:

$$\eta_c \equiv \frac{T_1}{T_2 - T_1} \left\{ \left(\frac{P_2}{P_1} \right)^{0.285} - 1 \right\}$$

where η_c = compression isentropic efficiency
 T_1 = compressor inlet absolute temperature
 T_2 = compressor outlet absolute temperature
 P_1 = absolute pressure at compressor inlet
 P_2 = absolute pressure at compressor outlet

In all tests, air flow rate, A/F, compressor efficiency, rotor speed, and compressor pressure boost varied with the nozzle position, and size of the variation depended on speed-load condition. The ratio of exhaust to intake pressure also varied slightly. A summary of brake specific fuel consumption results for all speeds and loads is shown in the following table:

Summary of Brake Specific Fuel
Consumption Results

Speed RPM	Load Lb	BMEP psi	Nozzle Position		
			-8 and -10	0	+8 and +10
1000	31	25.7	.571	.574	.576

	111	92	.411	.404	.408
	148	122.7	.394	.395	.382

4. Comparison with Fixed Nozzle TC Results

The fuel economy (BSFC) and air flow rates determined for these two turbochargers under part-load conditions are summarized in Figures 8 and 9. These figures show that at low speeds the fuel economy with the Aerodyne turbocharger set at 0° nozzle position was significantly higher than that with the AiResearch turbocharger, and at higher speeds the differences were not significant. Similarly, one could compare the results of +10° nozzle position to those of AiResearch turbocharger.

Also, it was expected that the Aerodyne turbocharger would produce significantly higher boost pressure at lower speeds. But it did not produce this higher boost consistently with +10° nozzle position. This lack of consistency was probably due to difficulty in reproducing the same nozzle position. A related parameter, air flow rate, was also compared. At higher speeds (2000 rpm and above) the Aerodyne turbocharger, set at +10° nozzle position, had a higher flow rate than the conventional turbocharger, but at other conditions the flow rate was lower.

In view of the early development status of the Aerodyne turbocharger, it is best to judge its performance by comparing its overall performance against its own performance derived with a fixed nozzle position. The object of the foregoing comparison with the conventional (AiResearch) turbocharger was to explore whether there is any room for further improvement in the basic design of the Aerodyne turbocharger. It appears from the low speed test results discussed earlier that there is some room for further improvement since compressor

FIGURE 9 - AIR FLOW RATE WITH AIRESEARCH AND AERODYNE TURBOCHARGERS AT PART LOAD CONDITIONS

efficiency of the Aerodyne turbocharger was lower than the conventional. However, at 2500 rpm, and full load, the boost pressure ratio of the Aerodyne device could be controlled between 1.5 and 2.29 by varying the nozzle position. This range is probably adequate to eliminate the use of a "waste gate" under these conditions.

5. Transient Tests

In these tests, load, speed, and fuel flow were recorded using the instrumentation described in our previous report. Two different sets of tests were performed with nozzle settings at zero and 10°. In the first set, load was kept constant at 25 lbs. and fuel was supplied as a step function. The engine's speed response was recorded and is shown in Figure 10 for both settings. The response seems to be the same in both cases although one notices some delay for the fuel flow instrument to react.

In the second set of transient tests, the load was placed as step function and the response of fuel flow was recorded (Figure 11). Again, the differences in fuel flow response between zero and 10° nozzle settings were insignificant.

FIGURE 10 - SPEED RESPONSE OF THE ENGINE FOR A STEP INCREASE IN FUEL INPUT WITH THE AERODYNE TURBOCHARGER

FIGURE 11 - FUEL CONSUMPTION OF THE ENGINE FOR A STEP INCREASE IN LOAD WITH THE AERODYNE TURBOCHARGER

IV. EMISSIONS TESTS

The Emission tests are divided into two classes: 1) conventional and 2) smoke tests. The conventional emissions include hydrocarbons (HC), carbon monoxide (CO), and oxides of nitrogen (NO_x). These results will be presented first.

A) Conventional Emissions

The baseline tests were conducted with and without the production turbocharger. In each case, the emissions were determined by the standard 13-mode Federal Diesel Emissions Test procedure. A speed-torque schedule of this procedure is shown in Appendix E. The speeds, loads, air-fuel ratios, and emissions recorded in these tests are also shown in this appendix. These results (averages) are shown in a bar plot in Figure 12. The influence of the turbochargers is quite vivid in this figure.

The oxides of nitrogen and the other two emissions (hydrocarbons and carbon monoxide) varied in opposite directions with and without the turbocharger. The hydrocarbon and carbon monoxide emissions were about 4 times higher without the turbocharger while the oxides of nitrogen decreased by twofold. The benefit of the turbocharger on fuel economy is about 16%. This trend appears to hold also with the variable nozzle turbocharger while the same differences are more pronounced with 10° nozzle position. However, difference in fuel economies between zero and 10° positions is negligibly small.

B) Smoke Tests

These tests were performed at full load and previous baseline test conditions. However, the lowest loads in the baseline tests were not considered for these tests because the air-fuel ratios under these conditions would be certainly higher than 50 and no smoke can be measured. Therefore, altogether a set of 16 different load-speed combinations were chosen and 44 tests were performed under steady

FIGURE 12 - EMISSIONS AND FUEL ECONOMY OVER 13-MODE
FEDERAL DIESEL EMISSION CYCLE

conditions. These test conditions and the smoke results (in percent opacity) obtained are also shown in Appendix E. Along with the smoke, the air-fuel ratio is also listed. For comparison purposes among the turbochargers, the smoke results are shown in a bar plot in Figure 13. It appears that the smoke was lower with 10° position for which the air-fuel ratio was higher. To confirm this influence, the smoke in terms of percent opacity is plotted against the air-fuel ratio in Figure 14. The scatter in these results was probably due to repeatability which was about 1% at low levels and higher around 30% opacity. In general, the smoke decreased very rapidly up to an air-fuel ratio of about 25, and diminished slowly at higher air-fuel ratios. On the basis of these results, it can be concluded that the smoke is rigidly related to the air-fuel ratio regardless of load-speed condition and hardware. This is the reason why the fuel pump rack travel in baseline full load tests was controlled such that the air-fuel ratio would not fall below 20.

(ALL CONDITIONS)

V. DEVELOPMENT OF A MATHEMATICAL MODEL

In order to be able to predict the fuel economy and other operating characteristics of a diesel engine under steady state as well as transient conditions in vehicular applications, a mathematical model was developed for use with a computer. This model had provisions for incorporating the performance characteristics of a variable nozzle turbocharger. The model consisted primarily of a number of empirical formulae, which were derived from experimental data of various types of engines from Reference 1. Before this model was applied to the engines in vehicular applications, it was tested on naturally aspirated and turbo-charged engines operated under steady state conditions representing the 13-Mode Federal Heavy Duty Engine Cycle. A computer flow chart of this model for the case of a naturally aspirated engine operated over the 13-Mode Federal Diesel Emission Cycle is shown in Appendix F.

A. Model for Naturally Aspirated Engines

Two different naturally aspirated, direct injection type engines, for which experimental data was available, were chosen to verify the model. These were the Caterpillar Model 3208 and the Hino Model EH700E. The engine specification data, atmospheric conditions, and lower heating value of the fuel were supplied to the computer as input. The calculated results are shown in Tables F-1 and F-2. The actual experimental results obtained at Southwest Research Institute for these engines are shown in Tables F-3 and F-4.

In addition to the fuel consumption, the mathematical model also computed brake horsepower (Bhp), air flow rate, fuel-air ratio, specific exhaust energy and cylinder pressure just before the exhaust valve opens. The tabulated fuel consumption results are also plotted in Figures 15 and 16 for comparison purposes. The model results differed from those of experiments by only an average of about 5%. The maximum difference is about 11% at high load (Mode 8) for the Hino engine.

FIGURE 15 - COMPARISON OF ESTIMATED AND EXPERIMENTALLY DETERMINED FUEL CONSUMPTION RATES FOR CAT 3208 ENGINE - HEAVY DUTY 13 MODE TEST CYCLE

FIGURE 16 - COMPARISON OF ESTIMATED AND EXPERIMENTALLY DETERMINED FUEL CONSUMPTION RATES FOR HINO EH700E ENGINE - HEAVY DUTY 13 MODE CYCLE

An examination of Tables F-1 through F-4 shows that the computed and experimental fuel-air ratios are also very close to each other. Experimental results were not available to verify the specific exhaust energy and cylinder pressure (P4) shown in Tables F-1 and F-2.

B. Vehicular Application

With the agreement verified between the mathematical model and experimental results, the model was next applied to a small naturally aspirated diesel engine in vehicular use as a further check. The vehicle was a 1978 Volkswagen Rabbit. The measured fuel economy of this vehicle was available over the Light Duty Vehicle EPA cycle. The model was modified to include transmission gear ratios and drive shaft horsepower. The fuel consumed was estimated for each second of the cycle and the total consumption was determined by summing up over the entire cycle. A sample of the computer output is shown in Table F-5. The gear ratios and shift points used in this model are:

<u>Gear</u>	<u>Ratio</u>	<u>Speed Range</u>
1st Gear	3.45	0-15 mph
2nd Gear	1.94	15-25 mph
3rd Gear	1.37	25-40 mph
4th Gear (final)	1.10	40- mph
- - - - -		
Rear End (or Axle) Ratio	3.90	
Wheel Revolutions/Mile	918	

Several equations for the drive shaft horsepower were tried, including the one experimentally determined on a chassis dynamometer for a 2250 lb. compact car at Southwest Research Institute. These equations are given below along with fuel economies obtained on the computer.

Equation	Computed Fuel Economy	
	City mpg	Highway mpg
(1) $P = \frac{V}{375} \left(\frac{12W}{1000} + \frac{1.24AV^2}{1000} \right)$	69	63
(2) $P = 4.182 - .267V + \frac{1.1235V^2}{100} - 4.417V^3/10^5$	57	59
(3) $P = 4 + \frac{V}{338000} (8W + 1.1 AV^2)$	48	55
(4) $P = 5 + \frac{V}{338000} (8W + 1.1AV^2)$	45	53

where V = speed, mph

W = weight, lb.

A = frontal area, ft²

P = power, hp

Equation (1) = from Reference 2

Equation (2) = from unpublished Southwest Research Institute
experimental results

Equation (3) = from Wood, C.D., and Hambright, R.N.,
"Assessment of Supercharging Systems for
Gasoline Engines", Final Report prepared for
IHI Industries, Tokyo, Japan, August 14, 1977

Equation (4) = Modified equation (3)

The corresponding fuel economies obtained by EPA in their
actual tests were 40 and 53 mpg for City and Highway cycles, respectively.
Our computed fuel economy for the City cycle is somewhat higher than that
determined by EPA.

VI. MATHEMATICAL MODEL PREDICTIONS

The mathematical model which was employed earlier was further modified to accept the Aerodyne variable nozzle turbocharger. In this model, the intake manifold conditions were estimated by using the characteristics of the Aerodyne turbocharger, which were derived from the large number of tests we have conducted in this program. These characteristics were transformed into empirical equations and incorporated into the model.

A. Development of Empirical Equations

The important characteristics required for the model were those which could determine the conditions in the intake and exhaust manifolds. These were exhaust backpressure, compressor pressure boost, and temperature rise across the compressor. In order to evolve these characteristics in the form of empirical equations, the variables were plotted on several graphs in generalized form. These plots are shown in Appendix F (Figures F-2 through F-10). The variables were chosen such that these characteristics can be applied to any size engine.

Figures F-2 through F-4 depict the relationship between the pressure boost (P_i/P_n) and a function of BMEP and engine speed for all the nozzle positions. Similarly, the temperature rise across the compressor was plotted with respect to pressure boost in Figures F-5 and F-7. We attempted to develop the relations for temperature rise using the compressor efficiency and generalized engine variables. These efforts were not successful. Therefore, this temperature rise was plotted with respect to pressure boost. As can be seen from these figures, a fairly close relationship existed between these two variables.

The relationship between exhaust backpressure (P_e), intake manifold pressure (P_i) and BMEP is shown in Figures F-8 through F-10. Unlike in previous plots, a fairly linear relationship was found between P_e/P_i and BMEP. For all these plots empirical equations were developed with the help of a computer and shown on each plot. These

equations were later incorporated in the math model to determine the intake and exhaust manifold conditions. The complete model was again tested against the results obtained in the 13-mode Federal Heavy Duty Engine Emission Cycle for the John Deere engine with the Aerodyne turbocharger.

B. Model Prediction of Fuel Consumption in 13-Mode
Federal Emission Cycles

The experimental results for the 13-mode cycle obtained with the John Deere engine with the Aerodyne TC are shown in Tables E-4 through E-5. These were discussed in an earlier section. However, for comparison purposes, the results of fuel consumption were extracted from these tables and are shown along with the math model predictions in Figures 17 through 19. The model predictions for the naturally aspirated engine (Figure 17) differed by less than 8.1% from those of the experimental results except in Mode 12. In the case of turbocharged engine with +10° nozzle position (Figure 18) the maximum difference was about 8.7% in Mode 8. With zero degrees nozzle position (Figure 19) the agreement between the model predictions and experimental results was even better. Consequently, the empirical equations developed were considered to be satisfactory and were incorporated in the model to predict the fuel economy in vehicular applications. The results of this phase are discussed below.

C. Model Predictions of the Fuel Economy in Vehicular
Applications

Earlier, the fuel economy of a 1978 VW Rabbit equipped with a naturally aspirated diesel engine was determined over both the Urban and Highway cycles. The same vehicle and engine combination was chosen again, and the fuel economy was estimated for various combinations of transmission gear ratios and nozzle positions. Because the engine with a turbocharger can produce higher power output, the gear ratios were reduced from those of the naturally aspirated case. The following table shows the effective ratios of engine speed (N) to vehicle speed (V) in different gears.

TURBOCHARGER, -10° NOZZLE LEVER POSITION

N/V RATIOS AND IDLE SPEEDS
EMPLOYED IN THE MODEL

<u>Gear</u>	<u>Case 1*</u>	<u>Case 2</u>	<u>Case 3</u>	<u>Case 4</u>	<u>Case 5</u>
1	205.86	172.48	141.13	109.77	78.405
2	115.76	97.0	76.36	61.72	44.09
3	81.75	68.5	56.0	43.59	31.14
4	65.65	55.0	45.0	35.0	25.0
IDLE					
SPEED, RPM	975	875	775	675	575

The fuel economy was first estimated over both the cycles for different nozzle positions at a fixed N/V of 35. The results are given below:

MODEL ESTIMATES OF FUEL ECONOMY FOR VARIOUS NOZZLE POSITIONS

N/V in final gear = 35

<u>Nozzle Position</u>	<u>Urban Cycle mpg</u>	<u>Highway Cycle mpg</u>
-10	59	70
0	60	72
+10	61	73
-10°, 0° and 10°	60	72
Best of Three	61	73

In the fourth case of the nozzle position, the following schedule was used to select one of the three nozzle positions.

Schedule of Nozzle Position with BMEP

In the fifth case, called "best of three", the computer estimated the fuel consumption for all the three positions at every second of the cycle (Urban and Highway cycles are respectively 1369 and 764 seconds long) and chose the smallest of the three for estimating the final fuel economy. A counter employed in the program indicates that the fuel consumption with $+10^\circ$ position was the lowest all the time. Therefore, identical results were obtained for both $+10^\circ$ position and "best of three" positions.

The fuel economy for various N/V ratios and the best nozzle position ($+10^\circ$) were estimated in the same manner and shown below. These results are also plotted with respect to N/V ratio in Figure 20. The fuel economy very nearly increased linearly with decrease in N/V in the range tested.

MODEL ESTIMATES OF FUEL ECONOMY FOR VARIOUS N/V RATIOS

Nozzle Position $+10^\circ$

<u>N/V in Final Gear</u>	<u>Urban Cycle mpg</u>	<u>Highway Cycle mpg</u>
65.64	45	54
55	50	60
45	56	66
35	61	73
25	65	77

These figures are impressive for a vehicle of 2250 lbs. However, the model was not programmed to check out whether the engine had enough reserve power to accelerate the vehicle over the cycles. The model only predicts the maximum fuel economy theoretically possible by extrapolating the engine and turbocharger characteristics to lower speed operation. Therefore, caution has to be exercised in using these figures. Nevertheless, it is possible to design a low speed engine and produce enough power to drive a 2250 lb. vehicle over these two cycles without difficulty.

Reference 3 (referring to VW test results) indicates that the limit for final N/V is about 38 below which the performance

FIGURE 20 - MODEL ESTIMATION OF FUEL FOR VARIOUS N/V RATIOS

(i.e., acceleration) of the turbocharged VW engine in the Rabbit vehicle is not acceptable.

Also note that our model gave higher fuel economy for the naturally aspirated VW engine/vehicle than that experimentally obtained by EPA for the naturally aspirated engine over the EPA Urban cycle. Therefore, all the estimates for the Urban cycle are somewhat high.

VII. CONCLUSIONS

The following conclusions can be drawn from this initial study on a variable nozzle turbocharger:

1. The higher power output obtained from turbocharging allows the engine to operate at lower speeds and obtain higher fuel economy in vehicular applications.
2. Under some steady-state conditions the turbocharger yielded better fuel economy than that obtained with a fixed nozzle turbocharger.
3. At low speeds and part loads, the fuel economy with variable nozzle area turbocharger, set at zero degrees nozzle position, was significantly higher than that with conventional turbocharger, and at higher speeds the differences were not significant. This was probably due to different boost and exhaust pressure characteristics generated by the variable area turbocharger.
4. The variable nozzle area turbocharger did not consistently produce boost pressures higher than the conventional turbocharger at low speeds as expected, probably due to difficulty in reproducing the same nozzle position from test to test.
5. At 2500 rpm and full load conditions, the nozzle position regulated the boost pressure ratio between 1.5 and 2.29. This range of control is probably adequate to eliminate the need for a "waste gate" in the system.
6. On theoretical grounds, it was expected that an engine equipped with a variable nozzle area turbocharger would produce different power outputs with different turbonozzle areas. However, when tested under transient conditions, there was no change in transient response of the engine between zero and $+10^\circ$ nozzle lever positions.
7. The mathematical model predicts that a vehicle similar

to the VW Rabbit equipped with an Aerodyne type variable nozzle turbo-charger yields highest fuel economy over EPA driving cycles with +10° nozzle position.

8. The model estimates that the fuel economy increases almost linearly with decreases in final N/V ratio.

9. Either turbocharger used over the standard 13-mode Federal Heavy Duty Engine Emission cycle decreased hydrocarbon and carbon monoxide emissions by about four fold and increased the oxides of nitrogen about two times.

10. Either turbocharger decreased the smoke emission in the entire operating range of the engine. The Aerodyne turbocharger operating at the 10° position was somewhat better in smoke emissions than the production turbocharger at almost all speed-load conditions.

11. In general, the air delivery and compressor efficiencies of the variable nozzle turbocharger were lower than those of the production turbocharger.

APPENDIX A
CHOICE OF THE ENGINE

CHOICE OF THE ENGINE

The first task in this program was to select a diesel engine to match the turbocharger being developed at Aerodyne Dallas. A map of the compressor characteristics was furnished by Aerodyne for selecting a suitable engine. This map is shown in Figure A-1. The characteristics portrayed in this map were estimates and intended only for guidance.

Engine Size Determination

Normally, a turbocharger is selected from the performance characteristics of an engine. In this case, owing to the special nature of this project, an engine was selected from the characteristics of the turbocharger. The following procedure was followed:

According to Figure A-1, the compressor has a maximum flow capacity of about 320 cubic feet per minute (CFM). When this flow is compressed, the temperature and specific volume of the air in the intake system change. These thermodynamic quantities were determined and are shown in dimensionless form for various pressure boosts and compressor efficiencies in Figure A-2. Note that the plots indicated by $\eta_c = 1.0$ are for reversible adiabatic (isentropic) compression. Also computed and shown in Figure A-3 is the volume rate of air consumption for a 4-stroke engine. For the purpose of selecting the size of the engine, it was assumed that compressor and volumetric efficiencies would be 70% and 80%, respectively. A point shown by a circle on the high side of the compressor map (Figure A-1) was chosen as a design point. This circle marks the point at which the compressor is capable of delivering 285 CFM with 70% efficiency at a pressure boost ratio of 2.9. When the air is compressed to a 2.9 pressure ratio, the specific volume at the outlet decreases to 52% of inlet specific volume (Figure A-2). Hence, the volume rate of flow to the engine would be 148.2 CFM. To achieve this flow rate, the engine, which has a volumetric efficiency of 80%, should have a maximum NV_d (speed $\times$ CID) of about 6.4×10^5 (Figure A-3). Diesel engines, however, vary in their maximum speed. Therefore, another plot

(Figure A-4) for determining the displacement of the engine from NV_d was written. For the case of $NV_d = 6.4 \times 10^5$, if the maximum speed is 3500 rpm, the displacement would be about 190 cubic inches. On the other hand, if the maximum speed is only 2500 rpm, the displacement would be about 250 cubic inches.

Additional Considerations

The other factors which were considered include availability of parts, combustion chamber design, and type of intake system. For the purposes of this program in which the characteristics of the variable nozzle turbocharger are to be determined, the design of the combustion chamber (open or precombustion chamber) would not make a great deal of difference. Since it was intended as a part of the testing plan to compare the performance of the variable nozzle turbocharger with that of the fixed nozzle type of turbocharger, an engine already equipped with a turbocharger would be preferable.

A list of available diesel engines in the size range of 175 to 250 cubic inches is included in Table 1. In this size range, there is only one engine which is equipped with a turbocharger. This is the John Deere Model 4239T. Therefore, this engine was chosen. If a higher speed engine was to be selected, the Perkins Model 6-247 would have been a logical choice. The specifications of the Deere Model 4239T are shown in Table 2.
