INVESTIGATION OF VELOCITY FIELD ABOUT
A TWO DIMENSIONAL PLEXIGLASS OGIVAL
FOIL USING THE LASER DOPPLER ANEMOMETER

by

GARY J. TETTELBACH

Submitted to the Department of Ocean Engineering on May 12, 1978, in partial fulfillment of the requirements for the degrees of Ocean Engineer and Master of Science in Naval Architecture and Marine Engineering.

ABSTRACT

Until recently measuring the velocity of a fluid required the insertion of some instrument into the flow which would disturb the flow. The development of the laser dopler anemometer has created a means of measuring flow velocity using two intersecting monochromatic light beams, one of which has been shifted in frequency a prescribed amount. In order to use the type of laser dopler anemometer owned by M.I.T. the light beams must be able to traverse the test section and the scattered light be collected by the receiving optics. This requires a transparent model in order to measure the flow around the entire model. This thesis demonstrates the feasibility of such a method and is an account of the special techniques used to obtain the data.

ACKNOWLEDGEMENTS

The author wishes to thank his advisor, Professor J.E. Kerwin, for his guidance, efforts, and patience throughout this project. Also the assistance of Peter Min and Dean Lewis in the operation of the laser and tunnel is very greatly appreciated.

To John Hammond and Bill Shepherd the author also owes the many hours of work they saved him by letting him use their computer program and plexiglass foil respectively.

Finally the author wishes to thank Fred Haberlandt, Mark Lipsey and Pat Weiland for their help in reaching the point where he could do this thesis and then finish it.

I. INTRODUCTION

A variable speed water tunnel in a common laboratory for conducting hydrodynamic experiments involving Reynolds Number scaling. Until recently, however, there has been no reliable method in water tunnels of measuring either point velocities or pressures in a flow without disturbing the flow. Hot wire anemometers or pitot tubes require the insertion of an instrument into the flow and can cause a disturbance of the flow. The recent development of the laser dopler anemometer, LDA, has led to a method of obtaining point velocities without the insertion of any instrument into the flow which could alter the characteristics of the flow. The detailed operation and theory of the LDA will be covered in another section so let it suffice to say now that by having two monochromatic light beams, one of which has been shifted in frequency, intersect the velocity of the water at the point of intersection can be measured by collecting the scattered light.

The LDA at MIT is only capable of collecting the light scattered in the direction in which the beams are aimed. This means that the light must be able to pass completely through the water tunnel when attempting measurements. There is no problem with this if the only measurements needed are upstream or downstream of the model in the tunnel because the viewing ports or windows are transparent plexiglass. Measurements cannot be taken around a model which is opaque, however.

The purpose of this thesis is to demonstrate that by using a transparent model; in this case a two dimensional, plexiglass, ogival section foil; the entire velocity field around the model can be obtained. The problems associated with this involve both the optical characteristics of the model and the intensity of the scattered light when it has passed through the model. The positioning of the instrumentation that receives the scattered light is critical and resolution of the optical effect of the model on the scattered light becomes difficult. Any imperfections in the model also tend to diminish the intensity of light which eventually reaches the receiving optics. The results contained within this thesis are not necessarily intended to be extraordinarily revealing in hydrodynamic significance but rather are intended to describe and verify a new technique in collecting detailed accurate velocity data around a transparent model in the variable speed water tunnel using a laser dopler anemometer.

II. EXPERIMENTAL SET UP

This experiment was conducted in the variable speed water tunnel at MIT. The tunnel is a recirculating type tunnel with a test section which is basically a rectangle twenty inches high, twenty inches wide and with a region of undisturbed parallel flow approximately four feet in length. The model was held in place using the rudder and keel dynamometer on the top and just a sealed shaft through the bottom window. This is the normal method for testing two dimensional foils at the MIT facility. No splitter plate was used in order to allow maximum span of the foil which would reduce any end or wall effects. The foil was aligned in the tunnel to zero angle of attack by measuring the distance from the wall. The telescope atop the dynamometer was then zeroed and used to adjust the angle of attack thereafter.

Because of the lens effect of the foil, velocity measurements were only taken on the transmitter side of the foil. The lens effect changed the crossing angle of the beams which made the calibration of volts to feet per second and the position of the measuring volume unknown. To obtain measurements on both sides of the foil, the foil was flipped end for end.

The actual construction of the foil was done by Bill Shepherd for a 13.04 project and donated to the author. The method of construction was to take a rectangular piece of plexiglass and first use a milling machine and large rotating

table bed to get a circular arc. The second step was to polish the foil until transparent with progressively finer sandpaper and polishing compound. The difficult areas were the leading and trailing edges because of their fineness. Keeping the circular arc and yet getting rid of all defects and scratches requires more sophisticated equipment than was available. However, the foil is a masterpiece of hand craftsmanship and far better than the author could have done personally. The final foil dimensions are shown in figure 1.

The laser itself was resting on a base capable of movement in two degrees of freedom. The one degree of freedom in which the laser could not move was a chordwise movement. This was a very time consuming restriction because to move from station to station along the chord both the transmitting and receiving optics had to be manually picked up, moved, and realigned again. The base on which the laser rested never had to be moved because large enough plywood platforms were installed to allow enough laser movement to position the laser at all stations on the chord. Figure 2 shows the receiving optics, test section and dynamometer with telescope. Testimony to the quality of the foil is that it was in the test section when the picture was taken. Figure 3 shows the transmitting optics, vertical adjustment wheel and the station marking taped on the outside of the test section window.

FIGURE 1 - Foil Dimensions

FIGURE 2 - Receiving Optics, Test Section, Dynamometer

FIGURE 3 - Transmitting Optics, Vertical Adjustment, Station Spacing

To determine the precise position of the measuring volume, the chordwise position of the stations had to be determined. This was done by using the laser to mark on a tape placed on the outside window of the test section the exact position of the leading and trailing edges. This tape was then marked off in cosine spacing and left taped to the window for the duration of that test. The chordwise positioning of the laser was the least precise measurement of the experiment.

The rest of the electronics including the signal processor and tracker for the laser, the voltage to frequency converter, the time averagers for the impeller RPM and converter, and the oscilloscope were all mounted on a table or moveable stand. These locations are strictly a matter of personal preference and of no relevance to the experiment.

III.1 LASER THEORY

The author had difficulty when beginning his research finding a reference which was either complete, concise, or clear on the actual theory of laser dopler anemometer operation. In the following section is a brief overview of laser theory, but for anyone interested in specifics Peter Min's doctoral thesis, "Numerical and Experimental Methods for the Prediction of Field Point Velocities Around Propellor Blades" is to be completed in May 1978 and contains the best reference the author has been able to find.

The laser dopler anemometer is comprised of three major groups, the transmitting optics, the receiving optics, and the signal processing electronics. The transmitting optics produces a single monochromatic beam which is then split by a prism into two beams. One of these beams then passes through the Bragg cell which shifts the frequency of the light by a piezo-electric process. This shift can be varied from .01 to 20 megahertz depending on the expected water velocity fluctuations, and allows the electronics to recognize negative velocities. The two beams are then focused by a lens of known focal length. In this experiment the focal length was 309 mm. A longer focal length is necessary if data is to be taken the complete width of the tunnel but this lens was adequate because data was only taken on one-half of the tunnel. The point of intersection of the beams is the measuring volume,

which is approximately .227 mm in diameter. In the measuring volume the intersection of the light beams sets up a series of frequency fringes. As a particle in the water passes through these fringes light is scattered at a frequency proportional to the speed of the particle. The light is scattered in all directions but the maximum intensity is in the direction of the laser beams and equidistant from each beam. The velocity measured is the velocity in the plane of the two beams and perpendicular to the line that bisects the two beams.

The receiving optics is placed on the same structure as the transmitting optics on the opposite side of the tunnel and aligned with it so as to collect the maximum intensity of scattered light. There is a lens which focuses the light on a photo-detector. This photo-detector produces a voltage proportional to the frequency of the scattered light.

The electronics takes the signal from the photo-detector processes it through a series of filters, and tracks it. The tracker produces a visual display of the voltage over each second. With the electronics the number of particles counted per second and the filtering can all be adjusted to the conditions present. To average the voltage over ten seconds the voltage was converted to frequency and averaged over ten seconds.

III.2 LASER DOPPLER ANEMOMETER TECHNIQUES

This section is intended to be a documentary on the author's learning process while conducting this experiment. Hopefully, by reading this anyone who attempts a similar experiment can avoid many frustrations and pitfalls.

To operate a laser dopler anemometer takes patience and experience. There is an art involved and practice is the best way to acquire expertise. Probably the most intelligent move the author made in the collection of data was to start testing in the first week of November of 1977. This one week was not very productive in the way of data taking but extremely important in learning how to operate the laser. Between this week and the next opportunity the author had to test in the water tunnel there was time to evaluate methods and procedures and study more on the aspects of operation that needed improvement. The data collected in February of 1978 not only has a higher confidence level it also was taken much faster and more easily.

The first step in the learning process was in determining the position of the measuring volume. The method of determining chordwise position was improved by two simple procedures. First, the author learned that by unscrewing two screws the laser beams could be aligned vertically. This greatly aided in determining the exact position of the leading and trailing edges. Secondly, there is a smoked glass filter

which decreases the intensity of the laser beams. By decreasing their intensity aligning was easier and the positioning at each station more accurate because the light could be made to a much finer dot on the marking tape.

An order of magnitude improvement in accuracy was made in determining the distance of the measuring volume from the foil surface between November and February. For the initial tests the distance of the laser lens from the tunnel window was measured and measuring volume position was in terms of a distance from the tunnel wall. The problem was determining the exact position of the foil in terms of distance from the wall. The solution was to place the measuring volume just on the edge of the foil visually and then record the laser position by reading the pointer on the movable base of the laser. The other data points were determined by a simple linear relationship of laser movement to measuring volume movement. The only problem with this method was at stations one and nine. There the foil was so thin it became difficult to determine on which side of the foil the measuring volume was.

The determination of free stream velocity was also improved between test periods. The procedure of reading the manometer for each data point was not only tedious to record but tedious to convert to speed later. By taking and averaging the impeller RPM over ten seconds and taking a manometer reading over that same ten seconds a linear relationship

between RPM and free stream velocity was developed. By averaging twenty-five of these readings a coefficient in terms of velocity per RPM was developed. A new coefficient had to be determined for each angle of attack, however, because the blockage of the model changed for each case. Another convenience of this was that the output of the laser tracker was averaged over the same ten second period.

To overcome the problem of the optical effect of foil acting like a lens was of great concern at first but really turned out to be a minor problem. After a brief study of optics, the author decided calculating the position of the receiving optics would be futile at best. The best method turned out to be visual adjustment. First two pieces of tape were placed on the window on the receiving optics side to block the two laser beams from exiting the tunnel test section. This was important for safety to prevent any eye damage while visually focusing. The receiving optics was then manually moved on the plywood base until the focusing pattern was symmetrical and at maximum brightness. As a result of the focusing effect of the foil the receiving optics were only perpendicular to the window at zero degrees angle of attack and at station five. Maneuvering the receiving optics while looking through the eyepiece was awkward and certainly not precise but it was effective. At the stations near the leading and trailing edges re-focusing was required about every other data point and this

was tedious, but there was no better alternative. To align the receiving optics exactly so as not to require such frequent refocusing would have taken exorbitant amounts of time if possible at all.

In November it was obvious that there were defects in the foil, particularly near the leading and trailing edge. By moving just fractions of an inch spanwise, reception of the signal improved greatly because the light was not being dispersed by a nick or imperfection in milling. This vertical movement was also used to avoid window scratches. Another method of improving reception, dealing with the model and windows was to ensure they were clean. Wiping them both with soft tissues and alcohol has a much more dramatic effect than it would appear.

Of the three areas of adjustment; the foil, the water, and the laser; the water could be least affected or adjusted. If the water is very cold, below sixty degrees fahrenheit, readings are very difficult to obtain. The number and type of particles also is important. There are several types of additives on the market today which can be added to improve water characteristics but they are costly and do not stay in the system. Ordinarily there were enough particles in the water for adequate laser operation, but if more particles were needed the addition of four teaspoonsfull of "Coffeemate" was helpful. These particles dispersed evenly in the tunnel

and appeared to be the correct size to improve operation. The question of when should particles be added is best answered by experience. If all else seems to be functioning properly but the signal will not track the addition of particles can't hurt.

Most of what appears to be "tricks of the trade" in obtaining meaningful data are involved with adjustment of the laser itself. The references mentioned in section 3.1 are very helpful in understanding how the laser operates and how to obtain a signal when conditions are ideal. In the case of this experiment, however, conditions were seldom even close to ideal. Therefore, several ways to improve the signal characteristics or detect weak signals were devised. The first step was to do the easiest station, station five, first to ascertain that all of the equipment did indeed operate and the laser was aligned. Once the laser beams were aligned they did not abruptly go out of alignment. The deterioration was gradual and if suddenly one data point would not track the chances were very slim that it was due to misalignment of the laser if the previous data point had a good signal. The quality of the signal oftentimes could be improved by blocking out unwanted beams. The beam that was shifted in frequency in the Bragg cell came out of the transmitting optics surrounded by three extraneous beams of weaker intensity. These beams often

would scatter light when they impinged on the foil and increase the noise in the received signal enough to make the signal indecipherable. By taking a small piece of black tape and carefully placing it on the tunnel window these beams could be removed. To insure the correct beam was still entering the water the Bragg cell was turned off. This eliminated the frequency shift and left only one beam, the correct one. Once it was determined the correct beam was not blocked the Bragg cell was turned on again.

The laser dopler anemometer will always produce a reading of some kind. To master the LDA is to know when that reading is the correct reading for the water velocity in the measuring volume. The most helpful instrument in doing this was the oscilloscope. Unfortunately, the author did not use the scope until test forty-four out of sixty-nine tests. But in terms of accuracy of data this was a major breakthrough. What the oscilloscope did was visually display the signal coming from the photomultiplier and allowed confirmation that it was indeed the true signal. It could, of course, display more but the key to determining good data from erroneous noise was looking at the raw signal before it entered the signal processor. Sometimes this was more difficult than others. If the signal was very weak and there was very little noise, a magnificent looking signal showed on the scope. This was the frequency shifter dominating the

signal. Whatever megahertz shift was set on the frequency shifter showed up on the oscilloscope looking very much like the true signal. An easy way to discern this was to vary the water speed in the tunnel. The wave length of the raw signal was proportional to the speed of the water. If the wave length increased as the water speed decreased, the true signal was being received. If the wave length remained constant, the signal was actually the frequency shifter.

When the signal was very weak coming from the photomultiplier two things helped to improve its visibility. First, if the signal went strictly to the oscilloscope the power was at a maximum. It was much more convenient to use a T connection and have the signal go to both the signal processor and the scope but this reduced the power of the signal and often made it too weak to discern. When even this was not enough, a second alternative was to have the signal go through the signal processor and display the amplified input on the oscilloscope. This was only used when the signal was too weak by itself and the confidence in this signal was much lower than the raw signal.

The oscilloscope could in no way have replaced the optical focusing procedure, but it did assist. After the visual pattern was focused and centered and the photomultiplier put in place, fine adjustments in centering could be made while watching the signal on the scope. The

best way to go about this was to visually focus using the large aperture mask. This gave a more clearly defined pattern to focus. Before replacing the photomultiplier, the small aperture mask was placed on the receiving optics to reduce the noise and make the signal clearer. Then the centering set screws were adjusted while watching the raw signal on the oscilloscope.

At seven of the sixty-six stations there arose a problem which the author could never resolve. Each of these cases occurred near the leading or trailing edge but most dramatically near the trailing edge. At particular distances from the foil a beam would impinge on the very tip of either the leading or trailing and in essence spray light directly into the focusing optics. This not only made enough noise to drown the signal but made visual focusing hazardous at best. Figures 4 and 5 show this phenomenon. The author believes this was caused by the leading and trailing edges being the least perfect in curvature and thus causing strange optical effects. Vertical movement made no difference, however, so this theory is suspect. The problem was more acute at the trailing edge because of the multiple beams coming from the beam which went through the frequency shifter. These beams came from the upstream side of the laser transmitter, crossed the other beam and then impinged on the foil downstream of the other beam. This meant that the trailing edge had a greater range in which a beam could hit the edge and scatter light into the receiving optics.

FIGURE 4 - Trailing Edge Scattering

FIGURE 5 - Trailing Edge Scattering

IV. DISCUSSION

The reason for picking an ogival shaped foil was to facilitate the manufacture of the foil and the theoretical calculations. By using a Karman-Trefftz transformation the conformal mapping of a uniform flow around a circle to a uniform flow around the foil shape was relatively easy. A computer program entitled Karman (Trefftz) developed by John Hammond for Professor Kerwin made the process of calculating pressure coefficients very easy. The parameters used were circle center coordinates of $x = 0.0$, $y = .105098$ and $\lambda = 1.8743593$. Figures 6 through 10 show the pressure distributions calculated. The actual data was initially plotted into the velocity profiles shown in figures 11 through 13. The points just outside the boundary layer were determined from these plots and used to calculate the pressure coefficient, C_p , which was defined as

$$C_p = 1 - (U_n)^2$$

where U_n is the nondimensional velocity. Determining where the boundary layer ended was not very distinct at some stations but a best visual estimate was used. The plots of the experimental pressure coefficients are shown in figures 14 through 16.

FIGURE 7 - Karman-Trefftz Pressure Distribution; $\alpha = +2.0$

FIGURE 8 - Kármán-Trefftz Pressure Distribution, $\alpha = 0.0$

FIGURE 9 - Karman-Trefftz Pressure Distribution, $\alpha = -2.0$

FIGURE 12 - Velocity Profiles, $\alpha = 0.0$

FIGURE 13 - Velocity Profiles, $\alpha = -4.0$

FIGURE 14 - Experiment Pressure Distribution, $\alpha = +4.0$

FIGURE 15 - Experimental Pressure Distribution, $\alpha = 0.0$

FIGURE 15. Experimental Pressure Distribution, $\alpha = -4.0$

Obviously the difference in comparing the theoretical pressure distributions with the experimental is viscous effects. These effects cause approximately a 75 percent reduction in lift as a result of the boundary layer growth. To compare experimental results with the inviscid results, a simple calculation can be made using the approximation

$$C_L = 2\pi\alpha + 4\pi\left(\frac{f_o}{C}\right)$$

where $2\pi\alpha$ is the flat plate approximation and $4\pi\left(\frac{f_o}{C}\right)$ is the camber approximation for the linearize problem with $\left(\frac{f_o}{C}\right)$ being the camber ratio. At zero angle of attack all lift is from camber and any reduction in lift due to viscous effects would appear as an apparent reduction in the angle of attack. A 25 percent reduction would then mean

$$2\pi\alpha' = .25\left[4\pi\left(\frac{f_o}{C}\right)\right]$$

where α' is the apparent reduction angle. For this foil $\left(\frac{f_o}{C}\right) = .05$ and thus

$$\alpha' = 1.4^\circ$$

This means that figure 15, $\alpha = 0.0$ of the experimental results should compare with figure 9, $\alpha = -2.0$ of the theoretical results most closely as it does.

The same approximation of C_L can be used to determine the angle of zero lift.

$$C_L = 2\pi\alpha + 4\pi\left(\frac{f_o}{C}\right) = 0$$

$$\alpha = -5.7^\circ$$

The experimental results in figure 16, $\alpha = -4.0$, show close to a zero lift distribution.

The boundary layer growth shown in the velocity profile graphs of figures 11 through 13 is at times inconsistent. This is most likely due to the fact that the closer to the foil the more difficult it was to obtain good data. Therefore, accurate reliable data in the boundary layer was not taken until the learning process with the laser dopler anemometer was completed. However, there are several significant observations to be made on each figure.

In figures 14 and 15, $\alpha = +4.0$ and 0.0 , station 0 shows no distinct boundary layer but a gradual retardation of the flow upon approaching the stagnation point. At station 10 on the convex side of figure 14, $\alpha = +4.0$, the profile shows the very beginning of backflow around the trailing edge. The figure of most interest is figure 16, $\alpha = -4.0$. Here both station 0 and station 1 on the convex side show a gradual retardation suggesting the stagnation point is on the upper

surface between the two stations as would be expected. The flat side at station 2 shows a backflow indicating or hinting at the presence of a separation bubble in that region and then reattachment by station 3. The entire flat side of this figure shows a region thicker than the boundary layer should be of retarded flow. Since the laser dopler anemometer gives an average velocity this could be assumed an area of major turbulence.

V. CONCLUSIONS AND RECOMMENDATIONS

This thesis shows that using the laser dopler anemometer and a transparent model is a good method of obtaining accurate and reliable data about the velocity field around the model. The method does require, however, a certain expertise in the operation of the LDA and this can only be gained by experience. The comparison of theoretical calculations and actual data bears out that the technique is a good one. They also show in the case of the boundary layers in the velocity profiles that as the author gained more experience the data became much better. The fabrication of the foil also is very important and the better job done on that, the easier the collection of data would be.

Although this method is adequate, the author recommends that an attempt or detailed analysis be made of collecting the same data with a different foil orientation. By placing the foil in a horizontal position between the two side windows and having the laser beams radiate parallel to the foil span, the need to pass the beams through the foil would be eliminated.
