NOTICE

When U.S. Government drawings, specifications, or other data are used for any purpose other than a definitely related Government procurement operation, the Government thereby incurs no responsibility nor any obligation whatsoever, and the fact that the Government may have formulated, furnished, or in any way supplied the said drawings, specifications, or other data is not to be regarded by implication or otherwise, as in any manner licensing the holder or any other person or corporation, or conveying any rights or permission to manufacture, use, or sell any patented invention that may in any way be related thereto.

This interim report was submitted by Computational Sciences Division, Air Force Human Resources Laboratory, Brooks Air Force Base, Texas 78235, under project 6323 with HQ Air Force Human Resources Laboratory (AFSC), Brooks Air Force Base, Texas 78235.

This report has been reviewed by the Office of Public Affairs (PA) and is releasable to the National Technical Information Service (NTIS). At NTIS, it will be available to the general public, including foreign nations.

This technical report has been reviewed and is approved for publication.

20. ABSTRACT (Continue on reverse side if necessary and identify by block number)

This report contains the results of a study to compare the classification accuracy of the Motivational Attrition Prediction (MAP) method to the classification accuracy of other statistical algorithms capable of predicting involuntary separation within the Air Force enlisted force. The MAP computer program, which was implemented on the UNIVAC 1108 computer system at the Air Force Human Resources Laboratory, was modified to increase its data-handling and computational capabilities and was thoroughly tested. This report includes a description of the computerized statistical algorithms, subsample selection from the first-term airman population, independent and dependent variables, model formulation and analysis, comparison of required computer resources, and related research efforts.

PREFACE

The research was completed under project 6323, Personnel Data Analyses; task 632305, Development of Analytic Methodology for Air Force Personnel Research Data.

Work Unit 63230511 was established in response to a Request for Personnel Research (RPR 77-14), entitled "Development of Improved Methods for Predicting Involuntary Separation" and initiated by the Air Force Manpower and Personnel Center.

The author wishes to express his appreciation to SrA Westley J. Richards for implementing and testing the MAP computer program on the AFHRL UNIVAC 1108 computer system and to A1C Scott I. McFarlane for increasing the program's data-handling and computational capabilities. The author also wishes to thank both of these individuals for the assistance they provided in carrying out the computer processing and data reduction phases of this study. Special acknowledgment goes to Dr. Janos B. Koplyay and Mr. C. Deene Gott for their contributions in shaping the direction of this research effort and to Mr. Larry K. Whitehead for his programming assistance.

PREDICTING INVOLUNTARY SEPARATION OF ENLISTED PERSONNEL

I. INTRODUCTION

In the spring of 1977, Request for Personnel Research (RPR) 77-4, Development of Enlistment Standards for the Armed Forces, was sent from the Air Force Military Personnel Center (AFMPC) [now known as the Air Force Manpower and Personnel Center] to the Air Force Human Resources Laboratory (AFHRL). The basic objectives of RPR 77-4 included the following: (a) to develop a substitute for the current Air Force enlistment standard, (b) to evaluate the Military Service Inventory (MSI) as a predictor of attrition, and (c) to test the relative efficiency of the Motivational Attrition Prediction (MAP) method in a binary classification problem, such as the prediction of retention versus attrition. Evaluation of the request by the various divisions of AFHRL eventually led to the decision to cancel RPR 77-4 and to establish two new requests, RPR 77-13, Development of Alternative Air Force Enlistment Standards, and RPR 77-14, Development of Improved Methods for Predicting Involuntary Separation. The purpose of establishing two new requests in place of the original was to facilitate the appropriate separation of research responsibility within AFHRL, i.e., the first new request dealt with objectives (a) and (b) of RPR 77-4 listed above, and the second dealt with objective (c). The Personnel Research Division (AFHRL/PE) was tasked with RPR 77-13 and the Computational Sciences Division (AFHRL/SM) with RPR 77-14.

This report describes the research carried out by AFHRL/SM in support of RPR 77-14. The basic problem concerns predicting involuntary separation (attrition) within the Air Force enlisted force. Specific objectives of this study include the following: (a) to implement the MAP computer program on the AFHRL UNIVAC 1108 computer system, (b) to compare the predictive efficiency of the MAP method with that of the AFHRL multiple linear regression technique (referred to as TRICOR), (c) to compare MAP and TRICOR with other predictive methodologies capable of handling binary criterion situations, and (d) to evaluate the various predictive methodologies using other binary criteria such as graduation/elimination from Technical Training (TT), Basic Military Training (BMT), and Undergraduate Pilot Training (UPT). This last objective (d) is not addressed here but will be the subject of a subsequent report. The results included here are restricted to predicting involuntary separation.

The next section describes the statistical methodologies compared. Three predictive methodologies associated with regression theory were considered for use in this study. These methodologies will be referred to as ordinary least squares (OLS), standardized least squares (SLS), and weighted least squares (WLS). OLS was the methodology employed in the analyses described in Section V and, hence, is discussed in the following section. SLS has been compared to MAP with regard to classification accuracy in several problem settings (Beatty, 1977). Basically, the use of standardized least squares allows the creation of a predictive model that is independent of the units of measurement since the independent variables have been normalized to zero mean and unit variance. This methodology was tested in the present study and, as expected, yielded classification accuracy results equivalent to those for OLS. An in-depth examination of the predictive efficiency of SLS will be conducted in the follow-up efforts referred to in objective (d) and discussed briefly in the last section of this report. A consideration in applying OLS to a predictive problem involving a binary criterion is that the error variances are unequal. Although the application of OLS results in unbiased estimates of the regression coefficients, the estimates are inefficient since they will not have the minimum variance property among the class of unbiased estimators. Performance of the WLS computations (Draper & Smith, 1966) results in constant error variances allowing a possible decrease in the variance associated with each estimated regression coefficient. Although WLS offers a potential improvement to OLS, its capability to accurately classify individuals as successes/failures was not examined in detail since (a) a study using a quickly assembled WLS computer programming package produced classification accuracy results similar to those for OLS, (b) some WLS analyses yielded nonsensical results, and (c) implementation of an efficient WLS computer programming package to perform analyses similar to those for OLS would not have allowed timely completion of the milestones associated with this research effort.

Following the discussion of statistical methodologies employed are sections on the airman population, description of predictive variables, selection of subsamples, model formulation and analysis, and comparison of computer resources required. Numerous tables are displayed for comparative purposes, and results and recommendations are discussed last.

II. DESCRIPTION OF STATISTICAL METHODOLOGIES

The statistical methodologies examined in this study for their ability to correctly classify individuals as successes/failures are the following: TRICOR, a computer programming package containing a stepwise regression algorithm; MAP, a computerized algorithm based on maximum likelihood estimation and utility theory; and BAYS, a computerized algorithm utilizing Bayes' formula. The stepwise regression theory of TRICOR is described in numerous publications (Dixon, 1968; Draper & Smith, 1966; Efroymson, 1960; Goldberger, 1961; Goldberger & Jochems, 1961; Pope & Webster, 1972), and the maximum likelihood estimation and utility theory of MAP is documented in AFMPC publications (Dempsey & Fast, 1976; Dempsey, Fast, & Sellman, 1977). A brief description of the important characteristics of BAYS will be presented here, and a more detailed description is available in the computer-based SMSM program documentation library at AFHRL.

Although reader familiarity with stepwise regression theory and MAP maximum likelihood estimation and utility theory is assumed, a comparison of the limitations of the computerized implementations of the two methodologies as they exist on the AFHRL UNIVAC 1108 computer system is important to researchers who want to use either of the programs. When interfaced with a compatible hit table subroutine, TRICOR has the capability to accept a data file containing information on up to 399 predictor variables and 9,999 cases per subsample. In contrast, the current version of MAP can accept a data file containing information on 20 predictor variables and the maximum number of cases allowable can be estimated by the following formula:

$$\mathrm{NCASES} = \frac{160{,}000}{\mathrm{NVARS} + 3}$$

where NCASES represents the number of cases and NVARS represents the number of independent variables. For example, MAP problems utilizing 5, 7, 13, or 17 independent variables allow processing of data files containing approximately 2×10^4, 1.6×10^4, 10^4, or 8×10^3 cases, respectively. An important consideration for a potential MAP user is that the program utilizes an iterative technique (Brown, 1967) to solve a system of simultaneous nonlinear equations. As will be observed in subsequent analyses, the computerized algorithm does not always converge, denying the researcher a direct comparison of the predictive accuracies of MAP versus TRICOR or BAYS.

BAYS, a computer program whose development was based on the Attribute Bayesian Classification Decision (ABCD) technique (Moonan, 1972), utilizes Bayes' formula to compute probabilities of class membership for each case, with the result that an individual is assigned to the criterion category which has the highest a posteriori probability. An important improvement to the ABCD technique was the implementation of a stepwise procedure in the model-building algorithm whereby variables can be eliminated after they have been added to the predictive scheme. Hit tables, which indicate the number of cases correctly classified, are used to select the predictor variables that most effectively discriminate among the criterion categories. At each stage of the model-building procedure, the predictive composite is formed which corresponds to the highest classification accuracy resulting from all possible additions (or deletions) of one variable to (or from) the predictive composite existing at the previous stage. As described in Section V, several random samples of the population were constructed specifically to estimate empirical probabilities.

Aside from run time constraints which will be discussed later, BAYS has the capability to accept a data file containing information on 200 independent variables having 63 categories each; however, the total number of categories for all independent variables must not exceed 2000. Since the application of the

BAYS algorithm is restricted to analysis of categorical independent and dependent variables, a categorization was performed on each independent variable with the idea of minimizing the amount of information lost in the process. This categorization requirement precluded a BAYS analysis of models containing interactive terms. At present, BAYS does not have the capability to classify individuals in an operational setting since it does not retain information on the disposition of each case. Information is retained only on the disposition of a group of cases in the form of a hit table. The performance of a proposed work effort would rectify this deficiency. In addition, the work effort proposes that BAYS be modified to utilize a variable packing factor for storing cases on a record, dynamic storage allocation, and computational shortcuts to decrease the number of data file passes.

III. FIRST-TERM AIRMAN POPULATION

The population for this study, which consisted of 11,231 airmen who entered the Air Force between April and July 1972, was selected for two major reasons: (a) the data were immediately available since the population comprised a data file prepared to support RPR 77-13, and (b) the population was characteristically similar to the one examined by Dempsey et al. (1977) which consisted of airmen who entered the Air Force between June and August 1972. In order that each case could be classified into a criterion category in a meaningful way, separation designation numbers (SDNs) were grouped and recoded in the following manner: SDNs reflecting normal separations or active duty status were recoded to a value of one and SDNs reflecting undesirable losses such as marginal productivity/inaptitude, unfitness, or unsuitability were recoded to a value of zero. This definition of the criterion categories was coordinated with AFMPC. As a result, of the 11,231 airmen in the population, 7,694 were recoded to "one" with the remaining cases recoded to "zero" (i.e., 68.5% of the cases were coded as successes, and 31.5% were coded as failures).

IV. DESCRIPTION OF PREDICTOR VARIABLES

As previously mentioned in Section III, predictor variable information was available from a data file prepared to support RPR 77-13. Information used in the creation of that file originated from a data file created for a previous work effort and the Processing and Classification of Enlistees (PACE) file at AFHRL. Complete information on the following variables was available for all airmen in the population:

1. Scores from the aptitude tests (Administrative, Mechanical, Electrical, and General) of the Armed Services Vocational Aptitude Battery (ASVAB).

2. Scores from the Armed Forces Qualification Test (AFQT).

3. Prediction of drug use admission (PDA) score (LaChar, Sparks, Larsen, and Bisbee, 1974).

4. Military Service Inventory (MSI) score (Dempsey et al., 1977).

5. Education – Number of years required to reach highest level of education.

6. Dependents – Coded as 0 (1) denoting number of dependents at enlistment less than or equal to 2 (greater than 2), i.e., this variable was assigned a value of 0 if the number of dependents at enlistment was less than three, and assigned a value of 1 if the number of dependents at enlistment was greater than two.

7. High school courses – The following courses were coded as 1 (0) denoting completion (noncompletion):

   a. Algebra

   b. Biology

   c. Chemistry

   d. Art

e. Geometry

f. Photography

g. Physics

h. Trigonometry

i. English

j. Home Economics

8. Age – Age in years at enlistment.

Tables A1 through A13 in Appendix A present distributions, means, standard deviations, and intercorrelations of the predictor variables for the 11,231 case population. Many of the aforementioned variables were recoded (transformed) during the analysis phase of the study; however, a description of each transformation will be deferred until the next section.

V. DATA ANALYSIS

Creation and Characteristics of Subsamples

Three random samples of 1,500, 3,000, and 6,000 cases each were drawn from the population with the requirement that the three samples of each particular size contain 10%, 35%, and 50% involuntary dischargees. Each case could appear only once in each sample but could appear in more than one sample. Each of the nine samples was randomly separated into three subsamples. A schematic representation of the subsample layout is shown in Figure 1. Hereafter, the term "base rate" referred to in the figure is defined as the percentage of correct classifications that would result if all individuals in the subsample were classified into the criterion category representing normal separations or active duty status. Subsamples 3N + 1 and 3N + 2, N = 0, 1, 2, . . ., 8 were used as validation and cross-validation subsamples, respectively, in the analysis of each subsample size-base rate combination. The empirical probabilities for the BAYS computations were derived from subsamples 3N + 3, N = 0, 1, 2, . . ., 8. Although a wide range of base rates was studied in order that the subject methodologies could be compared in a variety of problem settings, attention was primarily focused on the 65% subsample base rate which closely approximates the 68.5% population base rate.

Sample #	Sample Size	Subsample #	Subsample Size	P	Q
		1	500	90	10
1	1,500	2	500	90	10
		3	500	90	10

Figure 1. **Subsample layout.**

Model Formulation and Analysis

The methodological comparisons began with the set of independent variables, called Variable Set I, which comprised the predictive model developed by Dempsey et al. (1977). Four additional sets of independent variables, denoted Variable Sets II–V, were examined and are listed in Table 1. Factors influencing the selection of Variable Sets II–V were the following: (a) results of analyses on Variable Set I, (b) a regression of the criterion on a large number of independent variables, (c) large increases in "turnaround" time as the number of independent variables increases associated with the BAYS computations, (d) limitations on the number of predictor variables compatible with a MAP analysis, and (e) coordination with the AFHRL focal point on RPR 77-13 concerning results of analyses supporting that research effort.

[a]Sum (normalized) of the scores from the administrative and electrical tests of the ASVAB.

[b]Normalized score.

[c]Coded as 0 (1) denoting number of years required to reach highest level of education less than 12 (greater than or equal to 12).

[d]Coded as 0 (1) denoting age (in years) at time of enlistment less than 19 (greater than or equal to 19).

[e]Coded as 0 (1) denoting age (in years) at time of enlistment equal to 17 (greater than 17).

Tables A14 through A27 in Appendix A, which will hereafter be referred to as "hit tables," present results of the MAP, TRICOR, and BAYS methodologies applied to a validation and cross-validation subsample for each subsample size/base rate/variable set combination. An examination of the first set of results in Table A14 provides the following information. For the 500 case validation subsample from a MAP problem involving a 50% base rate, 157 individuals who were successes (i.e., assigned a criterion value of 1) were classified as successes and 173 individuals who were failures (i.e., assigned a criterion value of 0) were classified as failures. In addition, 77 individuals who were failures were classified as successes, and 93 individuals who were successes were classified as failures. Therefore, for this particular validation subsample, 330 (or 157 + 173) individuals were correctly classified and 170 (or 77 + 93) individuals were incorrectly classified. The classification accuracy for the validation subsample was 66.0% and for the cross-validation subsample was 66.4%. The remaining hit tables comprising Tables A14 through A27 can be similarly interpreted.

As can be observed from these tables, there is little difference among the methodologies in their ability to correctly classify the sampled cases into the two criterion categories. For example, the classification accuracies from applying MAP and TRICOR to the validation and cross-validation subsamples using Variable Set I differed by no more than 2% for the 18 subsample size/base rate combinations, with neither methodology exhibiting clear superiority. In fact, 15 of the 18 differences were less than 1%. For the nine validation subsamples, the classification accuracies for MAP were greater than those for TRICOR for five problems and equal for two problems, and for the nine cross-validation subsamples, the classification accuracies for MAP were greater than those for TRICOR for four problems and equal for two problems. As shown in Tables A14 and A16, the classification accuracies from applying MAP and BAYS to Variable Set I differed by no more than 3% for all subsample size/base rate combinations with a majority of the differences being less than 1%. For the nine validation subsamples, the classification accuracies for BAYS were greater than those for MAP for five problems and equal for two problems, and for the nine cross-validation subsamples, the classification accuracies for BAYS were greater than those for MAP for three problems and less than those for MAP for six problems. A similar comparison for BAYS and TRICOR can be derived from Tables A14 and A15. As before, a majority of the differences were less than

1%. For the 18 subsample size/base rate combinations, the classification accuracies for BAYS were greater than those for TRICOR for eight problems and equal for two problems. A comparison of classification accuracies among the three methodologies across all variable sets provides similar results. Regarding the performance of the algorithms as a function of base rate, sample size, or variable set, there was little difference in their abilities to correctly classify individuals as successes/failures. The application of each methodology increases classification accuracy substantially (i.e., an improvement of approximately 13% to 23%) over the base rate for the subsamples containing 50% involuntary dischargees; however, the improvement in classification accuracy decreases dramatically (i.e., an improvement of at most 11%) for the subsamples containing 35% involuntary dischargees and becomes nearly non-existent (i.e., an improvement of at most 2%) for the subsamples containing 10% involuntary dischargees. As previously mentioned, the MAP algorithm did not converge for all problems which can be witnessed by the omission of several hit tables; therefore, all comparisons between MAP and BAYS or TRICOR will refer, of course, to the problems for which the MAP algorithm converged. It should be noted that for the three 65% base rate problems utilizing Variable Set III, the TRICOR classification accuracy was better than the MAP classification accuracy in all cases; however, when contemplating the significance of this result, consideration should be given to the large number of comparisons that were made in which none of the methodologies showed clear superiority.

Using the AFHRL automatic interaction detector algorithm, AID-4 (Gott & Koplyay, 1977; Koplyay, Gott, & Elton, 1973), interactive terms were identified in an effort to gauge the improvement of classification accuracy by adding these variables to the appropriate set of predictors. As mentioned earlier, the BAYS algorithm precludes analysis of models containing interactive terms. Since the classification accuracy results of this effort were so similar to the previous results, the corresponding hit table summaries were not reproduced in this report. When interactive terms were introduced into the MAP algorithm, significant convergence problems were encountered. For example, when Variable Sets II and III were augmented with interactive terms, the MAP algorithm did not converge for each problem. Some success in achieving convergence was realized by performing MAP analyses on a subset of the augmented Variable Set III; however, a similar attempt to achieve convergence was performed on the augmented Variable Set II with little success resulting. Based on the subsample size/base rate combinations for which the MAP algorithm converged for problems with and without interactions, little predictive efficiency was gained by allowing interactive terms to be included in the model. In fact, the largest improvement observed in classification accuracy was 1.4% with most of the differences being less than 1%. Similar results were observed for TRICOR since the largest improvement in classification accuracy was 1.6% with most of the differences being less than 1%. Although the inclusion of interactive terms in these analyses did yield some increases in classification accuracy, the magnitude of the increases would not justify development of a more complicated model.

Comparison of Required Computer Resources

Although the classification accuracy results are similar for TRICOR, BAYS, and MAP, there are differences in the computer resources required to perform the computations for each methodology. All of the comparisons to be presented refer to the version of each computer program presently operational on the AFHRL UNIVAC 1108. The magnitude of the differences could vary depending on the computer system employed, and with an extensive research effort, each predictive algorithm could probably be streamlined with respect to input/output (I/O) time, central processing unit (CPU) time or mass storage required; however, the contents of this section should serve as a valuable guide for researchers who wish to estimate the computer resources required to perform each methodology on the AFHRL UNIVAC 1108 or a similar computer system without drastically modifying the computerized algorithms. If one of these methodologies is to be used repeatedly as an operational tool to solve the type of problem investigated in this report, an effort should be initiated to tailor the identified algorithm to the specific requirements of that application.

As noted earlier, an increase in the number of independent variables associated with a BAYS problem results in a dramatic increase in "turnaround" time. The total times required for BAYS processing of 6, 9, and 14 member variable sets for 500 case subsamples were approximately 27, 42, and 65 minutes, respectively, with over 89% of those times allocated to I/O processing; moreover, an increase in the number of cases per subsample resulted in a proportionate increase in total (and I/O) processing time. The total times required for MAP processing of 6, 9, and 14 member variable sets were approximately 3% to 4%, 4% to 5%, and 7% to 10%, respectively, of the total times required to process a similar BAYS problem with the CPU times comprising approximately 77% to 92% of the total time. A direct comparison of TRICOR processing times with MAP and BAYS was not available since the TRICOR processing involved computations germane to a follow-up research effort but not required for the results herein; therefore, any estimates of TRICOR processing times should be considered overestimates. The total times required for TRICOR processing of 6, 9, and 14 member variable sets were approximately 13% to 17%, 8% to 13%, and 5% to 7%, respectively, of the total times required to process a similar BAYS problem with the CPU times comprising approximately 8% to 15% of the total time. In addition, the I/O times comprise approximately 64% to 65%, 72% to 74%, and 76% to 80% of the total times for the 500, 1000, and 2000 case subsamples, respectively.

The I/O time required for a MAP problem is small in relation to the total time required since a large amount of information is retained in mass storage, necessitating very little file handling; however, mass storage limitations restrict the size of problems that can be processed, as was reflected in an earlier discussion. The total time required to process a MAP problem surpasses the total time required to process a similar TRICOR problem for Variable Set 4 for most problems; therefore, it appears that the TRICOR algorithm becomes more efficient in relation to the MAP algorithm with respect to total time required as the number of independent variables associated with the problem increases. The CPU times required to process a BAYS or MAP problem are comparable, but the I/O times presently required to process BAYS problems limit the use of this methodology to the solution of smaller problems than could be processed by the TRICOR or MAP algorithms. Of course, for problems involving a large number of cases and predictor variables, the TRICOR algorithm presently provides a method to seek an acceptable solution within reasonable time and mass storage constraints.

VI. SUMMARY AND RECOMMENDATIONS

In order to measure the abilities of the MAP, BAYS, and TRICOR algorithms to correctly classify individuals as normal dischargees (including active duty status) or involuntary dischargees, a population of 11,231 airmen was selected that was characteristically similar to one that had served as a data base for a MAP analysis documented by Dempsey et al. (1977). The current effort is the first phase in a project to examine the capabilities of each methodology to correctly classify individuals in binary criterion situations such as graduation/elimination from various TT courses, UPT and BMT.

To examine the classification accuracies of the statistical methodologies in a variety of problem settings, subsamples were constructed so that all possible combinations of three subsample sizes (500, 1000, and 2000 cases) and base rates (50%, 65%, and 90%) could be analyzed for each set of predictor variables. Several subsets of the following variables and/or transformations of the variables were selected for development of predictive models by each methodology: (a) scores from the aptitude tests (Administrative, Mechanical, Electrical, and General) of the ASVAB, (b) AFQT score, (c) PDA score, (d) MSI score, (e) number of years required to reach highest level of education, (f) number of dependents at enlistment, (g) age in years at enlistment, and (h) high school completion of algebra, biology, chemistry, art, geometry, photography, physics, trigonometry, English, and home economics. The classification accuracies and computer resource requirements associated with the application of each statistical methodology to all subsample size/base rate/variable set combinations were compared, resulting in several general conclusions. Overall, there was very little difference among the methodologies in their ability to correctly classify individuals as successes/failures. Application of each methodology resulted in a substantial increase in classification accuracy over the base rate for the subsamples containing 50% involuntary dischargees; however, this improvement became less pronounced for the subsamples containing 35% involuntary dischargees and decreased even further for the subsamples containing 10% involuntary dischargees. The inclusion of AID-4 identified interaction terms in the model-building process did not yield a large enough increase in classification accuracy to justify the development of a more complicated model. Convergence problems were encountered during the MAP analyses especially when some of the sets of predictive variables were augmented with interactive terms; therefore, a comparison of predictive efficiencies among all methodologies does not exist for every subsample size/base rate/variable set combination.

Although the classification accuracy results were similar, there were differences in the computer resources required to process the data for each methodology. For all analyses, the total time required to process a BAYS problem was appreciably longer than the total time required to process a similar MAP or TRICOR problem, due mainly to the large amount of I/O time associated with performing the BAYS computations. If some proposed changes to the BAYS algorithm are implemented, the I/O time required for processing a BAYS problem possibly could be reduced by one-half; however, even with this reduction, the total times associated with the BAYS problems would have greatly surpassed the times for similar MAP or TRICOR problems. Although the total time required for processing each MAP problem was appreciably less than that required for BAYS, the CPU time required for processing a MAP problem increases rather rapidly as the number of independent variables increases; consequently, it is especially important with MAP, as with the other methodologies, to employ an efficient variable selection technique. Due to mass storage limitations, an increase in the number of independent variables associated with a MAP problem causes a corresponding decrease in the maximum number of cases allowable for analysis. If the number of cases and predictor variables associated with a particular problem is large, the superior data-handling capabilities of the TRICOR regression algorithm assume added significance; in fact, TRICOR may be the only feasible method of the three to obtain a solution.

Currently, AFHRL is conducting two follow-up studies to this effort. The first of these examines the capabilities of the MAP, TRICOR, and BAYS computerized methodologies to correctly classify individuals as TT graduates/failures and the second compares the abilities of each methodology to correctly identify BMT graduates/failures. A major difference between the present and new efforts is that the test design for the TT(BMT) study requires the validation subsamples to be randomly selected from personnel who entered TT(BMT) in 1976 and the cross-validation subsamples to be randomly selected from personnel who entered TT(BMT) in 1977 rather than selecting the validation and cross-validation subsamples from the same population. Also the predictive efficiency of standardized least squares will be measured in a variety of problem settings. Since the validation and cross-validation subsamples are not necessarily homogeneous, standardized least squares predictive models which are independent of the units of measurement, may fare better than ordinary least squares predictive models. The BMT and TT research efforts should be pursued since they more closely simulate a "real world" prediction problem in that data from one time period are used to develop a model for prediction into the next time period.
