| 16. Abstract<br>An experimental program was carried out to (1) develop empirical data on the deflagration-to-detonation run-up distance for flowing mixtures of gasoline and air in 15.2-cm- (6.0-in.-) diameter piping simulating a vapor recovery system, and (2) evaluate the quenching capability of eight selected flame control devices subjected to repeated stable detonations. The deflagration-to-detonation run-up distance was found to be 11.2 m (36.7 ft), or a length-to-diameter ratio of 74. The relative roughness of the run-up length of piping was 0.010 to 0.015. The stable detonation downstream of the transition point had a velocity of 1800 m/s (5906 ft/s) with a stable peak pressure of 1900 kN/m <sup>2</sup> (275 psia). There appeared to be no discernable correlation between the initial flow velocity used in testing and the resulting run-up distance. Detonations were obtained only at equivalence ratios greater than 0.8; however, there was no correlation between equivalence ratio and run-up distance for equivalence ratios ranging from 0.9 to 1.4. The successful detonation-flame arresters were: (1) spiral-wound, crimped aluminum ribbon, (2) foamed nickel-chrome metal, (3) vertically packed bed of aluminum Ballast rings, and (4) water-trap or hydraulic back-pressure valve. Installation configurations for two of the more applicable arresters, the spiral-wound, crimped stainless-steel ribbon and the vertically packed bed of aluminum Ballast rings, were further optimized by a series of parametric tests. The final configuration of these two arresters were demonstrated with repeated detonation tests at conditions that simulated vapor recovery system operation. On these tests, the combustible mixture of gasoline and air continued to flow through the piping for periods up to 120 seconds after the initial detonation had been arrested. There was no indication of continuous burning or reignition occurring on either side of the test arresters. |                                                                                                                                                         |                                                                                                                                       |

## PREFACE

The work described in this report was jointly sponsored by the DOT/U.S. Coast Guard, Marine Technology Division, Office of Research and Development, and NASA/Office of Space and Terrestrial Application, Technology Transfer Division, and was performed by the Control and Energy Conversion Division, Propulsion Systems Section, of the Jet Propulsion Laboratory.

## ACKNOWLEDGEMENT

This work was administered under the very able technical direction of LCDR Michael F. Flessner USCG, Marine Technology Division, and Mr. O.B. "Bud" Hartman NASA/OSTA, Terrestrial Applications Board. The experimental work was conducted at JPL Edwards Test Facility, where many people contributed to the success of the program. The authors would like to particularly acknowledge the assistance and contributions of C. R. Byers, M. E. Guenther, L. K. Jones, J. Newnham, D. P. Rice and C. S. Worthen.

## ABSTRACT

An experimental program was carried out to (1) develop empirical data on the deflagration-to-detonation run-up distance for flowing mixtures of gasoline and air in 15.2-cm- (6.0-in.-) diameter piping simulating a vapor recovery system, and (2) evaluate the quenching capability of eight selected flame control devices subjected to repeated stable detonations.

The deflagration-to-detonation run-up distance was found to be 11.2 m (36.7 ft), or a length-to-diameter ratio of 74. The relative roughness of the run-up length of piping was 0.010 to 0.015. The stable detonation downstream of the transition point had a velocity of 1800 m/s (5906 ft/s) with a stable peak pressure of 1900 kN/m<sup>2</sup> (275 psia). There appeared to be no discernable correlation between the initial flow velocity used in testing and the resulting run-up distance. Detonations were obtained only at equivalence ratios greater than 0.8; however, there was no correlation between equivalence ratio and run-up distance for equivalence ratios ranging from 0.9 to 1.4.

The successful detonation-flame arresters were: (1) spiral-wound, crimped aluminum ribbon, (2) foamed nickel-chrome metal, (3) vertically packed bed of aluminum Ballast rings, and (4) water-trap or hydraulic back-pressure valve. Installation configurations for two of the more applicable arresters, the spiral-wound, crimped stainless-steel ribbon and the vertically packed bed of aluminum Ballast rings, were further optimized by a series of parametric tests. The final configuration of these two arresters were demonstrated with repeated detonation tests at conditions that simulated vapor recovery system operation. On these tests, the combustible mixture of gasoline and air continued to flow through the piping for periods up to 120 seconds after the initial detonation had been arrested. There was no indication of continuous burning or reignition occurring on either side of the test arresters.

| I.   | SUMMARY -----                                                  | 1-1 |
| II.  | INTRODUCTION -----                                             | 2-1 |
| III. | TEST FACILITY DESCRIPTION -----                                | 3-1 |
|      | A. GENERAL -----                                               | 3-1 |
|      | B. AIR COMPRESSOR SYSTEM -----                                 | 3-1 |
|      | C. FUEL SYSTEM -----                                           | 3-1 |
|      | D. FUEL VAPORIZER AND CONDENSER LOOP -----                     | 3-4 |
|      | E. FUEL AND AIR INDUCTION SYSTEM -----                         | 3-4 |
|      | F. DETONATION TEST PIPING -----                                | 3-5 |
|      | G. HYDROGEN-AIR-SPARK IGNITOR -----                            | 3-8 |
| IV.  | INSTRUMENTATION AND CONTROLS -----                             | 4-1 |
|      | A. GENERAL DESCRIPTION -----                                   | 4-1 |
|      | B. STEADY-STATE DATA -----                                     | 4-1 |
|      | C. TRANSIENT-STATE DATA -----                                  | 4-4 |
|      | D. GAS SAMPLE ANALYSIS SYSTEM -----                            | 4-5 |
|      | E. PARAMETER MEASUREMENT AND CALCULATION<br>UNCERTAINTIES----- | 4-9 |
| V.   | TEST OPERATING PROCEDURES -----                                | 5-1 |
|      | A. GENERAL SAFETY REQUIREMENTS -----                           | 5-1 |
|      | B. OPERATING PROCEDURE CHECK LISTS -----                       | 5-1 |
|      | 1. Pretest System Checkouts -----                              | 5-1 |
|      | 2. Fuel Transfer Procedures -----                              | 5-2 |
|      | 3. Test Preparations -----                                     | 5-2 |
|      | 4. Blockhouse Preparation -----                                | 5-3 |

|       |                                                                                      |      |
|-------|--------------------------------------------------------------------------------------|------|
| 5.    | Countdown -----                                                                      | 5-3  |
| 6.    | Posttest -----                                                                       | 5-4  |
| VI.   | FACILITY CHECK-OUT TESTS -----                                                       | 6-1  |
| VII.  | CALIBRATION TESTS -----                                                              | 7-1  |
| VIII. | ARRESTER EVALUATION TESTS -----                                                      | 8-1  |
| A.    | PIPE TEES AND RUPTURE-DISC IN-LINE TEST ASSEMBLY -----                               | 8-1  |
| B.    | PIPE TEE, RUPTURE-DISC NOT-IN-LINE, AND<br>PIPE ELBOW TEST ASSEMBLY -----            | 8-1  |
| C.    | SHAND AND JURS SPIRAL-WOUND, CRIMPED<br>ALUMINUM RIBBON ARRESTER TEST ASSEMBLY ----- | 8-6  |
| D.    | AMAL SPIRAL-WOUND, CRIMPED STAINLESS-STEEL<br>RIBBON ARRESTER TEST ASSEMBLY -----    | 8-9  |
| E.    | WHESOE FOAMED METAL ARRESTER TEST ASSEMBLY -----                                     | 8-14 |
| F.    | WATER-TRAP ARRESTER TEST ASSEMBLY -----                                              | 8-15 |
| G.    | VERTICAL BED OF BALLAST RINGS ARRESTER<br>TEST ASSEMBLY -----                        | 8-16 |
| H.    | LINDE HYDRAULIC BACK-PRESSURE VALVE ARRESTER<br>TEST ASSEMBLY -----                  | 8-20 |
| IX.   | ARRESTER EVALUATION TESTS USING DOWNSTREAM IGNITION-----                             | 9-1  |
| A.    | REVERSAL OF TEST FACILITY PIPING -----                                               | 9-1  |
| B.    | LINDE HYDRAULIC BACK-PRESSURE VALVE<br>ARRESTER TEST ASSEMBLY -----                  | 9-1  |
| C.    | WATER-TRAP ARRESTER TEST ASSEMBLY -----                                              | 9-2  |
| X.    | CHEMICALLY PURE PROPYLENE DETONATION TESTS -----                                     | 10-1 |
| XI.   | DEFLAGRATION-TO-DETONATION TRANSITION LOCATION TESTS -----                           | 11-1 |
| XII.  | FACILITY PIPING RELATIVE ROUGHNESS DETERMINATION TESTS -----                         | 12-1 |

|                                                                                                        |      |
|--------------------------------------------------------------------------------------------------------|------|
| XIII. PARAMETRIC TESTS OF DETONATION-FLAME ARRESTERS -----                                             | 13-1 |
| A.    DOWNSTREAM PRESSURE PULSE -----                                                                  | 13-1 |
| B.    SHAND AND JURS SPIRAL-WOUND,<br>CRIMPED STAINLESS-STEEL RIBBON<br>ARRESTER TEST ASSEMBLIES ----- | 13-2 |
| C.    VERTICAL BED OF ALUMINUM BALLAST RINGS<br>ARRESTER TEST ASSEMBLIES -----                         | 13-8 |
| XIV. CONTINUOUS-FLOW TESTING OF DETONATION-FLAME<br>ARRESTERS -----                                    | 14-1 |
| A.    TEST FACILITY MODIFICATION -----                                                                 | 14-1 |
| B.    VERTICAL BED OF ALUMINUM BALLAST RINGS<br>ARRESTER TEST ASSEMBLY -----                           | 14-4 |
| C.    SHAND AND JURS SPIRAL-WOUND, CRIMPED<br>STAINLESS-STEEL RIBBON ARRESTER<br>TEST ASSEMBLY -----   | 14-5 |
| XV.    CONCLUSIONS -----                                                                               | 15-1 |
| XVI.   RECOMMENDATIONS -----                                                                           | 16-1 |
| REFERENCES -----                                                                                       | 17-1 |

## SECTION I

### SUMMARY

An experimental program was conducted to gather empirical data on the detonation of combustible mixtures of gasoline and air flowing in a 15.2-cm- (6.0-in.-) diameter simulated vapor recovery piping system, and to evaluate flame control devices capable of arresting the detonation. A special test facility had to be assembled in a suitable location to conduct these potentially hazardous experiments. Facility check-out tests were performed to develop reliable methods of generating stable detonations and to verify the operation of dynamic instrumentation used to measure flame velocities and peak-pressure pulses. A series of calibration tests, using both propane/air mixtures and gasoline/air mixtures, were made to determine the run-up distance to detonation, the flame velocity and peak-pressure pulse in both the transition and stable stages of detonation, and the pressure buildup resulting from reflected detonation shock waves. These tests were then followed by the experimental evaluation of eight selected flame arrester test assemblies to demonstrate their operating characteristics; these characteristics included pressure drop, flame quenching capability, and structural durability before and after repeated exposures to stable detonations. Two of the more successful flame arrester configurations were further evaluated with a series of parametric tests designed to reduce the level of the peak-pressure pulse passing through the device after the detonation had been arrested, and to optimize the overall size of the arrester configuration. A final series of tests were made to demonstrate the ability of these optimized configurations to arrest a detonation in simulated vapor recovery system piping under the condition where the combustible mixture of gasoline and air continued to flow through the system for periods up to 120 seconds after the initial deflagration-to-detonation transition had occurred.

The facility check-out tests using propane and air mixtures revealed that flame acceleration up to detonation transition could not be achieved in the smooth-bored shock-tube piping at the maximum available run-up distance of 31.5 m (103.5 ft). However, stable detonations were obtained after expanded metal tube liners were inserted into several lengths of run-up piping to create turbulence in the combustion process. Flame propagating velocities were determined using photomultiplier tube optical flame sensors. Peak-pressure pulse levels in the detonation wave were measured using quartz piezoelectric transducers. All dynamic data were recorded on FM tapes and analyzed using playbacks on oscillograph recorders at an expanded time base.

Calibration tests with both propane/air and gasoline/air mixtures determined that 13.7 m (45 ft) of turbulence-inducing liners were required to produce repeatable stable detonations in the combustion process. Additional calibration tests, using gasoline and air mixtures in a modified test configuration that included flame sensing instrumentation in the lined sections, showed that the run-up distance to detonation was 11.2 m (36.7 ft), or an L/D of 74 for the 15.2-cm- (6.0-in.-) diameter pipe system. These results generally held true for equivalence ratios ranging from 0.9 to 1.4 and initial flow velocities from 0 to 6.1 m/s (0 to 20 ft/s). The flame velocity in a stable detonation was measured at 1830 m/s (6000 ft/s),

and the peak-pressure level at  $1630 \text{ kN/m}^2$  (235 psia). During the deflagration-to-detonation transition, flame velocities were measured up to  $2700 \text{ m/s}$  (8858 ft/s), and peak pressures exceeded  $4000 \text{ kN/m}^2$  (580 psia). The peak pressure measured in a reflected detonation wave 30 cm (12 in.) from the reflecting surface was  $3300 \text{ kN/m}^2$  (479 psia), or about twice the level in the approaching wave.

A series of air-flow-only calibration tests were made to measure pressure drop through the lined and unlined piping. This pressure loss was used to determine the internal wall Darcy friction factor ( $f$ ) and the relative roughness ( $\epsilon/D$ ). For the lined piping, the friction factor ranged from 0.040 to 0.047 and the relative roughness from 0.010 to 0.015. This relative roughness is approximately equivalent to that of commercial riveted steel pipe. The unlined shock-tube piping had a friction factor around 0.020 and a relative roughness less than  $10^{-6}$ , which is lower than any commercial smooth piping.

The flame control devices experimentally evaluated for arresting detonations in simulated vapor recovery system piping consisted of two arrangements of standard high-pressure pipe fittings with rupture-disc assemblies, four commercially manufactured flame arresters or prototype models, and two JPL-manufactured arrester assemblies. All of these devices were subjected to a series of stable detonations resulting from the ignition of a flowing combustible mixture of gasoline and air. A standard condition for each repeated test firing was established at an equivalence ratio of 1.1 (air-to-gasoline weight ratio of 13.3), and an initial flow velocity of  $4.6 \text{ m/s}$  (15 ft/s). Depending on ambient conditions, the mixture temperature just before ignition ranged from  $30$  to  $60^\circ\text{C}$  (86 to  $150^\circ\text{F}$ ). Pressure level in the piping system was just slightly above ambient, as determined by the arrester pressure drop. The results of these test firings using an upstream ignition location are tabulated in Table 1-1 and briefly summarized as follows:

- (1) The pipe-tee and rupture-disc in-line test assembly sustained four detonations. Both rupture discs were blown out, but there was no physical damage. The detonation passed through the device in every test with very little reduction in flame velocity and peak pressure. Pre- and posttest pressure loss average was  $0.20 \text{ kN/m}^2$  (0.029 psid).
- (2) The pipe tee, rupture-disc not-in-line, and pipe-elbow test assembly sustained four detonations. The rupture disc was blown out in each test, but there was no physical damage. The detonation passed through the device in every test with an intermittent moderate loss of flame velocity and peak pressure. Pre- and posttest pressure loss average was  $0.214 \text{ kN/m}^2$  (0.031 psid).
- (3) The Shand and Jurs spiral-wound, crimped aluminum ribbon arrester test assembly sustained nine detonations without serious damage. The detonation did not pass through the arrester. Pre- and posttest pressure loss averaged  $0.152 \text{ kN/m}^2$  (0.022 psid).

- (4) The Amal spiral-wound, crimped stainless-steel ribbon arrester test assembly sustained four detonations without any visible damage. The detonation was arrested in the first firing, but passed through in the other three. Pre- and posttest pressure loss averaged  $0.428 \text{ kN/m}^2$  ( $0.062 \text{ psid}$ ).
- (5) The Whessoe foamed metal arrester test assembly using the 80-grade Retimet nickel-chrome alloy core element sustained three detonations. The detonation was stopped for all three tests, but the core element fractured during the last test. Pre- and posttest pressure loss before failure averaged  $0.241 \text{ kN/m}^2$  ( $0.035 \text{ psid}$ ). One additional test firing with a 45-grade Retimet nickel-chrome alloy core element failed to stop the detonation.
- (6) The water-trap arrester test assembly sustained six detonations without damage, but did display a measurable loss in water volume due primarily to evaporation. The detonation did not pass through the arrester as long as it contained water at or near the prescribed level. Pre- and posttest pressure loss averaged  $1.655 \text{ kN/m}^2$  ( $0.240 \text{ psid}$ ).
- (7) The vertical bed of the Ballast rings arrester test assembly sustained five detonations with only minor distortion of the rings caused by bed compacting. The detonation did not pass through the arrester. Pre- and posttest pressure loss averaged  $0.048 \text{ kN/m}^2$  ( $0.007 \text{ psid}$ ).
- (8) The Linde hydraulic back-pressure valve arrester test assembly sustained ten detonations without damage, but like the water trap, it did display a measurable loss in water volume due primarily to evaporation. The detonation was stopped for six test firings where the water level was at or near the prescribed level and was stopped for one test firing where there was only a small amount of water remaining in the arrester. The detonation was not stopped for three test firings with a dry arrester. Pre- and posttest pressure loss averaged  $2.027 \text{ kN/m}^2$  ( $0.294 \text{ psid}$ ).

Two of the arrester test assemblies were evaluated using a downstream ignition configuration. The maximum initial flow velocity was limited to  $1.5 \text{ m/s}$  ( $5.0 \text{ ft/s}$ ) because of the difficulty in getting the flame to propagate back upstream against the flowing gasoline and air mixture. The results of these test firings are tabulated in Table 1-1 and briefly summarized as follows:

- (1) The Linde hydraulic back-pressure valve arrester test assembly sustained six more detonations without damage. Some water was lost due to evaporation, but an additional quantity was displaced upstream by the force of the detonation wave. The detonation was stopped for all six test firings. Pre- and posttest pressure loss averaged  $1.92 \text{ kN/m}^2$  ( $0.278 \text{ psid}$ ).

- (2) The water-trap arrester test assembly sustained five more detonations without damage. The detonation was stopped for every test firing. Some water was lost from the arrester due to evaporation. However, no liquid appeared to be displaced by the incoming detonation wave. Pre- and posttest pressure loss average was  $1.393 \text{ kN/m}^2$  (0.202 psid).

The two arrester assemblies selected for parametric testing were (1) the Shand and Jurs spiral-wound, crimped stainless-steel ribbon arrester and (2) the vertical bed of aluminum Ballast rings arrester. The Shand and Jurs arresters all had the same ribbon crimp height and same core diameter, but three different core lengths. Both an indirect and a direct inlet pipe configuration with rupture-disc assembly were used. With the direct inlet installed, the rupture-disc pressure rating was increased in four steps to a blanked-off condition. The vertical bed of rings arrester was tested with four decreasing bed diameters, three decreasing bed lengths, and three increasing sizes of aluminum Ballast rings. The inlet pipe configuration was not varied, but the inlet rupture-disc pressure rating was increased in four steps up to a blanked-off condition. All of the parametric arrester configurations were subjected to a series of stable detonations developed in a flowing mixture of gasoline and air at the same standard test condition established for the preceding screening tests. The results of the parametric testing are tabulated in Tables 1-2 and 1-3, and briefly summarized as follows:

- (1) The 15.2-cm- (6-in.-) long stainless-steel Shand and Jurs arrester configuration, with the indirect inlet piping and a  $690\text{-kN/m}^2$  (100-psid) rupture disc, arrested four detonations. On the fifth test, the detonation passed through the arrester. Posttest inspection revealed a small separation in the crimped ribbon winding. Pre- and posttest pressure loss averaged  $0.151 \text{ kN/m}^2$  (0.022 psid). Downstream pressure pulse measurements averaged  $344 \text{ kN/m}^2$  (49.9 psia).
- (2) The 20.3-cm-(8-in.-) long stainless-steel Shand and Jurs arrester configuration, with the indirect inlet piping and a  $690\text{-kN/m}^2$  (100-psid) rupture disc, arrested six detonations. Pre- and posttest pressure loss averaged  $0.152 \text{ kN/m}^2$  (0.022 psid). Downstream pressure pulse measurements averaged  $320 \text{ kN/m}^2$  (46.4 psia), or 7% lower than the 15.2-cm- (6-in.-) long core element.
- (3) The 30.5-cm- (12-in.-) long stainless-steel Shand and Jurs arrester configuration, with the indirect piping and a  $690\text{-kN/m}^2$  (100-psid) rupture disc, arrested six detonations. Pre- and posttest pressure loss averaged  $0.230 \text{ kN/m}^2$  (0.033 psid). Downstream pressure pulse measurements averaged  $260 \text{ kN/m}^2$  (37.7 psia), or 25% lower than the 15.2-cm-(6-in.-) long core element.
- (4) The 20.3-cm-(8-in.-) long stainless-steel Shand and Jurs arrester configuration, with the direct inlet piping and rupture disc assembly, arrested six more detonations. During the first three tests, the inlet rupture-disc pressure rating was increased in steps through 690, 2068, and  $4137 \text{ kN/m}^2$  (100, 300, and 600 psid). On the last three tests, the

rupture-disc assembly was blanked-off. This variation in rupture-disc pressure rating made little difference in the downstream pressure pulse measurements, which averaged  $324 \text{ kN/m}^2$  (47.0 psia), or about the same level as that obtained with the indirect inlet piping. Pre- and posttest pressure loss on these tests averaged  $0.138 \text{ kN/m}^2$  (0.020 psid).

- (5) Three vertical bed arrester configurations, with a full-size bed diameter of 43.2 cm (17 in.), and decreasing bed depths of 63.5 cm (25 in.), 45.7 cm (18 in.), and 22.9 cm (9 in.) packed with 2.54-cm- (1.0-in.-) size aluminum Ballast rings, were each subjected to six stable detonations. The two longer bed configurations arrested all six detonations. The shortest bed configuration arrested four detonations, but then allowed two to pass through. Posttest inspections of this arrester showed some evidence of channeling through the compacted bed of rings. Pre- and posttest averaged pressure loss dropped slightly from  $0.075$  to  $0.052 \text{ kN/m}^2$  (0.011 to 0.007 psid) with the decrease in bed depth. The averaged downstream pressure pulse for an arrested detonation increased from 181 to 236  $\text{kN/m}^2$  (26.3 to 34.2 psia) with the decrease in bed depth.
- (6) Two full-size vertical bed arresters having a 43.2-cm- (17-in.-) diameter by 63.5-cm- (25-in.-) depth bed, one packed with 3.81-cm- (1.5-in.-) size aluminum Ballast rings and the other with 5.08-cm- (2.0 in.-) size aluminum Ballast rings, were tested. The configuration with the 3.81-cm- (1.5-in.-) size rings arrested two detonations and then allowed two to pass through. The configuration with the 5.08-cm- (2.0-in.-) size rings arrested only one detonation before allowing two to pass through. Posttest inspection revealed considerable distortion of these enlarged-size Ballast rings from the detonation impacts. Pre- and posttest averaged pressure loss decreased slightly with the enlarged ring sizes of 0.067 and  $0.056 \text{ kN/m}^2$  (0.010 and 0.008 psid). Averaged downstream pressure pulse for an arrested detonation increased to 290 and  $304 \text{ kN/m}^2$  (42.1 and 44.1 psia).
- (7) Three vertical bed arrester configurations, with a full-size bed depth of 63.5 cm (25 in.) and decreasing bed diameters of 33.7 cm (13.3 in.), 30.5 cm (12 in.), and 25.4 cm (10 in.) packed with 2.54-cm- (1.0-in.-) size aluminum Ballast rings, were each subjected to six or more stable detonations. All three configurations arrested the detonations. Posttest inspections showed about 30% compaction of the beds due to distortion of the rings. Pre- and posttest averaged pressure loss increased with each succeeding smaller bed diameter. The 25.4-cm- (10-in.-) diameter bed pressure loss was  $0.278 \text{ kN/m}^2$  (0.040 psid), which is about four times higher than the  $0.075\text{-kN/m}^2$ - (0.011-psid-) loss for the full size 43.2-cm- (17-in.-) diameter bed. The averaged downstream pressure pulse decreased from  $181 \text{ kN/m}^2$  (26.3 psia) for the full-diameter bed to  $132 \text{ kN/m}^2$  (19.1 psia) for the smallest 25.4-cm- (10-in.-) diameter bed.

- (8) The 25.4-cm- (10-in.-) diameter vertical bed arrester packed with 2.54-cm- (1.0-in.-) size aluminum Ballast rings to a reduced bed depth of 45.7 cm (18 in.) arrested six more detonations. During the first three tests, the inlet piping rupture-disc pressure rating was increased in steps through 690, 2068, and 4137 kN/m<sup>2</sup> (100, 300, and 600 psid). On the last three tests, the rupture-disc assembly was blanked-off. The averaged downstream pressure pulse for the three test firings with rupture discs installed was around 141 kN/m<sup>2</sup> (20.4 psia). When the rupture-disc assembly was blanked-off, the averaged downstream pressure pulse increased slightly to 164 kN/m<sup>2</sup> (23.8 psia). Pre- and posttest averaged pressure loss measurements increased from 0.162 kN/m<sup>2</sup> (0.023 psid) after the first detonation to 0.220 kN/m<sup>2</sup> (0.032) after the sixth detonation, due to a 28% compaction of the bed.

The two optimized detonation arrester configurations, developed from the parametric tests, were further evaluated after test facility modifications were made to provide continuous combustible mixture flow capability and an extended exit section with 16.5 m (54 ft) of 15.2-cm- (6.0-in.-) diameter pipe added to witness lingering flames or reignitions occurring downstream of the test arrester. The vertical bed of Ballast rings arrester configuration had a bed size 25.4 cm (10 in.) in diameter by 45.7 cm (18 in.) long packed with 2.54-cm- (1.0-in.-) size aluminum rings. An indirect inlet configuration for this arrester consisted of a not-in-line pipe tee, a blanked-off rupture-disc assembly, and a pipe elbow. The Shand and Jurs spiral-wound, crimped stainless-steel ribbon arrester configuration had a core size 30.5 cm (12 in.) in diameter by 20.3 cm (8 in.) long. A direct inlet configuration for this arrester was an in-line pipe tee with a blanked-off rupture-disc assembly. Both of these arresters were tested with a flowing combustible mixture of gasoline and air at the standard test conditions. The mixture continued to flow through the test piping for periods up to 120 seconds after the ignition and detonation had occurred. The results of these tests are tabulated in Table 1-4 and briefly summarized as follows:

- (1) The vertical bed of aluminum Ballast rings arrester test assembly arrested eight detonations. The first two detonation tests were followed by continuous mixture flow for a period of 30 seconds. On each succeeding two-test series, the flow periods were extended in steps through 60, 90, and 120 seconds. There was no indication of reignition or lingering flames either upstream or downstream of the test arrester on any of these firings. Pre- and posttest averaged pressure loss was 0.031 kN/m<sup>2</sup> (0.044 psid) and appeared to increase slightly during testing due to compaction of the bed of rings. The downstream pressure pulse averaged 14.6 kN/m<sup>2</sup> (21.1 psia) and had an average velocity of 398 m/s (1304 ft/s) through the pipe extension section. There was no evidence of increasing wave velocity or pressure in the extension section.
- (2) The Shand and Jurs spiral-wound, crimped stainless-steel arrester test assembly arrested eight detonations. The first two detonation tests were followed by continuous mixture flow

for a period of 30 seconds. On each succeeding two-test series, the flow periods were extended in steps through 60, 90, and 120 seconds. There was no indication of reignition or lingering flames either upstream or downstream of the test arrester on any of these firings. Pre- and posttest averaged pressure loss was  $0.136 \text{ kN/m}^2$  (0.020 psid). The downstream pressure pulse averaged  $297 \text{ kN/m}^2$  (43.1 psia) and had an average velocity of 555 m/s (1816 ft/s) through the pipe extension section. There was an indication of decreasing wave velocity and pressure in the extension section. Posttest inspection revealed no damage or distortion to the arrester core assembly and only minor distortion of the arrester retainer grid ring.

The following is a listing of source information for commercial flame arresters and components used in this program.

- (1) Shand and Jurs, spiral-wound, crimped metal ribbon arresters; G.P.E. Controls, 6511 Oakton Street, Morton Grove, Illinois, 60053.
- (2) Amal, spiral-wound, crimped metal ribbon arrester; Amal Ltd., Birmingham, England.
- (3) Retimet foamed metal arresters; Whessoe Systems and Controls, Ltd., Brinkburn Road, Darlington, Co., Durham DL3 6DS, England.
- (4) Linde hydraulic back-pressure valve arrester; Union Carbide, Linde Division, Gas Products Division, P. O. Box 42, 239 Old New Brunswick Road, Piscataway, New Jersey, 08854.
- (5) Ballast Rings; Glitsch, Inc., P. O. Box 6227, Dallas, Texas, 75222.

## SECTION II

### INTRODUCTION

The Clean Air Act of 1970 requires the Environmental Protection Agency (EPA) to establish air quality standards for principal air pollutants, and directed individual states to develop and implement plans to meet these standards. Regulations requiring the recovery of vapors emitted during the loading and unloading of gasoline and other volatile compounds from ships and barges have been considered, but their implementation has been repeatedly postponed because of the lack of information and experience in safe handling of combustible fuel and air mixtures in closed ducting.

The U.S. Coast Guard, under the Ports and Waterways Safety Act (PL 92340), is responsible for keeping U.S. ports and vessels within these ports safe from the inherent hazards of handling petroleum products. When U.S. cargo vessels and loading terminals are required to install vapor recovery systems (VRS) to reduce the amount of hydrocarbons released to the atmosphere, it will be imperative that the U.S. Coast Guard have data and experience factors concerning the adequacy of flame control devices used in the VRS installations.

Within certain limits of composition, combustible mixtures may burn in either of two modes: deflagration (flame) or detonation (explosion). Deflagration velocities are subsonic and the pressure change across the combustion front is small. Detonation velocities are supersonic, and a large step increase in pressure occurs across the combustion front. Under certain circumstances, a deflagration may accelerate and become a detonation. Flame propagation in a long tube filled with a quiescent combustible gas mixture and closed at the end at which ignition occurs provides the classic example of flame acceleration and the deflagration-to-detonation transition (DDT) (Reference 2-1). Since the tube is closed, the burned gas is not in motion; the hydrodynamic equations for flame propagation require the unburned gas to be in motion. (Reference 2-2). A shock wave that precedes the flame front is the means by which the unburned gas is set in motion. Not only does the shock set the unburned gas in motion, it also heats it. Flame speeds increase with increasing unburnt gas temperatures; hence the flame front accelerates as it proceeds into the shock-heated gas. In turn this strengthens the shock, and the rate of acceleration increases. However, this process accounts for only part of the observed flame acceleration. For the particular situation of flame propagation in a tube, a boundary layer develops on the tube wall behind the shock. Marked increases in flame propagation velocity occur when the boundary layer becomes turbulent, and a transition from laminar to turbulent burning occurs (Reference 2-3). As the preflame shock is further strengthened, the shock becomes sufficiently strong at some point to allow a transition to detonation. Several intermediate specific events, either singly or in combination, may immediately precede the actual development of detonation (Reference 2-4). Autoignitions (point explosions) in the shock-heated gas may provide the final impetus. Successive sudden increases in flame propagation produced by turbulence in the boundary layer of the shocked, unburned gases may result in several successive shock waves;

as these waves coalesce, the transition to detonation may occur. Transition may also occur immediately behind the shock front, if it is of sufficient strength.

Clearly, the deflagration-to-detonation transition is a complex phenomenon and depends not only on the properties of the burned and unburned gases, but also upon the conditions at the boundary of the combustible mixture. The distance required for development of detonation (the "run-up distance") is known to be shorter, e.g., in rough-walled tubes (Reference 2-5), since wall roughness will at first enhance nonuniformity of the boundary layer, and eventually enhance the transition to turbulence. Tube dimension effects are also to be expected, in that propagation times for transverse shocks or combustion fronts will be longer for larger tubes. Abundant evidence exists showing that the deflagration-to-detonation transition is not a one-dimensional phenomenon, but involves transverse compression waves and combustion fronts in tubes (References 2-6 and 2-7).

One other characteristic of this transition is the rapid pressure increase, which is of importance in considering safety precautions under conditions where detonations may develop. At the time of transition, pressure pulses in excess of the steady detonation pressure are often observed (References 2-4 and 2-8). Although these pulses are of very short duration, the pressure may be three to four times the steady detonation pressure. Neither the occurrence nor the magnitude of these pressure pulses is predictable; hence prudence demands that personnel be adequately shielded in the event the detonation tube shatters. These intense pressure pulses are related to another well-known detonation phenomenon, that of spinning detonation (References 2-9 and 2-10). Spinning detonation is a near-limit mode of detonation propagation. It is characterized by a rotating triple-shock intersection that propagates axially. Combustion occurs behind the triple-shock interaction, creating a localized region of high temperatures and pressures. Multiple fronts are also observed. Helical damage patterns in the DDT region are due to spinning fronts. Such fronts, in mixtures well inside the detonation limits, are unstable and do transform to stable planar detonation fronts as the transition process is completed (Reference 2-11).

In evaluating hazards, a number of factors need to be considered. Among these are the pressure developed behind a detonation wave in the combustible mixture in question, the run-up distance for the transition, and the quenching requirements. Other factors of importance that will not be dealt with here are actual mixture compositions and sources of ignition. The particular application of interest in this work is the lengthy, large-diameter piping required for vapor recovery systems at marine terminals. Hydrocarbon/air mixtures will be present in this piping. Maximum detonation velocities and maximum detonation pressures in such mixtures occur at equivalence ratios of about 1.1. Maximum pressure ratios across the wave for hydrocarbon/air mixtures are about 20, corresponding to an impulse pressure of about  $2070 \text{ kN/m}^2$  (300 psia). If it is impractical to construct the vapor recovery system of pipe sufficiently strong to contain a detonation of maximum strength, the run-up distance becomes very important in that it establishes the minimum spacing of flame arresters required to prevent the development of detonation. If, on the other hand, the system can be constructed of piping that will contain the detonation, then the question

of the need for detonation arresters becomes important. Detonation arresters in the piping serve to prevent detonation from propagating into the large volumes (shipboard and dockside storage tanks) associated with the vapor recovery apparatus.

A review of literature on the deflagration-to-detonation transition was concerned with rationalizing (if possible) the available information on run-up distances, with a view toward developing correlations of run-up distances with pipe geometry and combustion characteristics, and with predicting detonation and reflected detonation pressures. The information developed was utilized in the design of the test apparatus and in the analysis of the results.

Many workers have studied the acceleration of flames and the transformation of a flame to a detonation wave (Reference 2-12). Emphasis has been on the details of the transition, rather than on measurements of run-up distance as such. In recent years, elegant laser methods of elucidating the sequence of events in the DDT have revealed, for  $H_2/O_2$  mixtures, a rich and complex set of physiochemical interactions that contribute to this striking phenomenon (Reference 2-4). It must be observed, however, that systematic studies of run-up distances per se are few. Bollinger and coworkers have provided a consistent set of data for several combustible mixtures in small diameter tubes (References 2-8 and 2-13). These workers have reported data on  $H_2/O_2$ ,  $C_2H_2/O_2$ ,  $C_2H_2/air$ ,  $CH_4/O_2$ ,  $CO/O_2$ ,  $H_2/O_2/N_2$ ,  $H_2/O_2/air$ , and  $H_2/O_2/CO_2$  mixtures at initial pressures of 1, 5, 10, and 25 atm. Correlations were developed for some of the mixtures, relating run-up distance to properties of the combustible gas and tube geometry. A function,  $K$ , was defined,

$$K = Re_b \left( \frac{S_u}{a_b} \right) \left( \frac{T_c}{T_b} \right) \quad (2-1)$$

where:  $Re_b$  is the Reynolds number based on unburned gas conditions, the normal burning velocity, and the pipe diameter;

$S_u$  is the burning velocity of the gas mixture;

$a_b$  is the speed of sound in the unburned gas;

$T_c$  is the combustion (detonation) temperature; and

$T_b$  is the unburned gas temperature.

Detonation induction distances were correlated with  $K$  for  $CO/O_2$  and  $H_2/O_2$  mixtures, but not for  $CH_4/O_2$  mixtures. Whereas all the data for  $H_2/O_2$  and  $CO/O_2$  mixtures lay on a single correlating curve, that for  $CH_4/O_2$  mixtures divided into two groups, depending on mixture ratio. Neither group of  $CH_4/O_2$  data fell on the correlating curve for the  $H_2/O_2$  and  $CO/O_2$  mixtures. The authors attempted to account for this as a manifestation of the increased ion concentrations observed in hydrocarbon flames as compared with those in  $H_2/O_2$  or  $CO/O_2$  flames. Unfortunately, their argument is not internally self-consistent. They state: "It is suspected that certain ionized

particles are created at the elevated temperature and pressure conditions across the shock discontinuities. The ionization probes are triggered by these ionized particles before the flame arrives..." They then discuss the well-established large concentrations of ions in hydrocarbon/air (or hydrocarbon/O<sub>2</sub>) flames in terms of ionization of carbon particles formed in rich hydrocarbon flames. Not all the ionization in hydrocarbon flames is properly attributable to ionization of carbon particles; but it is inappropriate to discuss this subject, which is deserving of separate treatment, in this report. The important point is that the authors argue on the one hand that ionizing particles are formed behind the shock wave and this flame front arrival, and on the other hand that the particles are the products of flames. Now, it is well documented that precursor ionization occurs in shock waves (Reference 2-14). However, this is probably due to photoionization, the short-wavelength radiation originating from the highly-ionized heated gas in the case of strong shocks (Reference 2-14), and from chemiluminescence in the case of flames in which CO is oxidized (Reference 2-15). These precursors precede the shock wave.

While the arguments of Bollinger and coworkers (References 2-8 and 2-14) cannot be accepted, the possibility of precursor ionization must be admitted. However, this ionization should be present in their CO/O<sub>2</sub> cases, as well as the CH<sub>4</sub>/O<sub>2</sub> cases, and thus is not unique. It must be noted that Bollinger, et al. (References 2-8 and 2-14), use Strauss and Edse's (Reference 2-16) methane-burning velocity data, which show that the burning velocity increases with increasing pressure. More recent work shows that methane burning velocities decrease with increasing pressure (Reference 2-17). Unfortunately, the direction of correction produced by this trend is to increase the difference between the CH<sub>4</sub>/O<sub>2</sub> data and the H<sub>2</sub>/O<sub>2</sub> and CO/O<sub>2</sub> data in the Bollinger, et al., correlation (References 2-8 and 2-14). A more likely explanation of the unique behavior of CH<sub>4</sub> as a fuel in these DDT studies lies in its ignition kinetics, which differ from those of CO/O<sub>2</sub> and of H<sub>2</sub>/O<sub>2</sub>.

Yet another approach to predicting run-up distances has been taken by Shchelkin and Troshin (Reference 2-18), who derive the expression:

$$x_1 \sim \frac{c_1^2 d}{C^3 K^3 (\sigma_3 - 1)^2 U_k} \quad (2-2)$$

where:  $x_1$  is the run-up distance;

$c_1$  is the speed of sound in the quiescent unburned gas;

$d$  is the tube diameter;

$C$  is a coefficient accounting for the enlargement of flame surface by nonuniform flow in the tube behind the shock front;

$K$  is the Karman number, the ratio of the mean velocity of turbulent fluctuations,  $V'$ , and the velocity of the disturbed unburned gas,  $w$  ( $K = V'/w$ );

$\sigma_3$  is the ratio of the density of unburned and burned gas across the detonation front ( $\sigma_3 = \rho_1/\rho_3$ ), and

$U_k$  is the burning velocity of the mixture.

Shchelkin and Troshin note that  $0.6 \leq KC (\sigma_3 - 1) \leq 2$ ; which is to say  $KC (\sigma_3 - 1)$  is of the order of 1, and further  $C$  is of the order of 2 or 3. The model used in deriving this expression, however, is that of successive shock waves forming during flame acceleration, and detonation occurring at the point of coalescence. They admit the possibility that detonation may occur after the point of coalescence. Experimentally, shock coalescence is but one mechanism for the transition to detonation. They concede (Reference 2-18) that the expression (2-2) is qualitative in nature and they offer no experimental evidence supporting it. Since the model fits but one of several modes of DDT, it is not surprising that it is of limited usefulness. In particular, no confidence may be placed in run-up distances computed from expression (2-2) in attempts to estimate hazards in the design of piping runs containing detonatable mixtures.

Holzappel and Schoen (Reference 2-19) obtained an experimental DDT run-up distance of approximately 12 m (39.9 ft) for propane/air mixtures at an equivalence ratio of 1.15 in a 15.0-cm- (5.9-in.-) diam stainless-steel pipe closed off at the ignition end. The internal wall finish of the pipe was stated to be of "technical grade roughness," but was not otherwise characterized. It was also noted that shorter DDT run-up distances were observed in a test configuration in which the flame was ignited in a vessel connected to the inlet end of the pipe. Safety considerations based on the knowledge of DDT run-up distances must take this effect into account.

Run-up distances, for propane/air and gasoline/air mixtures, were estimated from expression (2-2) to be about 30.5 m (100 ft). In fact, for the Coast Guard work described herein, no detonations developed in the shock tube filled with stoichiometric propane/air mixtures in 31.5 m (104 ft) before the tube was modified. Originally, this shock tube had been designed to provide a test gas volume of known properties. It has, therefore, been carefully honed and polished to eliminate surface irregularities. To obtain DDT within the available tube length of 31.5 m (104 ft), it was necessary to insert tube liners of expanded metal, thereby increasing internal wall roughness.

Neither expression (2-1) nor (2-2) explicitly allows for wall roughness. To be sure, expression (2-1) includes a Reynolds number; however, it is based on tube diameter. This is clearly inappropriate for large tubes such as the one employed in this work, or those for proposed vapor recovery systems. A more appropriate characteristic length would be related to boundary layer thickness behind the accelerating shock wave, or related to average surface profiles of the pipe interior wall. The importance of turbulence in flame acceleration has long been recognized. However, the time-dependent flow of DDT has resisted analysis, and is likely to do so for some time, in view of the complexity of the problem. Until better theoretical models are available, empirical correlations will be needed.

To provide the Coast Guard with needed information on the adequacy of flame control devices that could be used in vapor recovery systems and to develop empirical data on run-up distance to detonation for gasoline/air

mixtures, a test facility for experimental evaluation had to be constructed of full-scale hardware. The safety of operating personnel and adjacent activities was of prime concern in selection of the test site location and of pressure rating the test components. To this end, preliminary calculations of detonation pressures and of reflected detonation pressures were carried out for three selected hydrocarbon/air mixtures. The Lewis C.E.C. 71 computer program (Reference 2-20) was used in these computations. While steady detonation pressures are directly computed by this program, which uses stored thermodynamic data and composition data specified in the input data, reflected detonation pressures are not automatically computed. The velocity of the reflected shock wave was computed from the particle velocity ahead of the reflected wave (equal to the particle velocity behind the detonation wave) and the knowledge that behind the reflected shock the particle velocity is zero (the gas is brought to rest by the rigid wall) (Reference 2-21). Using the reflected shock velocity and postdetonation gas properties as input data, the reflected shock wave properties were computed using the "SHOCK" subroutine of the Lewis program.

The results of these calculations are shown in Figures 2-1, 2-2, and 2-3, which detail detonation wave velocities, pressures, and temperatures for toluene, N-heptane, and propane mixed with air at several stoichiometries. Reflected shock wave properties were computed for the same fuel/air mixtures at one stoichiometry,  $\phi = 1.1$ . The detonation wave and reflected shock wave properties are summarized in Table 2-1. The value of 1.1 was chosen for the equivalence ratio because gasoline and air mixtures have maximum flame speed at about  $\phi = 1.1$  (Reference 2-22), hence this was considered the most hazardous condition. Qualitatively, the higher the flame speed, the shorter the run-up distance, and although  $\phi = 1.1$  does not correspond to the maximum detonation wave pressure, the differences between the detonation pressures at  $\phi = 1.1$  and the maximum value is not great and would not compromise normal safety factors. A nominal working pressure of 4137 kN/m<sup>2</sup> (600 psia) was chosen as a design working pressure for the piping and component in the test assembly. A safety factor of somewhat less than four would result if the full reflected shock pressure were realized. One notes, however, that these pressures are for plane reflection from a rigid wall. In the actual experiment, reflection from a flame arrester would never result in the full pressure development due to flow through the arrester. Similarly, reflection at a pipe bend would result in an expansion wave (soon developing into a detonation) in the downstream leg of the bend, and again the full reflected shock pressure on the bend wall would not be realized.

Since it is not possible to calculate peak pressures during the transition, it was judged that the hazard could not be computed with sufficient certainty to assure that the run-up pipe would remain intact at the time of transition. The experimental hardware was therefore required to be located at a well-protected test site where the fuel-and-air mixing and firing could be conducted remotely.

The experimental program was performed at the Jet Propulsion Laboratory's Edwards Test Station (ETS) where suitable safety protection and support activities were available. A new facility that utilized the piping, structural supports, components, and instrumentation from the JPL-Pasadena shock-tube facility was installed on an existing test site. A photograph of this test facility is shown in Figure 2-4.

## SECTION III

### TEST FACILITY DESCRIPTION

#### A. GENERAL

All testing was performed at the B-Stand facility of the Jet Propulsion Laboratory's (JPL) Edwards Test Station (ETS). This is a remote site in the Mojave desert leased from Edwards Air Force Base for hazardous testing. B-Stand is one of five test installations in the liquid propulsion area of the test station. Other adjacent areas include solid propulsion, environmental simulation, solar thermal electrical power, and electrical vehicle testing. Most areas are remotely controlled and monitored from a barricaded building called the "blockhouse," which contains the control consoles and a central data recording system. The blockhouse is connected with the test stands by a series of underground walk-through tunnels containing electrical power conduits, high-pressure gas lines, instrumentation, and control cables. The B-Stand test area contains an air compressor system, fuel system, fuel vaporizer and condenser loop, fuel and air induction system, and the detonation test piping. The test facility flow system schematic diagram is shown in Figure 3-1. Table 3-1 gives a description of the symbols used in the diagram. A Firex system provides emergency water deluge to the fuel system, vaporizer and condenser loop, and the test section piping in the case of fire. A bank of lead-acid batteries at the stand provides emergency back-up power for the 28-Vdc electrical power in the control systems.

#### B. AIR COMPRESSOR SYSTEM

Air flow for testing was provided by a Spencer Model 80 x 10 SOH multi-stage centrifugal turbine compressor, rated at  $7.79 \text{ m}^3/\text{min}$  (275 icfm) at  $38.6 \text{ kN/m}^2$  (5.6 psid), that is driven by a 7.46-kW (10-hp) electrical motor. The compressor was provided with an inlet filter to assure clean air and a  $41.4\text{-kN/m}^2$  (6-psid) pressure relief valve in the event of complete system blockage. Air flow in the 10.2-cm- (4-in.-) diameter induction piping system was controlled by the remote positioning of an air metering valve and air by-pass valve. Valve position was controlled and monitored in the blockhouse. Air flow was determined by measuring upstream total pressure and differential pressure loss across a Meriam Laminar Flow Element (LFE). The air was heated by compression up to  $32^\circ\text{C}$  ( $90^\circ\text{F}$ ) above the ambient inlet temperature. The measured air temperature and flowmeter pressures were used by the on-line data system to calculate air mass flow for continuous display and digital data recording.

#### C. FUEL SYSTEM

Liquid fuel was supplied from a  $0.049\text{-m}^3$  (13-gal) spherical aluminum pressure vessel with a  $6895\text{-kN/m}^2$  (1000-psia) working pressure. It was pressurized for fuel expulsion by means of a remotely-regulated gaseous nitrogen supply, with remotely-operated valves to deliver and vent the pressurant.

Table 3-1. Symbols and Description for Flow System Schematic Diagram

| Symbol                                                                              | Description                                                    |
|-------------------------------------------------------------------------------------|----------------------------------------------------------------|
|    | Manual Globe Valve                                             |
|    | Electric solenoid operated valve                               |
|    | Electric motor operated valve                                  |
|    | Electric motor operated ball valve                             |
|    | Air piston operated ball valve                                 |
|    | One-way flow check valve                                       |
|    | Pressure relief safety valve                                   |
|    | Dome pressure regulator valve                                  |
|    | Manual set pressure regulator valve                            |
|    | Electric motor operated pressure Regulator valve (dome loader) |
|    | Pressure rupture-disc assembly                                 |
|  | Pressure gage                                                  |
|  | Voltmeter transducer                                           |
|  | Ammeter transducer                                             |
|  | Temperature transducer                                         |
|  | Pressure transducer                                            |
|  | Flame sensor transducer                                        |
|  | Flowmeter transducer                                           |

The fuel tank valve, pressure relief valve, and rupture disc were all manifolded to a burn stack fired by natural gas. A gaseous nitrogen purge kept the venting lines clear of fuel vapors. Liquid level in the fuel tank was determined from a high-pressure sight glass. Liquid fuel was delivered through a 0.95 cm-(0.375-in.-) diameter line containing a manual isolation valve, remote isolation valve, 10-micron filter, turbine flowmeter, and remote metering valve for flow control. Valve positioning was controlled and monitored in the blockhouse. Fuel temperature and pressure, and turbine hertz were used by the data system to calculate fuel mass flow for continuous display and digital data recording. The data system also calculated and displayed air-to-fuel mass flow ratio and equivalence ratio.

#### D. FUEL VAPORIZER AND CONDENSER LOOP

An electrical heater was used to vaporize the fuel before injection into the flowing air stream. The vaporizer consisted of a 10.2-cm- (4.0-in.-) diameter by 36.6-cm- (14.4-in.-) long aluminum cylinder heated by four 2.5-kW electrical resistance elements. Thirteen turns of fuel line were coiled around the aluminum core and insulated with a Fiberfrax ceramic fiber blanket. A sheet-metal housing provided weather protection. The vaporizer heater power was controlled by motor-driven Powerstat Model No. 60 MB-1256-DT-2S with the input voltage and current monitored in the blockhouse. A controller limit switch in the heater circuit, triggered by a thermocouple measuring core temperature, was used to prevent overheating of the vaporizer.

A fuel condenser loop was used to prevent the exhausting of vaporized fuel into the atmosphere during pretest warm-up and system stabilization. In the "condenser" position, a remotely-operated three-way fuel mixer valve directed the vaporized fuel into a water-cooled heat exchanger, where most of the fuel was reliquified and collected in a storage tank for later disposal. The noncondensables were vented through the collector tank and passed along to the burn stack. With the three-way fuel mixer valve energized in the "run" position, the vaporized fuel was directed to the fuel and air induction system.

#### E. FUEL AND AIR INDUCTION SYSTEM

A 4.9-m- (16-ft-) long induction system consisting of 10.2-cm- (4-in.-) diameter standard weight pipe and fittings was used to assure thorough mixing of the vaporized fuel and air in the detonation run-up piping. Fuel was injected at the start of this pipe run through the seven-tube manifold shown in Figure 3-2. Each tube discharged into an equal portion of the cross-sectional flow area of the pipe. Initially it was positioned to inject the fuel vapor in the downstream direction, but was later reversed to inject upstream against the flow of air to improve the fuel-to-air distribution. A four-element Komax triple-action motionless mixer was installed downstream of the injector for additional turbulent mixing. This was followed by a 90-deg turn in flow through a pipe tee containing a low-pressure rupture-disc assembly in one branch and a one-way flow check valve in the other branch. A gas-sample collection rake was located further downstream, just ahead of two additional pipe

Figure 3-2. Vaporized Fuel Injector Manifold

tees containing low-pressure rupture-disc assemblies. The induction system was terminated by a remotely-operated high-pressure isolation valve at the inlet to the detonation test piping. A photograph of the combined air, fuel, vaporizer, condenser, and induction systems is shown in Figure 3-3.

#### F. DETONATION TEST PIPING

Most of the piping, structural supports, and components used in the detonation test system were obtained from the JPL-Pasadena shock-tube facility. The piping was made from heavy-walled stainless-steel tubes that were bored, honed, and polished to a 15.32-cm (6.03-in.) internal diameter with a very smooth finish. Special extra-strong stainless-steel flanges, with O-ring seals, were used to join the pipe section. These flanges were drilled with an eight-bolt hole pattern that required an adapter plate for mating with the twelve-bolt hole pattern in the standard extra-strong 15.2-cm- (6-in.-) diameter pipe flanges used on the newly-fabricated test components.

The upstream end of the detonation test piping began with a 15.2-cm- (6-in.-) diameter extra-strong pipe tee mounted in a thrust support stand bolted to a concrete foundation slab to absorb the axial force of the detonation. The induction system piping was attached to the side branch of the inlet tee and a high-pressure rupture-disc assembly was mounted on the upstream branch. A flow straightener made from a spiral-wound, crimped stainless-steel ribbon assembly 15.2 cm (6 in.) in diameter by 5.08 cm (2 in.) long, shown in Figure 3-4, was mounted on the downstream branch of the tee at the inlet to the ignition section (No. 1 of Figure 3-1). This flow straightener was later changed to a Shand and Jurs spiral-wound, crimped aluminum ribbon flame arrester for the final phase of testing performed under conditions of continuous mixture flow. All of the detonation test piping mounted downstream of the thrust stand were supported by a pair of overhead I-beams with trolley hangers and saddles for easy servicing and flexibility in making various piping arrangements.

The number of pipe sections used and their order of installation depended on the specific test requirements. The total number of shock-tube piping sections available was eleven, which provided a total assembly length of 31.5 m (103.5 ft). A brief description of the various shock-tube pipe sections shown schematically in Figure 3-1, their normal function, and instrumentation capabilities follow:

- (1) Ignition section (No. 1): one piece 1.68 m (5.5 ft) long containing the hydrogen-air-spark igniter, two flame sensors, and one temperature sensor.
- (2) Flame stabilization section (No. 2): one piece 3.05 m (10 ft.) long containing two flame sensors.
- (3) Run-up sections (No. 3, No. 4, and No. 5): three pieces each 4.57 m (15 ft) long containing an expanded metal tube liner to generate turbulence in the propagating flame. No instrumentation ports were available in these sections.
- (4) Verification sections (No. 6, No. 7, and No. 8): three pieces: one 3.05 m (10 ft) long with two flame sensors and two pressure sensors, one 1.52 m (5 ft) long with two flame sensors and two pressure sensors added later in the program, and one 1.83 m (6 ft) long with two flame sensors, two pressure sensors, one temperature sensor, and one pressure port for test section upstream differential pressure measurement.
- (5) Test section (No. 9): one piece 3.05 m (10 ft) long with no instrumentation. This section was replaced with the experimental detonation arrester during evaluation tests.
- (6) Witness section (No. 10): one piece 1.52 m (5 ft) long with two flame sensors, two pressure sensors, one temperature sensor, and one pressure port for the test section downstream differential pressure measurement.
- (7) Extension section (No. 11): one piece 2.13 m (7 ft) long with no instrument ports, used to minimize the amount of ambient light entering the witness section.

Two additional extension sections (No. 12 and No. 13), each 6.8 m (22.4 ft.) long and made from standard weight 15.2-cm- (6-in.-) diameter pipe, were added later for the final test phase.

The exit gas sample rake was normally installed between the flanges of the witness section and the extension section. Individual fuel/air mixture samples were collected for laboratory analysis at this location or a continuous sample was fed directly into the on-site hydrocarbon gas analyzer described in the next section of this report. In either case, the sample line was closed-off by a remotely operated valve 10 seconds before the detonation test to protect the collection system from possible high-pressure shock waves. For this same reason, the

Figure 3-3. Combined Air, Fuel, Vaporizer, Condenser, and Induction Systems on B-Stand

Figure 3-4. Spiral-Wound, Crimped Stainless-Steel, Ribbon Air Flow Straightener

highly sensitive pressure transducers used to measure the air-flow pressure loss across the test section arrester before and after each detonation test were also isolated by remotely operated valves.

#### G. HYDROGEN-AIR-SPARK IGNITER

The hydrogen-air-spark igniter installation shown in Figure 3-5 consisted of two insulated high-voltage electrodes, Auburn Model I-28, extending into the center of the flowing stream from opposite sides of the ignition section pipe. A spark gap of 0.24 cm (0.094 in.) was maintained between the two electrodes. Power for the spark igniter was obtained from a Webster Model 312 high-voltage transformer having a 120-vac, 2.2-A, 60-Hz primary and a 10,000-vac, 0.023-A secondary. Directly upstream of the electrodes, a small injector head discharged a stoichiometric mixture of hydrogen and air through the spark gap. The flow of hydrogen and air could be adjusted to suit the ignition energy required by the fuel/air mixture flow conditions. The initiation of spark current and the operation of the hydrogen and air solenoid-operated valves were all controlled simultaneously by a preset sequence timer to assure accurate and repeatable ignition timing. The igniter "on-time" was normally set at 500 ms, but was later reduced to 180 ms during the final phase of testing.

## SECTION IV

### INSTRUMENTATION AND CONTROLS

#### A. GENERAL DESCRIPTION

The potentially hazardous nature of detonation testing required that all instrumentation and controls be remotely operated and monitored. Test system parameters were measured at the test site using electrical transducers with their signals conducted to the blockhouse for conditioning, recording, and display. Location and identification of all the principle instrumentation parameters and controls are shown in Figure 3-1. Table 4-1 is a listing of the nomenclature for instrumentation and calculated parameters.

Test system parameters were divided into two groups: (1) steady-state (low-speed) data and (2) transient-state (high-speed) data. Steady-state data includes all the measured and calculated parameters for the air system, fuel system, fuel vaporizer and condenser loop, fuel and air induction system, hydrocarbon gas analyzer, and the pre- and posttest pressure loss measured across the test arrester. Transient-state data includes the measured and calculated flame velocities and peak pressures developed in the facility piping during the transition from deflagration to detonation and the success or failure of the detonation flame arrester. Steady-state data was recorded and calculated on the JPL-developed Integrated Digital Acquisition and Controls System (IDAC). Transient-state data was recorded on two high-frequency FM tape recorders and played back on an oscillograph at an expanded time scale. Flame velocities and peak pressures were manually scaled and calculated from the oscillograph traces.

All critical control functions were either manually positioned on the control console or automatically operated by the preset sequence timer. These operations were selectively recorded using contact closures on IDAC, FM tape, or a second high-speed oscillograph. This latter oscillograph also recorded several important facility parameters to provide a time history of the test facility operations during detonation firings that could be used to diagnose any malfunctions or unusual incidents.

Two strategically-placed television cameras, with displays in the blockhouse, monitored the fuel systems area and the test section piping during test operations. A motion picture camera also recorded any events at the test section during actual test firings. Visual coverage and controlled access to the test area were maintained by a safety monitor in an observation tower located over the blockhouse.

#### B. STEADY-STATE DATA

Air-mass flow was calculated from measurements made on a Meriam LFE Model 50 MC2-4 flowmeter. A Statham Model PL 280 TC pressure transducer was used to measure the upstream total pressure, and a Statham model PM 5 TC pressure transducer was used to measure the differential pressure across the flow element. Air temperature was measured with a Thermo-Electrical Model K18G-1600 chromel-alumel thermocouple.

Table 4-1. Instrumentation and Calculated Test Parameters Nomenclature

| Steady State<br>Parameters | Units<br>S.I. (Engr.)    | Description                                 |
|----------------------------|--------------------------|---------------------------------------------|
| PBO                        | kN/m <sup>2</sup> (psig) | Air flowmeter inlet pressure                |
| DPO                        | kN/m <sup>2</sup> (psid) | Air flowmeter differential pressure         |
| TOI                        | °C (°F)                  | Air flowmeter temperature                   |
| PFT                        | kN/m <sup>2</sup> (psig) | Fuel tank pressure                          |
| TFT                        | °C (°F)                  | Fuel tank temperature                       |
| PDF                        | kN/m <sup>2</sup> (psig) | Fuel tank dome loader pressure              |
| PFL                        | kN/m <sup>2</sup> (psig) | Fuel line pressure                          |
| TFL                        | °C (°F)                  | Fuel line temperature                       |
| FMF                        | Hz (cps)                 | Fuel flowmeter frequency                    |
| PVI                        | kN/m <sup>2</sup> (psig) | Fuel vaporizer outlet pressure              |
| TVI                        | °C (°F)                  | Fuel vaporizer outlet temperature           |
| TV2                        | °C (°F)                  | Fuel vaporizer core temperature             |
| TMF                        | °C (°F)                  | Fuel injector inlet temperature             |
| PMI                        | kN/m <sup>2</sup> (psig) | Fuel/air mixer outlet pressure              |
| TMI                        | °C (°F)                  | Fuel/air mixer outlet temperature           |
| TCF                        | °C (°F)                  | Fuel condenser inlet temperature            |
| TCI                        | °C (°F)                  | Fuel condenser outlet temperature           |
| TWI                        | °C (°F)                  | Coolant water inlet temperature             |
| TW2                        | °C (°F)                  | Coolant water outlet temperature            |
| P1                         | kN/m <sup>2</sup> (psig) | Inlet tee pressure                          |
| TI                         | °C (°F)                  | Inlet tee temperature                       |
| T12                        | °C (°F)                  | Ignition section temperature                |
| PA1                        | kN/m <sup>2</sup> (psig) | Test section inlet pressure                 |
| DPAI                       | kN/m <sup>2</sup> (psid) | Test section differential pressure-pretest  |

Table 4-1. Instrumentation and Calculated Test Parameters Nomenclature  
(Continuation 1)

| Calculated<br>Parameters | Units<br>S.I. (Engr.) | Description                                                 |
|--------------------------|-----------------------|-------------------------------------------------------------|
| MA                       | kg/h (lb/h)           | Air mass flow                                               |
| MF                       | kg/h (lb/h)           | Fuel mass flow                                              |
| A/F                      | ratio                 | Air mass flow to fuel mass flow ratio                       |
| $\phi$                   | ratio                 | Equivalence ratio                                           |
| VA                       | m/s (ft/sec)          | Air flow velocity through 15.2-cm- (6.0-in.-)<br>diam. pipe |

Fuel-mass flow was calculated using measurements made with a Cox Model LF-G-1 turbine flow meter to determine volumetric flow, a Taber Model 206 pressure transducer measured fuel pressure, and a Thermo-Electrical Model K18G-1600 chromel-alumel thermocouple measured fuel temperature. Fuel pressure and temperature were used to determine fuel density from standard tables stored in the computer memory.

The air-to-fuel mass ratio and equivalence ratio in the induction system were determined from the calculated air-mass flow and fuel-mass flow noted above. The equivalence ratio of the air and fuel mixture passing through the test arrester and into the witness section was determined by a gas sample fed directly into an on-line total hydrocarbon gas analyzer. A detailed description of this system and the method of calculation is presented later in this section.

Operating pressures in the fuel vaporizer and condenser loop and the fuel/air mixer were measured with Taber Model 217 pressure transducers. Temperature measurements in the vaporizer fuel outlet line, fuel injector line, fuel/air mixer, and fuel condenser loop were all made with chromel-alumel thermocouples.

Pre- and posttest pressure loss measured across the test arrester were made with air only flowing through the facility piping. The upstream total pressure was measured with a Satham Model PL 280 TC pressure transducer and the differential pressure across the arrester was measured with a Satham Model PM 80 TC pressure transducer.

All of the preceding pressure measurements were made using either gage-type pressure transducers or differential pressure transducers with the low side vented to ambient pressure. To convert these measurements to an absolute pressure level, the barometric pressure had to be added. Local barometric pressure was obtained from the weather station at Edwards Air Force Base. A Taber Model 254 absolute pressure transducer installed at the test stand was adjusted to read this value of barometric pressure at the beginning of each test series. The IDAC computer program used this locally varying barometric pressure input for all calculations.

### C. TRANSIENT-STATE DATA

The detonation facility piping flame sensors were DuMont Type 6291, 10-stage multiplier phototubes with flat end-window photo cathodes. These instruments have an average luminous sensitivity of 60 A/lm and a spectral response from 3500 Å to 5850 Å with maximum response at 4400  $\pm$  500 Å. The blue-colored stoichiometric hydrocarbon/air flame falls well within this response range. These optical sensors have been successfully used in the JPL shock-tube facility for many years to detect very-high-velocity shock waves generated by a high-capacitance arc discharge driver. The phototube viewing port was constructed with front and rear collimating slots 1.27 cm (0.50 in.) high by 0.013 cm (0.005 in.) wide, separated at a distance of 7.62 cm (3.0 in.). These slots limit the amount of light that reaches the phototubes and eliminate reflected beams. The result is a very sharp signal with a rise time response on the order of microseconds, which was required for shock-wave velocity determination. The flame sensor slots required only minor modifications for the deflagration-to-detonation flame velocity measurements.

There were three distinct flame intensity sections in the detonation piping. In the ignition section (No. 1) and stabilization section (No. 2), flame intensity was weak; however, the flame velocity was beginning to accelerate. It was necessary to remove the rear collimator slot from the viewing port and to increase the amplification gain to record a good signal. In the verification sections (No. 6, No. 7, and No. 8) the detonation flame was very intense, with a velocity of around 1800 m/s (5900 ft/s). Both front and rear slots were used in the viewing ports and the amplifier gain was normally low. The third region was the witness section (No. 10). Here it was important to detect any flame that may have penetrated the detonation arrester; therefore, the rear slot was removed from the viewing ports and the amplifier gain was high.

High-response pressure sensors were installed directly opposite the flame sensors in two verification sections (No. 6 and No. 8) and in the witness section. These were PBC Piezotronic Model 113 AP quartz-crystal, high-frequency pressure transducers flush-mounted to the inside wall of the pipe. They were capable of measuring peak pressure levels up to 20,700 kN/m<sup>2</sup> (3000 psi) with a frequency response of 100,000 Hz for the advancing and reflected detonation shock waves. PBC Model 402 in-line amplifiers were installed with the pressure transducers to drive the signals over the long transmission lines to the blockhouse.

During the last two phases of the test program, the two quartz-crystal pressure transducers in the witness section were relocated upstream to unused ports in the verification section (No. 7). In their place, two Statham Model PG 856 G bonded strain-gage-type pressure transducers were installed in the witness section. These lower-range instruments provided higher accuracy in measuring the peak-pressure pulses passing through the arrester from an arrested detonation flame.

A 100-Hz coded time pulse and the spark igniter current were recorded on both high-frequency FM tape recorders and the on-line oscillograph. These signals were used as reference points for test initiation and time correlation between recorders. Typical examples of transient-state data

from the FM tape recorders played back on an oscillograph with an expanded time base of 32 to 1 are shown in Figure 4-1.

#### D. GAS-SAMPLE ANALYSIS SYSTEM

A gas-sample analyzer was installed at the test site to provide an on-line indication of the gasoline and air mixture flowing through the test section piping. The laboratory analysis method using individual gas-sample cylinders, that was used for propane and air mixtures during the facility check out, was too slow and costly for routine testing. The laboratory analysis method, however, did provide an accurate verification of the instrumentation measurements for on-line calculations of air flow and fuel flow. It also demonstrated the effectiveness of the vaporized fuel injection and mixing techniques by showing that very little of the vaporized propane condensed on the cold walls of the test system piping. This was not the case with vaporized gasoline and air mixtures because of the lower condensation temperature of gasoline. The amount of gasoline vapor that would be condensed was a function of many variables including: ambient air temperature, vaporized fuel temperature, fuel-and-air-flow rates, equivalence ratio, and pretest run-in time. To assure that a combustible mixture would be flowing through the test arrester at the time of ignition, an on-line total hydrocarbon gas analyzer was required.

The gas-analyzer system was designed to use an existing Beckman Model 400 hydrocarbon analyzer instrument. This analyzer automatically and continuously measures the concentration of hydrocarbons in a flowing gas sample, utilizing the flame ionization method of detection. A premixed fuel gas consisting of 40% hydrogen ( $H_2$ ) and 60% nitrogen ( $N_2$ ) was used to obtain the analyzer's highest rated hydrocarbon sensitivity of 10% methane ( $CH_4$ ) equivalence. For propane ( $C_3H_8$ ), this sensitivity is reduced to 1/3 or 3.3%  $CH_4$  equivalence because of the greater number of carbon atoms per molecule.

The percentage of propane in the fuel/air mixture at an equivalence ratio ( $\phi$ ) of 1.0 is about 4.0%. At the established standard test condition, where the equivalence ratio is 1.1, the percentage of propane is about 4.4%. In either case, the percentage of hydrocarbons in the test sample to be analyzed is beyond the upper range of the Beckman analyzer. The test sample had to be diluted with a known amount of air to be within the measurement range.

A 2%  $C_3H_8 + N_2$  gas mixture was selected as the calibration span gas to adjust the gas analyzer to read 50% of full scale. A second calibration gas containing 4%  $C_3H_8 + N_2$  was diluted by an air mixing system with one part air to one part gas mixture so that it would also read 50% of full scale. Using the same dilution ratio, a 4.4%  $C_3H_8$  plus air test sample gas mixture would record about 56% of full scale on the gas analyzer.

The Indolene HO III clear gasoline used in this test program was analyzed to have a total carbon-to-hydrogen ratio of 1.93 ( $CH_{1.93}$ ). In calculating a stoichiometric air-to-fuel ratio it was assumed that the gasoline has a simplified molecular structure containing 8 carbon molecules or a chemical formula of  $C_8H_{15.44}$ . The balanced chemical equation for ideal combustion of Indolene gasoline and air would then be as follows:

Figure 4-1. Typical Example of Transient-State Data Played Back on an Oscillograph at an Expanded Time Base of 32 to 1

The stoichiometric air to fuel ratio (A/F) on a weight basis was calculated to be 14.62 ( $\phi = 1.0$ ). For the standard test condition ( $\phi = 1.1$ ), A/F = 13.29 and the percentage of gasoline in air is 1.92%. Using the 2%  $\text{C}_3\text{H}_8 + \text{N}_2$  calibration gas to span the analyzer to 50% of full scale and the same one-to-one air dilution rate for the gasoline-and-air mixture sample, the carbon ratio between propane and gasoline is 3 to 8, which should give an analyzer reading of 64% of full scale.

A significant amount of vaporized gasoline will condense out of the flowing mixture onto the cold walls of the test facility piping. An extremely rich fuel mixture would be required at the upstream injection section to provide the ideal mixture ( $\phi = 1.1$ ) at the downstream test section. It was doubtful that a fuel-rich mixture at the upstream ignition location would result in the rapidly accelerating flame needed to produce a detonation. On the other hand, any gasoline condensed on the piping walls should be reevaporated by the propagating flame front and enter into the combustion process. It was determined to maintain the ideal mixture ratio at the point of injection, and monitor the test section exit for evidence of a combustible mixture. The lower flammability limit of gasoline at the nominal test condition would be an A/F = 20.89 ( $\phi = 0.7$ ), and the gas analyzer should read 41% of full scale.

The hydrocarbon gas analyzer was located as close to the test section exit as practical, to minimize response time. It was placed in a steel-walled protective enclosure, which unfortunately had no provision for thermal control. Although the Beckman Model 400 analyzer has an internal controller for maintaining the desired 40°C (120°F) operating temperature under normal laboratory conditions, it was doubtful that it could accommodate the broad range of temperatures to be experienced on the test site. The absolute accuracy of this instrument was not determined; however, a 1-to-2% zero shift was noticed during the morning, midday, and late-afternoon calibrations. Used primarily as an indicator for the existence of a combustible mixture in the test section, a gasoline and air test firing was made whenever the analyzer reading exceeded 41% of full scale.

A flow-system schematic diagram of the hydrocarbon analyzer and air dilution system is shown in Figure 4-2. Starting with the gas-sample rake in the test section piping, the sample mixture is directed into a close-coupled three-way solenoid valve. When deenergized, this valve isolates the sample rake and allows a continuous flow of 100%  $\text{N}_2$  at low pressure to purge the sample delivery line. When the valve is energized, the purge is closed off and the sample gas is directed into either a sample collection cylinder or through a by-pass line into a visual flowmeter. The gas-sample pressure level at this point is witnessed on a pressure gage and relayed to a combination air- and spring-loaded pressure regulator. This regulator delivers the dilution air from a compressor and receiver tank, at the same pressure as the gas sample, to a second visual flowmeter. Flow-control needle valves at the inlet of each flowmeter are used to proportion the air and gas-sample flow rates to the desired dilution level. A gas-transfer pump then delivers the diluted sample through a third visual flowmeter to the total hydrocarbon analyzer. To minimize system response time, an internal sample-bypass feature provides high-velocity sample flow through

Figure 4-2. Hydrocarbon Gas Sample Analyzer and Air Dilution Flow System Schematic Diagram

the analyzer, with only a small portion of the sample fed into the ionization flame burner. The bypass flow is witnessed on a fourth visual flowmeter.

A regulated supply of 100%  $H_2$  was used to enrich the ionization flame burner only during the ignition and start-up procedure. The ionization flame is maintained by the pressure-regulated flows of 40%  $H_2$  + 60%  $N_2$  gas mixture and 100% pure (oil-free) air. The pure air can also be directed into the analyzer inlet for zero calibrations. A pressure-regulated supply of 2%  $C_3H_8$  +  $N_2$  gas mixture, which can be directed into the analyzer inlet, is used for calibration span of the visual output indicator. A second pressure-regulated supply of 4%  $C_3H_8$  +  $N_2$  gas mixture can be directed into the sample line ahead of the dilution system to verify the desired dilution ratio setting.

The only difficulty with this gas-analyzer installation, other than the lack of adequate temperature control, was that the detonation shock wave, blowing out through either the rupture disc port or the exit of the extension piping, would extinguish the ionization flame burner. Consequently, after each test, the burner had to be relit and stabilized. The 100%  $H_2$  enrichment greatly simplified this reignition operation. Analyzer response time after actuation of the three-way sample solenoid valve was 30 seconds, plus another 30 seconds to fully stabilize the reading. Line length between the sample rake and the analyzer inlet was approximately 6.1 m (20 ft.)

#### E. PARAMETER MEASUREMENT AND CALCULATION UNCERTAINTIES

To get maximum accuracy from the instrumentation systems used at ETS, an end-to-end system calibration method is employed. All calibration signals are initiated at the transducer or between the transducer and the first piece of signal conditioning equipment, and recorded on the digital recorder, FM recorders, and oscillograph recorder. All calibration signals recorded are at known values and are independent of amplifier gain changes and power supply setting inaccuracies.

Three calibration points are recorded for each instrumentation parameter: (1) "Cal Low", (2) "Cal Ambient," and (3) "Cal High." Cal low is a power-off or shorted input signal. Cal ambient is an ambient pressure, temperature, voltage, etc. For gage pressures and voltages, this is normally a zero condition; if a zero condition is not possible, the cal ambient is a known pressure or voltage. Cal high is a voltage substitution or a known unbalance condition on top of the ambient calibration. For thermocouple readings, voltages, and most special parameters, known substitute voltages are recorded. For bridge measurements, an external shunt resistor is used to unbalance the bridge.

The Integrated Digital Data and Control System (IDAC) is the primary recorder for steady-state data. The system also has computer capability that converts input data to engineering units, and outputs it on a printer or the television (TV) monitors. A special IDAC software program was written for the air and fuel systems data to calculate air-mass flow, fuel-mass flow, air-to-fuel mixture ratio, and equivalence ratio.

Each IDAC input channel, calculation parameter, or calculation result can be displayed singly on the TV monitor to five significant figures, with engineering units and channel identification number. Alternate preselected displays with up to four parameter values, but without engineering units or channel identifications, can also be monitored on TV.

The IDAC printer is capable of outputting 50 lines per second, with one channel per line, of real-time data in engineering units from assigned channels. The printer output was used as prime steady-state data reporting the test results. All IDAC data was also recorded on magnetic tape for off-line computer reduction if required. The following is a summary of the detailed analysis of the uncertainties associated with pressure and temperature measurements and the IDAC program-calculated parameters presented in Appendix A. These values can be assured with only a 95% ( $2\sigma$ ) probability.

- (1) Uncertainty for pressure measurement is  $\pm 0.39\%$  of transducer full-scale range.
- (2) Uncertainty for temperature measurement in percent of reading is:
  - (a) 10.0 to 31.8°C (50 to 100°F) =  $\pm 2.7\%$
  - (b) 37.8 to 93.3°C (100 to 200°F) =  $\pm 1.4\%$
  - (c) 93.7 to 148.9°C (200 to 300°F) =  $\pm 0.85\%$
  - (d) 148.9 to 204.4°C (300 to 400°F) =  $\pm 0.65\%$
  - (e) 204.4 to 276.7°C (400 to 530°F) =  $\pm 0.49\%$
  - (f) 276.7 to 1260°C (530 to 2300°F) =  $\pm 0.43\%$
- (3) Uncertainty for air-velocity or air-mass-flow calculations is  $\pm 1.82\%$  of value.
- (4) Uncertainty for fuel-mass-flow calculation is  $\pm 1.93\%$  of value.
- (5) Uncertainty for calculated air-to-fuel mixture ratio and equivalence ratio is  $\pm 2.65\%$  of value.

Using the uncertainties listed above, the maximum uncertainty that can be expected for the measured and calculated test parameters associated with the standard test condition are listed in Table 4-2.

The transient-state data were recorded on an Ampex Model FR 2200 and an Ampex Model FR 3020 high-frequency FM tape recorders. Photodetector flame sensors were the primary instruments used to determine flame velocities. Quartz-crystal pressure transducers were primarily used to measure peak-pressure pulses in the detonation wave, but they also served as back-up instruments to determine wave velocities. There was usually good agreement in calculated velocities between the flame sensors and the pressure sensors witnessing a stable detonation wave. This was not the case, however, when the sensors were located in the deflagration-to-detonation transition zone. The spinning detonation phenomenon, reported in References 2-9 and 2-10, would most likely explain this discrepancy.

Flame sensor and pressure sensor test data, along with the pre-and posttest calibrations recorded on the FM tapes, were played back on an oscilloscope at an expanded time base of 32 to 1. The peak-pressure

pulse deflections and the calibration parameter equivalents were scaled from these recordings and used to calculate the detonation wave pressures. The elapsed time between sequential flame sensor signals (or pressure sensor signals) were also scaled from the oscillograph recordings. Using this time data and the known distances between adjacent instrumentation transducer ports, the average flame velocities through each succeeding section of the detonation test piping were calculated.

The following is a summary of the Appendix A detailed analysis of uncertainties associated with transient-state measured detonation peak-pressure pulses and rise-time response limits of data recorded on FM tapes with a 32-to-1 time-expanded playback onto an oscillograph. These values can be assured with only a 95% ( $2\sigma$ ) probability.

- (1) The uncertainty for the peak-pressure pulse measurement is  $\pm 3.1\%$  of transducer span.
- (2) The response time limit for photodetectors and quartz-crystal pressure transducers is:
  - (a) 3.5 s on Ampex Model FR 3020 recorder.
  - (b) 7.0 s on Ampex Model FR 2200 recorder.

Using the uncertainties listed above, combined with an oscillograph readability uncertainty of  $\pm 5.0\%$  and a measured transducer spacing uncertainty of  $\pm 0.25\%$ , the maximum uncertainty that can be expected for measured and calculated parameters associated with a stable detonation wave at standard test conditions are listed in Table 4-2.

Table 4-2. Maximum Uncertainty for Measured and Calculated Parameters at the Standard Test Condition

| Parameter                           | Symbol  | Uncertainty                                         |
|-------------------------------------|---------|-----------------------------------------------------|
| Steady-State Data                   |         |                                                     |

| Air flowmeter differential pressure | DPO     | $\pm 0.0083 \text{ kN/m}^2 \pm 0.0012 \text{ psid}$ |
| Air flowmeter exit temperature      | TOI     | $\pm 1.3^\circ\text{C} (\pm 2.8^\circ\text{F})$     |
| Fuel line pressure                  | PFL     | $\pm 14.0 \text{ kN/m}^2 (\pm 2.0 \text{ psia})$    |
| Fuel line temperature               | TFL     | $\pm 1.0^\circ\text{C} (\pm 2.7^\circ\text{F})$     |
| Fuel flowmeter frequency            | FMF     | $\pm 0.8 \text{ Hz}$                                |
| Test section inlet pressure         | PAI     | $\pm 0.27 \text{ kN/m}^2 (\pm 0.039 \text{ psia})$  |
| Test section differential pressure  | DPA     | $\pm 0.028 \text{ kN/m}^2 (\pm 0.004 \text{ psid})$ |
| Test area ambient pressure          | PAMB    | $\pm 0.538 \text{ kN/m}^2 (\pm 0.078 \text{ psia})$ |
| Air mass flow                       | MA      | $\pm 5.67 \text{ kg/h} (\pm 12.5 \text{ lb/hr})$    |
| Air velocity                        | VA      | $\pm 0.08 \text{ m/s} (\pm 0.27 \text{ ft/s})$      |
| Fuel mass flow                      | MF      | $\pm 0.05 \text{ kg/h} (\pm 1.00 \text{ lb/hr})$    |
| Air to fuel mass ratio              | A/F     | $\pm 0.35$                                          |
| Equivalence ratio                   | $\phi$  | $\pm 0.12$                                          |
| Transient-State Data                |         |                                                     |
| Detonation peak-pressure pulse      | PXX     | $\pm 241 \text{ kN/m}^2 (\pm 35 \text{ psia})$      |
| Detonation flame velocity           | FXX-FYY | $\pm 98 \text{ m/s} (\pm 322 \text{ ft/s})$         |
| Detonation pressure wave velocity   | PXX-PYY | $\pm 98 \text{ m/s} (\pm 322 \text{ ft/s})$         |

## SECTION V

### TEST OPERATING PROCEDURES

#### A. GENERAL SAFETY REQUIREMENTS

All test operating procedures involving fuel transfer, or performed with the fuel system pressurized, required the safety tower operator to be in position, monitor all communication on a headset, and control access to the test area with the safety status lights. The test stand is normally in a GREEN condition, which permits open access to all personnel. Fuel transfers and test preparations were performed in an AMBER condition, which restricts nonoperating personnel to the workshop area, unless permission is granted to enter other areas. A RED condition was used during actual tests, which isolates the test stand and the surrounding designated area from all personnel.

A minimum of two men was required at the site during fuel transfers and test preparations. Personnel safety equipment included hard hats, face shields, gloves, and fire-retardant coveralls. Additional safety equipment was available including MSA breathing devices, safety showers, eye washes, and the Firex water deluge system. All operations, except the servicing and reconfiguration of the test arrester section, were performed using formal procedures in the form of check lists, with individual pages dated and timed, and with each step initialed by two persons witnessing the event.

An ignition-completion key switch, which prevented the actuation of the hydrogen-air-spark igniter except during checkouts and test operations, was located at the test stand. Igniter checkouts required that the air compressor be in operation to minimize the build-up of combustible mixtures in the test piping.

#### B. OPERATING PROCEDURE CHECK LISTS

The following is a description of the operating procedures and check lists used in the detonation tests.

##### 1. Pretest System Checkouts

- a. Preliminary Check. This check confirms proper installation of the test item, instrumentation and control cable connections, readiness of the nitrogen pressurant and purge systems, requested photographic coverage, and that the safety system is operational.
- b. Electromechanical Checkouts. These checks examine, at the test stand, the overall control system readiness by individual confirmation of proper operation of each control in the blockhouse.
- c. Sequence Timer/Emergency Circuit Checkout. This checkout operates the preset automatic sequence timer, without actual fuel flow, while recording control-element actuations on the facility oscillograph.

Sequence times of the various elements were measured and adjusted where necessary. The sequence was then repeated, adding a shutdown with the emergency switch to confirm proper emergency switch actuations.

d. Leak Checks. These checks provide a gaseous nitrogen system leak check at maximum operating pressure for the fuel system, fuel vaporizer and condenser loop, fuel induction system, and the air-compressor system.

NOTE: The four check-list procedures described above were not performed before each test, but were done when special circumstances, such as component changes, malfunctions, or severe weather, were encountered.

## 2. Fuel Transfer Procedures

a. Propellant (fuel) Fill Check Lists. These procedures are provided for transferring either propane or gasoline from their storage containers into the test stand fuel supply tank. Propane was transferred via its own vapor pressure. Gasoline was transferred from drums by means of an air-motor-driven pump. It was common to expect up to six separate tests in a day, each of which required approximately  $4.6 \times 10^{-3} \text{ m}^3$  (1 gal) of fuel. Therefore, the fuel supply tank was topped off for each test day.

b. Propellant (fuel) Offload. These transfers from the fuel supply tank were normally returned to the appropriate storage container. Small quantities of propane could also be disposed of through the burn stack. Gasoline from the vaporizer/condensor loop remaining in the collector tank was not suitable for recycling and was disposed of as waste. It was necessary to empty the collector tank after every two days of testing.

## 3. Test Preparations

The Test Preparations Check List for instrumentation and test systems was completed concurrently on the day of testing. In the blockhouse, all patchboard connections were completed and instrumentation was setup. An end-to-end instrumentation system calibration was performed. At the test stand, various safety check and facility setups were made: condenser cooling water was turned on, the hydrocarbon analyzer was put in operation, and the hydrogen and air gas pressures were adjusted for the igniter. At the control console, the air compressor was started and the air flow adjusted by means of the air metering valve and the air bypass valve. After the air system temperature and flow were stabilized at the desired values, the test item's pretest pressure loss was measured and recorded.

The fuel vaporizer heater was activated, and nitrogen purge gas flowed through the heater coils and into the condenser for the preheat cycle. The test stand safety condition was changed from GREEN to AMBER. The fuel supply tank was pressurized with nitrogen up to the desired operating pressure. When the heater core reached approximately 260°C

(500°F), the nitrogen purge gas was turned off and fuel flow was metered at a low level. The fuel flow was increased up to the desired test condition as the vaporizer heater reached the operating temperature.

Final visual checks were made of the test stand area, and the ignition completion key switch was turned on. All operating personnel evacuated the test stand area and its safety condition was changed to RED.

#### 4. Blockhouse Preparation

Blockhouse preparation begins with a weather station confirmation of wind velocity and direction and the local barometric pressure. Control console circuits for ignition and emergency shutdown functions were armed and each significant panel switch had its position confirmed. With all test personnel at their operating position, the test conditions were reviewed and confirmed. A pretest instrumentation calibration was recorded and the countdown procedure was begun.

#### 5. Countdown

A typical "countdown" procedure follows:

- (1) An announcement was made over the public address system to alert personnel in the general area that a detonation would occur. Generally, the detonation noise was very intense and sharp, capable of creating an indirect hazard. A horn signal was also sounded.
- (2) The IDAC tape, printer, and the oscillograph were turned on to a slow speed.
- (3) The hydrocarbon analyzer purge was turned off, allowing the analyzer to sample the mixture flowing through the witness section.
- (4) The fuel mixer valve was changed to the RUN position, allowing fuel to flow to the test piping for the first time in the test sequence. The burn stack purge valve was opened to sweep out combustible gases from the collector tank vent line. The oscillograph was turned off.
- (5) As the fuel and air mixture traveled through the test piping, the hydrocarbon analyzer responded with a steadily increasing signal. The countdown timer was then stopped for a HOLD period, while fuel and air-flow rates were confirmed or adjusted, if necessary.
- (6) When the countdown was resumed, the IDAC tape and printer were switched to continuous mode and the oscillograph and movie camera were turned on.

- (7) The hydrocarbon analyzer purge was turned on, again isolating it from the test piping to protect it from the detonation pressure wave.
- (8) Valves were actuated to isolate the low-pressure transducers from the detonation pressure wave.
- (9) The igniter was armed by a console switch, the high-frequency tape recorders were turned on, and the oscillograph was switched to high speed.
- (10) The sequence timer was turned on. For the noncontinuous flow tests, this first automatically changed the fuel mixer valve to the CONDENSER position, preventing further fuel flow from entering the induction section of the test piping. Residual fuel downstream of the injector was sufficient for ignition on this type of test. The sequence timer then fired the igniter, turned on the vaporizer warm-up purge valve, closed the fuel-tank outlet valve, and turned off the vaporizer heater. For the continuous flow tests, the sequence timer was used only to fire the igniter, and the other items were performed manually by means of the emergency cutoff switch after the desired flow time had elapsed. Temperatures in the test piping on each side of the test arrester were monitored on the video display during the continuous flow of fuel after ignition and detonation to check for flame penetration and flame holding.
- (11) The igniter was unarmed, the oscillograph changed to low speed, and the high-frequency tape turned off.
- (12) The fuel metering valve was closed and the movie camera was turned off.
- (13) Fuel supply tank pressure transducers were vented and a posttest calibrate was performed on the instrumentation.
- (14) Fuel supply tank pressure transducers and the test arrester pressure transducers were reopened to the test system, the oscillograph turned off, and the IDAC tape and printer were switched to a slow speed.
- (15) Compressor air flow was maintained to purge residual fuel and combustion by-products from the test piping.

## 6. Posttest

The Posttest procedure included a visual inspection of the test stand. The test stand safety condition was changed to AMBER. Reentering personnel inspected all rupture disc assemblies. If they were intact,

a posttest pressure loss across the test item was measured and recorded. If any rupture disc was blown out, the air compressor was turned off while the discs were replaced. The air compressor was then turned back on, the air flow stabilized, and the posttest measurement recorded.

If a repeat test was to be made, the hydrocarbon analyzer was checked out; normally, it had to be reignited because the detonation shock wave usually blew out the ionization flame. The Test Preparation procedure would then be restarted from the point of fuel vaporizer heater activation.

Following the last test of the day, a posttest end-to-end calibration of the instrumentation system was made. Fuel in the induction system was pushed back into the supply tank and the system thoroughly purged with nitrogen gas.

Immediately after each test, the data recorded on the FM tape recorder was played back onto a quick-look oscillograph at an expanded time scale of 8 to 1. This data told the test conductor that he did or did not get ignition and detonation, or that the flame arrester worked or did not work.

After a day of testing, a playback record was made of the FM tape data at an expanded time scale of 32 to 1. This record contains both calibration and test data for all parameters, and was used for reductions of flame velocities and peak pressure pulse data.

## SECTION VI

### FACILITY CHECK-OUT TESTS

A number of tests were required to check out facility systems that were designed and installed specifically for the Detonation Flame Arrester Evaluation Program. During the facility check-out tests, it was determined that propane and air mixtures would not ignite and burn predictably with spark ignition only. The test procedure allowed 0.50 second from fuel shut-off to spark initiation to clear the fuel/air induction system and prevent flash-back flame damage. A hydrogen-air-spark ignition system was developed that produced the desired results. The only disadvantage in this method was that the addition of hydrogen to the fuel/air mixture imparted an initially higher velocity to flame propagation in the pipe than would normally be associated with an hydrocarbon/air mixture alone. It required about 10 to 12 pipe diameters to diminish this effect.

Chemically pure (CP) propane was used during the check-out tests to allow a reliable determination of the effectiveness of the fuel injection and air mixing procedure, as well as to verify the accuracy of flow measuring instrumentation. Gas samples were collected at both the inlet and outlet of the test piping (see Figure 3-1 for location of sampling rakes and collection cylinders). The samples were analyzed in the laboratory using a gas chromatograph mass spectrometer (GCMS). Adjustments were made to the fuel/air systems until an acceptable agreement was obtained between the measured flow and the GCMS analyzer results. One effective change involved the redirection of the fuel injector from a parallel-flow orientation with the air stream to a counter-flow orientation. This modification provided better mixing, which was confirmed by the inlet sample results. An eventual close agreement between the inlet and outlet samples showed that there was little condensation of propane on the walls of the test piping. The GCMS analysis indicated from 4.0- to 4.2-mole-percent propane in the samples at a flow-measured equivalence ratio of 1.1 (air-to-propane mass mixture ratio of 14.3).

The initial length of 15.2-cm- (6.0-in.-) diameter piping in the check-out test configuration (see Appendix B) was 8.4 m (25.5 ft). In some tests, the individual pipe sections were modified and used for alternate functions as noted in Appendix B. Test firings were made at an initial flow velocity of 4.6 m/s (15.0 ft/s) and a propane/air equivalence ratio of 1.1. A detonation was not obtained at this run-up distance, so an additional section of pipe was installed. Test firings were repeated that did not result in detonations, so additional sections of piping were added to test configuration Nos. 100 to 117. This procedure continued until all available piping was installed, resulting in a total run-up distance of 31.5 m (103.5 ft). Both equivalence ratio and initial flow velocities were varied, but none of these test conditions produced a detonation. The maximum flame velocities recorded were around 244 m/s (800 ft/s).

The chemically pure propane was removed from the fuel supply tank and replaced with commercial grade (CG) propane. Test firings

were made at an equivalence ratio of 1.1 and varying initial flow rates, but no detonations were obtained. The recorded flame velocities were about the same as those obtained with CP propane. It was theorized that the smooth-bored, honed, and polished shock-tube piping did not develop sufficient turbulence in the boundary layer flow, even during combustion, to accelerate the propagating flame up to the stable detonation velocity. To increase turbulence, a coil of 0.32-cm- (0.13-in.-) diameter wire was stretched through one of the 4.6-m- (15-ft-) long run-up pipe sections with a coil spacing of about one every 0.3 m (1.0 ft). This configuration produced one detonation, but failed to produce any more in subsequent firings. Posttest inspection revealed that the coils had been displaced by the rarefaction wave following detonation and was compressed together at the inlet end of the pipe in which it was installed. The coil of wire was replaced by a cylindrical liner of rolled and welded expanded metal mesh (shown in Figure 6-1) that fitted closely against the pipe inner wall. This test configuration (No. 117) produced detonations at initial flow velocities of 3.0, 4.6, and 6.1 m/s (10, 15, and 20 ft/s), but not at 1.5 m/s (5 ft/s). Enough data on detonations was obtained during these tests to complete the instrumentation check-out of optical flame sensors, dynamic pressure transducers, and the high-speed FM data recording system.

Figure 6-1. Expanded Metal Tube Liner

## SECTION VII

### CALIBRATION TESTS

The calibration tests for detonation run-up distance with CG propane were started with a test assembly configuration (No. 118) similar to the one shown in Figure 3-1, the difference being that there were only two lengths of 4.6-m- (15-ft-) long run-up pipe lined with the turbulence-producing, expanded metal-mesh tubes. This test assembly produced detonations at all initial flow velocities from 0 to 6.1 m/s (0 to 20 ft/s) (see Appendix C).<sup>1</sup> The flame velocity after transition to detonation stabilized around 1830 m/s (6000 ft/s). The peak pressure pulses recorded during transition ranged broadly between 1000 to 5000 kN/m<sup>2</sup> (145 to 725 psia), but stabilized around 2000 kN/m<sup>2</sup> (290 psia) after transition (see Appendix D).<sup>1</sup> Based on these measured flame velocities and peak pressures, the location of detonation transition appeared to be very close to the downstream end of the 9-m (30-ft) length of lined run-up piping or at a total distance of 20 m (66 ft) from the point of ignition. A plot of flame velocity and peak pressure as a function of pipe length for these tests is shown in Figure 7-1.

To evaluate the influence a flame arrester may have on the run-up distance, a sharp-edged orifice plate with an 8.192-cm- (3.225-in.-) diameter bore, designed to simulate the back pressure an arrester may produce, was installed on the exit of the extension section (No. 11). With this test configuration (No. 119), the flame accelerated down the pipe, reaching a maximum velocity of only 1000 m/s (3281 ft/s) at a distance of 23 m (75.5 ft), and then decelerated through the remaining length of run-up pipe. The peak pressures reflected the same phenomena, obtaining a maximum level of 1200 kN/m<sup>2</sup> (366 psia) and then decreased, as shown in Figure 7-1. Since these velocities and pressures were below the required stable detonation levels, the test configuration was judged to be unstable.

The orifice plate was removed and another 4.6-m (15-ft) length of expanded metal tube liner was installed into the remaining run-up pipe section (No. 5), making the total pipe length with turbulent liners 13.7 m (45 ft). This test configuration (No. 120), shown in Figure 3-1, produced a very stable detonation in the verification sections (No. 6, No. 7, and No. 8). The flame velocity averaged around 1800 m/s (5960 ft/s) at a peak pressure of 1650 kN/m<sup>2</sup> (240 psia) for a stable detonation wave. After one firing, the orifice plate was installed at the inlet of the test section (No. 9) (Test configuration No. 121). On the subsequent firings, a fully-developed and stable detonation was recorded in the verification sections. A reflected shock wave was evident 0.3 m (1.0 ft) upstream of the orifice plate, where peak pressures of about 3000 kN/m<sup>2</sup> (435 psia) were recorded. Both the flame

---

<sup>1</sup>Parameter nomenclature is presented in Table 4-1.

velocity and the peak pressure in the detonation wave normally decreased after passing through the orifice plate into the witness section (No. 10). However, in one test firing (No. 1431 E) they were only slightly reduced. A plot of the results of these tests is shown in Figure 7-2.

After development of a successful configuration for stable detonation with CG propane and air mixtures, the next step was to determine if it were equally suited for gasoline and air mixtures. The CG propane was replaced in the fuel supply tank with Indolene HO III clear (unleaded) gasoline. Indolene, a product of the Standard Oil Division of Amoco Oil Company, complies with the EPA specifications in the Federal Register for standard test motor fuel (Reference 7-1). Test conditions for gasoline and air were the same as for propane and air. Initial flow velocities were reduced from 6.1 to 1.5 m/s (20 to 5 ft/s). The test configuration (No. 122) without the orifice plate produced very stable detonations where the flame velocity through the test section was about 1830 m/s (6000 ft/s) and peak pressure was about 1630 kN/m<sup>2</sup> (235 psia). The deflagration-to-detonation transition location appeared to be well within the turbulent liner run-up pipe sections. This provided some distance for the detonation wave to stabilize in the verification sections before entering the test section. With the orifice plate installed at the inlet to the test section, the reflected peak-pressure wave measured 30 cm (12 in.) upstream showed a sharp increase, reaching a level of 3300 kN/m<sup>2</sup> (479 psia). This pressure level reduced quickly as it moved upstream. Both the flame velocities and peak pressures decreased significantly after passing through the orifice plate into the witness section. A plot of the results of these tests is shown in Figure 7-3.

The successful attainment of stable detonations with gasoline and air mixtures completed the calibration test series. The test program was started to evaluate selected flame arrester devices subjected to a fully-developed detonation. To reduce the required number of comparative tests, a standard test condition was established that would use an equivalence ratio of 1.1 and an initial flow velocity of 4.6 m/s (15 ft/s) for all subsequent arrester evaluation tests.

## SECTION VIII

### ARRESTER EVALUATION TESTS

#### A. PIPE TEES AND RUPTURE-DISC IN-LINE TEST ASSEMBLY

The first device to be evaluated was not an arrester in the true sense, but a combination of two extra-strong 15.2-cm- (6.0-in.-) diameter pipe tees and rupture discs. They were assembled in an arrangement that caused the detonation wave to make two 90-deg turns before proceeding along the length of pipe. The test section was removed from the test assembly and replaced with the pipe tees as shown schematically in Figure 8-1. The first rupture disc was placed in the leg of the pipe tee in-line with the approaching detonation wave. A second rupture disc was placed in the leg of the tee in line with the receding detonation wave. The restrictor orifice plate was installed in the downstream side of the second tee, just ahead of the witness section.

Four test firings were made with variations of this test configuration (No. 124 to No. 127), where the pressure ratings of both rupture discs were reduced in the following steps: 4137, 2068, 690, and 345 kN/m<sup>2</sup> (600, 300, 100, and 50 psid). Both rupture discs were blown out in all test firings and the detonation passed through the test assembly. There was only a slight reduction in flame velocity and peak pressure in the witness section downstream of the orifice plate. There appears to be no correlation between the magnitude of this loss and the rupture-disc pressure rating. A plot of the results of these tests is shown in Figure 8-2. The measured pressure drop across the test assembly, including the orifice plate, averaged 0.20 kN/m<sup>2</sup> (0.029 psid) at an average air-flow velocity of 4.68 m/s (15.35 ft/s).

#### B. PIPE TEE, RUPTURE-DISC NOT-IN-LINE, AND PIPE ELBOW TEST ASSEMBLY

The safest orientation for a rupture disc in a pipeline is normally vertically-up so that the release of flame and high-pressure gas will not impact adjacent installations. The pipe tee, rupture-disc not-in-line, and pipe elbow test assembly was developed to provide this orientation and to lower the piping inlet interface with an arrester. This lower interface was also used with two of the selected arrester test assemblies, which were evaluated later. This test assembly is shown schematically in Figure 8-3.

Four test firings were made with this test configuration (No. 128 to No. 131) where the pressure rating of the rupture disc was reduced in the same steps as above. The rupture disc was blown out in all test firings and the detonation passed through the test assembly. Figure 8-4 is a plot of the results for these tests. For two tests, the flame velocity and peak pressure in the witness section showed only a slight drop in levels. For the two other tests, the drop was more significant. However, there is still no apparent correlation between this loss and the rupture-disc pressure rating. It appears to be a random phenomenon. The measured pressure drop across the test

assembly, including the orifice plate, averaged  $0.214 \text{ kN/m}^2$  (0.031 psid) at an average air flow velocity of  $4.71 \text{ m/s}$  (15.46 ft/s).

C. SHAND AND JURS SPIRAL-WOUND, CRIMPED ALUMINUM RIBBON ARRESTER TEST ASSEMBLY

The spiral-wound, crimped aluminum ribbon core element was removed from a Shand and Jurs commercial flame arrester housing model No. 94/305/16/11. The 15.2-cm (6.0-in.) wide (L) aluminum ribbon had a crimp height (H) of 0.137 cm (0.054 in.), which gives a flow passage hydraulic diameter ( $D_h$ ) of 0.114 cm (0.045 in.) and a length-to-diameter ratio ( $L/D_h$ ) of 133. This core element was installed into a high-pressure housing made from an extra strong 30.5-cm- (12-in.-) diameter pipe 15.2 cm (6.0 in.) long. A mounting ring with a retainer grid was placed on each end of the housing as shown in Figure 8-5. The arrester test assembly consisted of a pipe tee, rupture disc not in line, and pipe elbow on the upstream side of a pair of 30.5- to 15.2-cm- (12-to 6-in.-) diameter concentric and eccentric extra-strong flanged pipe reducers. The arrester housing assembly was mounted between the two 30.5-cm- (12-in.-) diameter flanges as shown in Figure 8-6.

The Shand and Jurs arrester test configurations (No. 132 to No. 136) were subjected to nine stable detonations. There was no evidence in the witness section that detonation passed through the arrester. A low-level peak pressure pulse of around  $290 \text{ kN/m}^2$  (42 psia) was measured at the downstream side in the witness section. In four tests, the rupture-disc pressure rating of the inlet pipe tee was increased in four steps from 690 to  $4137 \text{ kN/m}^2$  (100 to 600 psid). This had no effect on the capability of the arrester in stopping the detonation, even when the highest rated disc failed to blow out. In the final test firing, the arrester housing was removed from the test assembly and the two 30.5-cm- (12-in.-) diameter flanges were bolted together. The rupture disc was blown out and the detonation passed through the test assembly, verifying the functional capability of the flame sensors in the witness section. The results of these tests are plotted in Figure 8-7.

The pre- and posttest-measured pressure drop across the arrester test assembly averaged  $0.152 \text{ kN/m}^2$  (0.022 psid) at an average air flow velocity of  $4.68 \text{ m/s}$  (15.35 ft/s). Posttest inspection of the arrester showed a slight indentation of the retainer grid on the downstream side of the core element. The retainer grid was bowed downstream about 0.16 cm (0.063 in.) at the axial center line. There was a separation of the crimped ribbon layers near the outer perimeter of the core at the upstream interface with the mounting ring as shown in Figure 8-8. This separation continued through the full depth of the core in some places. It was probably caused by the radial component of the detonation wave reflected off the inner pipe wall or the inlet of the mounting ring.

D. AMAL SPIRAL-WOUND, CRIMPED STAINLESS-STEEL RIBBON ARRESTER TEST ASSEMBLY

The Amal spiral-wound, crimped stainless-steel ribbon arrester core element was a model No. 188/905/15/18/CN. The stainless-steel ribbon was 3.81 cm (1.5 in.) wide with a crimp height of 0.046 cm (0.018 in.), which gives a flow passage hydraulic diameter of 0.038 cm (0.015 in.) and a length-to-hydraulic-diameter ratio of 100. This core element was installed in a high-pressure housing of 25.4-cm (10-in.) diameter by 3.8-cm (1.5-in.) length. Mounting rings with support grid, similar to the Shand and Jurs arrester, were placed on each end. Figure 8-9 is a photograph of this arrester assembly. The test assembly was also similar, except that the extra-strong pipe reducers were 25.4 to 15.2 cm (10 to 6 in.) in diameter to accommodate the smaller core size. A rupture-disc pressure rating of 690 kN/m<sup>2</sup> (100 psid) was used. Figure 8-10 is a photograph of this test installation.

Figure 8-7. Shand and Jurs Spiral-Wound, Crimped Aluminum Ribbon Arresters Assembly Test Results

Figure 8-8. Shand and Jurs Spiral Wound, Crimped Aluminum Ribbon Arrester Core Posttest Showing Ribbon Separation

The Amal arrester test configuration (No. 137) was successful in stopping the detonation in only the first of four test firings. The rupture disc was blown out on all tests. Flame velocity recorded in the witness section was only 600 m/s (1968 ft/s) in the last three tests. When the detonation was stopped, the peak pressure pulse downstream of the arrester measured about 360 kN/m<sup>2</sup> (52 psia), but increased to 600 kN/m<sup>2</sup> (87 psia) when the flame penetrated. A plot of the results of these tests is shown in Figure 8-11.

The pre- and posttest pressure drop across the Amal arrester test assembly did not vary appreciably. It averaged 0.428 kN/m<sup>2</sup> (0.062 psid) for an average air flow velocity of 4.78 m/s (15.68 ft/s). Posttest inspection of the core element showed no evidence of damage that could have caused the failure. The retainer grid was bowed downstream 0.64 cm (0.25 in.) at the axial centerline, indicating that some distortion had occurred to the core element under the detonation wave loading, but apparently the core element had returned to its original shape.

Figure 8-9. Amal Spiral-Wound, Crimped Stainless-Steel Ribbon Arrester Assembly

#### E. WHESOE FOAMED METAL ARRESTER TEST ASSEMBLY

The Retimet 80-grade foamed nickel-chrome alloy core element was removed from a prototype Whessoe arrester and installed into a high-pressure housing 25.4-cm (10-in.) diameter by 1.3-cm (0.5-in.) length. Mounting rings with support grids were placed on each side. Figure 8-12 is a photograph of the arrester components before assembly. This arrester assembly was mounted between the same pipe reducers used for the Amal arrester tests. A rupture-disc pressure rating of  $690 \text{ kN/m}^2$  (100 psid) was used.

The Whessoe arrester test configuration (No. 138) was successful in stopping the detonation in three tests. The rupture disc was blown out on all tests. Pre- and posttest pressure drop measured across the arrester test assembly averaged  $0.241 \text{ kN/m}^2$  (0.035 psid) at an average air flow velocity of 4.74 m/s (15.54 ft/s). After the third test, the measured pressure loss dropped to  $0.110 \text{ kN/m}^2$  (0.016 psid). Posttest inspection revealed that a section of the Retimet foamed metal core element had been extruded through the downstream retainer grid, leaving a large hole as shown in Figure 8-13.

Figure 8-10. Amal Spiral-Wound, Crimped Stainless-Steel Ribbon Arrester Test Installation

The 80-grade foamed metal was replaced in the housing with the alternate 45-grade foamed metal and reinstalled into the arrester test configuration (No. 139). One additional test firing was made, but this arrester failed to stop the detonation. The test results presented in Figure 8-14 show a large drop in flame speed to 45 m/s (148 ft/s) at the downstream side of the arrester after penetration. A low-level peak pressure pulse ranging from 250 to 470 kN/m<sup>2</sup> (36 to 68 psia) was measured in the witness section on all test firings. Pre- and posttest pressure loss measured across the 45-grade foamed-metal arrester test assembly was 0.130 kN/m<sup>2</sup> (0.019 psid) at an air-flow velocity of 4.78 m/s (15.68 ft/s). The posttest inspection showed no damage to this arrester core element.

#### F. WATER-TRAP ARRESTER TEST ASSEMBLY

The water-trap arrester test assembly was installed into the test section. This arrester vessel was made using 45.7-cm- (18.0-in.-) diameter extra-strong piping 91.4 cm (36 in.) long with a pipe cap on the lower end and a flanged cover containing a blowout port on the top. There were two 15.2-cm- (6.0-in.-) diameter flanged side ports. One of these ports contained a pipe elbow inside the vessel with a 30.5- to 15.2-cm- (12- to 6-in.-) diameter concentric pipe reducer

directed towards the bottom. The lower end of the reducer had three rows of 2.54-cm- (1.0-in.-) diameter holes drilled through the wall so that the assembly functioned as a bell-mouth diffuser. A schematic drawing of this arrester assembly is shown in Figure 8-15. The inlet piping consisted of a pipe tee, not-in-line rupture disc, and a pipe elbow. A similar reversed assembly was used at the arrester exit. A third rupture-disc assembly was installed on the blow-out port of the water-trap vessel cover. All rupture discs had a burst pressure rating of 690 kN/m<sup>2</sup> (100 psid). Water was added to the arrester vessel until the inlet piping and top row of holes in the diffuser bell were immersed 15.2 cm (6.0 in.) below the surface. A photograph of the test installation is shown in Figure 8-16.

Five test firings were made with the water-trap test configuration (No. 140), and the detonation was stopped for all tests. The upstream rupture disc on the inlet pipe tee was blown out in each firing. The downstream rupture discs on the arrester cover and exit pipe tee remained intact. There was no measurable peak-pressure pulse passing through the witness section in any of these firings. Water level in the arrester was reduced by 0.64 to 1.91 cm (1/4 to 3/4 in.) during testing and was replaced before the next firing. This amounts to 1/2 to 2 liters of water loss that can be related to the length of air-flow run time before each test firing. There was no evidence of water in the downstream piping or at the shock tube exit, so the loss had to be due to evaporation and convection caused by air flow. Pre- and posttest pressure loss measured across the water-trap arrester test assembly averaged 1.655 kN/m<sup>2</sup> (0.240 psid) at an average air-flow velocity of 4.66 m/s (15.29 ft/s).

In the sixth test, all the water was drained from the arrester vessel before firing. The detonation passed through the arrester test configuration (No. 141), as shown in the plot of these test results in Figure 8-17. Flame velocity in the witness section was measured at 950 m/s (3117 ft/s) and a peak-pressure pulse at around 900 kN/m<sup>2</sup> (130 psia) was experienced. All the rupture discs were blown out in this last test firing. Posttest inspection showed no damage to the arrester test assembly.

#### G. VERTICAL BED OF ALUMINUM BALLAST RINGS ARRESTER TEST ASSEMBLY

The vertical bed arrester test assembly utilized the water-trap vessel for the lower housing. The vessel was disconnected from the inlet pipe elbow and reversed 180 deg, exchanging the inlet and outlet ports. A blind flange was used to close off the unused outlet port. The vessel cover was removed and a 45.7-cm- (18-in.-) diameter flange pipe spool section, 91.4 cm (36 in.) long, was installed on top of the lower housing. The outlet pipe elbow and pipe tee were inverted and relocated to an outlet port on the downstream side of the spool section. A support grid ring covered with heavy wire mesh was installed into the housing assembly just above the inlet port. The internal volume between the inlet port and the outlet port, a distance of 63.5 cm (25 in.), was filled with 2.54-cm- (1.0-in.-) diameter by 2.54-cm- (1.0-in.-) long aluminum Ballast rings (identical in conformation to Pall rings) obtained

from Glitsch, Inc. A second wire-mesh-covered grid ring was installed on top of the bed of rings and held securely in place. The vessel cover, with a rupture disc, was installed on the top of the spool section. A water spray injector for the top of the bed was installed, but was not plumbed in. Figure 8-18 is a schematic drawing of the vertical bed arrester test assembly and a photograph of the test installation is shown in Figure 8-19.

Five test firings were made with the vertical bed arrester test configuration (No. 142);  $690 \text{ kN/m}^2$  (100 psid) rupture discs were installed on all blow-out ports. The detonation was arrested in all tests and only the rupture disc on the inlet tee was blown out. There were no measurable peak-pressure pulses passing through the witness section. A plot of these test results is shown in Figure 8-20.

Pre- and posttest pressure loss measured across the arrester test assembly averaged  $0.050 \text{ kN/m}^2$  (0.007 psid) at an average air-flow velocity of  $4.64 \text{ m/s}$  (15.23 ft/s). Posttest inspection of the arrester assembly revealed compaction of the bed due to distortion of the Ballast rings. This was probably caused by the fact that the lower support grid ring was not restrained in the vertical direction. The incoming detonation pressure wave forced the bottom grid ring up, crushing the bed of rings against the top restrained grid ring. Both support grid rings were to be restrained against any vertical forces in later tests.

The repeated success with the dry bed of Ballast rings in arresting the detonation eliminated the need for water irrigation that would have been used to increase the available heat sink. Therefore, the irrigated bed configuration was deleted from the test series.

#### H. LINDE HYDRAULIC BACK-PRESSURE VALVE ARRESTER TEST ASSEMBLY

The Linde Model No. H-20 hydraulic back-pressure valve was a standard commercial unit, that had to be modified slightly by removing a 7.6-cm- (3.0-in.-) diameter one-way check valve on the inlet piping and the enlargement of the inlet port to a 10.2-cm- (4.0-in.-) diameter nominal pipe size. Two 15.2- to 10.2-cm- (6.0- to 4.0-in.-) diameter pipe reducer elbows were used to adapt this arrester to the 15.2-cm- (6.0-in.-) diameter pipe tees on the inlet and outlet piping as shown on the schematic drawing in Figure 8-21. The rupture discs had to be installed on the vertically-down legs of both the inlet and outlet pipe tees. The Linde arrester was filled with water up to the gaging port. This placed the lower end of the 10.2-cm- (4.0-in.-) diameter inlet port approximately 15.2 cm (6.0 in.) under the water in the two parallel 20.2-cm- (8.0-in.-) diameter vertical pipe chambers. A photograph of this test installation is shown in Figure 8-22.

Five test firings were made on the Linde arrester test configuration (No. 143) with  $690 \text{ kN/m}^2$  (100 psid) rupture discs installed on the two blow-out ports. The detonation was arrested for all tests. Only the rupture disc on the inlet pipe tee was blown out. There was no measurable peak pressure pulse passing through the witness section. These test results are plotted in Figure 8-23. The water level loss

ranged from 0.63 to 4.45 cm (1/4 to 1 3/4 in.), depending on the length of run-in time. The volume of water loss was equivalent to 1/2 to 3 liters and was replaced after each test. No visible quantity of water was detected in the downstream piping or at the exit of the shock tube. Pre- and posttest pressure loss across the arrester averaged 2.027 kN/m<sup>2</sup> (0.294 psid) at an average air-flow velocity of 4.65 m/s (15.27 ft/s).

The water was removed from the Linde arrester through a drain valve, and a sixth test firing made. The detonation was arrested and only the inlet rupture disc was blown out. This was an unexpected turn of events that required further investigation. The drain valve, along with the mounting pipe reducer bushing, was removed for closer inspection. A small amount of water remaining in the bottom of the arrester was drained out. The drain valve was reinstalled and two more test firings were made with the dry Linde arrester configuration (No. 144) with 690 kN/m<sup>2</sup> (100 psid) rupture discs installed. The detonation was not arrested and both the inlet and outlet rupture discs were blown out.

In trying to duplicate the previous anomaly, the arrester was again filled with water up to the gaging port. Another test firing was made

where the detonation was arrested and only the inlet rupture disc was blown out. At this point, the water was removed from the arrester through the drain valve, just as in the previous test series. A final test firing was made with the dry arrester. The detonation was not arrested and both rupture discs were blown out. It is believed that the drain valve became plugged with some foreign object in the first attempt to remove the water, and this small amount of water caused the unexpected quenching of the detonation in the supposedly dry test firing. Pressure loss across the dry arrester averaged  $0.407 \text{ kN/m}^2$  ( $0.059 \text{ psid}$ ) at an average air-flow velocity of  $4.63 \text{ m/s}$  ( $15.2 \text{ ft/s}$ ). Posttest inspection showed no damage to the Linde arrester.

## SECTION IX

### ARRESTER EVALUATION TESTS USING DOWNSTREAM IGNITION

#### A. REVERSAL OF TEST FACILITY PIPING

The test facility 15.2-cm- (6.0-in.-) diameter piping was completely removed and reassembled for the downstream ignition tests. All of the pipe sections between the inlet tee section and the exit extension section (No. 11) were reversed 180 deg. This was done to retain continuity in the test configuration and instrumentation locations from the ignition section (No. 1) to the witness section (No. 10). The hydrogen-air-spark igniter was oriented to fire downstream with the gasoline-and-air-mixture flow directed into the extension section. The orifice restrictor plate was installed at the exit of the extension section to assist flame propagation back upstream against the flow. The exit gas sampling rake remained in its original position at the entrance to the extension section. All of the flame sensors and pressure transducers remained in their same locations and retained the same identification in relation to flame propagation direction from the ignition section to the witness section.

The water-trap and the Linde arresters were the only two arresters selected for evaluation with downstream ignition. Both of these devices have significant differences in the geometric arrangements between the inlet and outlet configurations. Also, they accept flow-through in only one direction.

#### B. LINDE HYDRAULIC BACK-PRESSURE VALVE ARRESTER TEST ASSEMBLY

The Linde arrester was installed in the upstream test section (No. 9). Oriented in the normal flow-through direction, the same inlet and outlet adapter piping shown in Figure 8-21 was used with 690 kN/m<sup>2</sup> (100 psid) rupture discs installed in the blow-out ports. Water was added to the arrester up to the gaging port.

For the first test using downstream ignition configuration (No. 145), the initial flow velocity was 1.5 m/s (5.0 ft/s). Ignition was obtained, but there was no detonation. Flame did not propagate upstream beyond the ignition section. The second test was made with the inlet valve closed after the piping was filled with the gasoline and air mixture, so there was no mixture flowing at the time of ignition. Ignition was obtained, but again there was no detonation. The flame had propagated up through the stabilizer section (No. 2), but did not continue through the turbulent liner run-up sections (Nos. 3, 4, and 5). A third test at no-flow condition was made after the injection direction of the hydrogen-air-spark igniter was reversed 180 deg from downstream to upstream orientation. Again, ignition was obtained, but no detonation. The flame had not propagated through the turbulent liner run-up sections. To eliminate any influence water vapor may have had on flame propagation, the water was drained from the Linde arrester. A final test firing was made with the no-flow condition, but the results were no different.

At this point a configuration change was made in the piping test assembly. The ignition section (No. 1) and the stabilizer section (No. 2) were interchanged, placing the ignition section upstream adjacent to the turbulent liner sections, and the stabilizer section downstream next to the extension section. Also, the orifice plate was relocated upstream at the flanged joint between the ignition section and the stabilizer section, so that it was positioned just downstream of the hydrogen-air-spark igniter. A facility piping schematic diagram of this test assembly is shown in Figure 9-1.

The Linde arrester in this test configuration (No. 148) was refilled with water up to the gaging port. Three test firings were made with no initial flow velocity; all resulted in ignitions and detonations. The detonation was arrested for all tests. Only the downstream rupture discs were blown out.

Three additional test firings were made with this same Linde test configuration at an initial flow velocity of 1.5 m/s (5.0 ft/s). Ignition and detonation were again obtained for each test. The detonation was arrested for all tests and only the downstream rupture disc was blown out. The test results, plotted in Figure 9-2, show no significant change in the detonation wave terminal velocity or peak pressure pulse from the levels obtained in the no-flow tests. There was no measurable peak pressure pulse passing into the witness section.

Pre- and posttest pressure loss measured across the arrester assembly averaged  $1.92 \text{ kN/m}^2$  (0.278 psid) at an average air-flow velocity of 1.61 m/s (5.28 ft/s). Water level in the arrester had dropped 2.54 to 3.18 cm (1 to 1-1/4 in.) during each test. This represents a loss of 1-1/2 to 3 liters of water, which was replaced after each test. Some of the water displaced from the arrester was driven upstream by the detonation and collected in the vertically-down leg of the inlet pipe tee. This water was drained off after each test by loosening the flange bolts retaining the rupture-disc assembly.

#### C. WATER-TRAP ARRESTER TEST ASSEMBLY

The water-trap arrester was installed into the upstream test section (No. 9). Oriented in the normal flow-through direction, the same inlet and outlet adapter piping shown in Figure 8-15 was used with  $690 \text{ kN/m}^2$  (100 psid) rupture discs installed on the pipe tee blow-out ports. A blind flange was installed on the blow-out port in the water-trap vessel cover. Water was added to the arrester vessel up to the gaging port.

Five downstream ignition test firings were made with the water-trap arrester test configuration (No. 149) at an initial flow velocity of 1.5 m/s (5.0 ft/s). Ignition and detonation were obtained for each test. The detonation was arrested and only the downstream rupture disc was blown out. There was no measurable peak-pressure pulse passed into the witness section. A plot of the test results is shown in Figure 9-3.

Figure 9-1. Facility Piping Schematic Diagram for Detonation Testing with Downstream Ignition

The water level in the arrester vessel dropped around 0.48 to 2.22 cm (3/16 to 7/8 in.) during each test. This represents a loss of 1/2 to 2 liters of water, which was replaced after each test. There was no visible sign of water in the upstream piping, possibly because there were no traps in the line, as was the case with the Linde arrester. Posttest air flowing through the piping would normally blow any water collected upstream back into the arrester vessel. Pre- and posttest pressure loss measured across the arrester assembly averaged 1.39 kN/m<sup>2</sup> (0.202 psid) at an average air flow velocity of 1.52 m/s (5.0 ft/s).

A summary of the test results for all the detonation-flame arresters is presented in Table 1-1.

### CHEMICALLY PURE PROPYLENE DETONATION TESTS

A detonation was never obtained in the facility check-out tests using chemically pure (CP) propane, whereas calibration tests with commercial grade (CG) propane resulted in stable detonations. California Liquid Gas Corporation, the suppliers of the CG propane used, could not provide specific information on the composition of their propane, but they did indicate that it was in compliance with the Gas Producers Association Liquified Petroleum Gas Specification. According to this specification, the composition is required to be predominantly propane and/or propylene. Matheson Gas Products provided a more definitive specification for CG propane as having a minimum purity of 65.0 mole percent propane, with the main impurity being propylene.

Initial in-house efforts to determine the CG propane composition using gas chromatography analysis were unsuccessful. While this problem was being worked out, a series of tests was conducted to determine the detonation capability of CP propylene.

The test facility piping was reassembled into the upstream ignition configuration that was successful in producing detonation with CG propane during the calibration tests. This is the configuration (No. 150) shown in Figure 3-1. Gasoline in the fuel supply system was replaced with CP propylene. Test firings were made at an initial flow velocity of 4.6 m/s (15.0 ft/s) and a propylene/air equivalence ratio of 1.1. Ignition was obtained, but the transition to detonation did not occur. The restrictor orifice plate was removed from the test assembly and a second test firing was made at the same condition. Ignition and detonation were achieved with this test configuration (No. 151). A third test firing was made at the same test condition. Ignition and detonation were achieved, but there was an unexplained slow flame velocity transition through the turbulent liner sections. All attempts to obtain a stable, repeatable detonation with CP propylene were unsuccessful so the tests were terminated.

The previous problem with the gas chromatography analysis was solved by the acquisition of a new "Porasil-B" column and by the revision of the analytical method. The CG propane being used was found to have a composition of 97% propane, 1.2% ethane, 0.2% butane, less than 0.1% propylene, with the balance being heavier hydrocarbons. The values used in the propane quantitation determination were checked against certified samples and found to be accurate within approximately  $\pm 3\%$ .

The calibration test results and gas chromatography analysis support the possibility that a small percentage of ethane and butane mixed with propane will produce stable detonation in pipe run-up testing. CP propylene and CP propane appear to have poorly defined detonation properties.

## SECTION XI

### DEFLAGRATION-TO-DETONATION TRANSITION LOCATION TESTS

In the initial calibration tests, a pipe run-up configuration was developed that would produce stable and repeatable detonations with gasoline and air mixtures. The deflagration-to-detonation transition location was well within the run-up piping containing the turbulent liners. Limited variations in test conditions, including initial flow velocity, mixture ratio, and back pressure, did not suppress the detonation. The actual location of the point of transition remained to be identified. A relocation of flame sensors and dynamic pressure sensors into the lined run-up piping was required to make this determination.

The last run-up section (No. 5) was removed from the test assembly, and its turbulent liner was removed, modified, and reinstalled into three instrumented sections (Nos. 7, 8, and 10). Special holes had to be cut into the liner and aligned with the instrumentation ports to give a clear field of view for the flame sensors and pressure sensors. The instrumented lined sections were moved upstream to join the first two uninstrumented lined sections (Nos. 3 and 4). The unlined run-up section (No. 5) was reinstalled downstream between the remaining verification section (No. 6) and the orifice plate at the inlet to test section (No. 9). Overall make-up length of the test piping remained the same.

A series of three test firings was made with the new test configuration (No. 165) at an initial flow velocity of 4.6 m/s (15.0 ft/s) and a gasoline/air equivalence ratio of 1.1. A detonation was produced in each test. The transition from deflagration to detonation appeared to be located either in the first instrumented lined section (No. 7) or just upstream from it, but the actual location was not well defined.

A second uninstrumented run-up section (No. 4) was removed from the test assembly. The turbulent liner was withdrawn, modified, and reinserted into the remaining instrumented verification section (No. 6). These two sections were then interchanged to produce the facility piping assembly shown in the schematic diagram in Figure 11-1. Thirteen test firings were made with this test configuration (No. 166 and No. 167). Initial flow velocity was varied through 0, 1.5, 3.0, 4.6, and 6.1 m/s (0, 5, 10, 15, and 20 ft/s) with the gasoline/air equivalence ratio of 1.1. The results of these tests are plotted in Figure 11-2. Although there is some scatter in both flame velocity and peak pressure data, attesting to the complexity of the transitional process, the preponderance of data indicates that the location of the transition point is about 15.4 m (50.5 ft) from the point of ignition. The run-up length through turbulent liner pipe was 11.2 m (36.7 ft) giving an L/D of 74. There appears to be no discernible correlation between the initial flow velocity used in testing and the resulting run-up length. The stable detonation wave velocity downstream of the transition is 1800 m/s (5906 ft/s) with a peak pressure of 1900 kN/m<sup>2</sup> (276 psia). Some

Figure 11-2. Deflagration-to-Detonation Transition Test Results for Gasoline and Air Mixtures at Selected Initial Flow Velocities

peak pressures measured near the point of transition exceeded 4000  $\text{kN/m}^2$  (580 psia).

To determine the influence the equivalence ratio has on the detonation run-up length, nine additional test firings were made at a constant initial velocity of 4.6 m/s (15.0 ft/s). The equivalence ratio was varied from 0.7 to 1.4 in steps of 0.1 for these tests. The results of these tests are plotted in Figure 11-3. At an equivalence ratio of 0.7, the flowing gasoline and air mixture would not ignite. Increasing the gasoline flow to an equivalence ratio of 0.8, the flowing mixture was ignited, but the flame acceleration was too slow to reach detonation velocity within the test length of run-up piping. The maximum flame velocity in this test was measured at 600 m/s (1969 ft/s) and the peak pressure at 900  $\text{kN/m}^2$  (131 psia) in the last instrumented section (No. 10). Stable detonations were obtained for all test conditions where the equivalence ratio ranged from 0.9 to 1.4. The data are scattered to the extent that there is no obvious correlation between equivalence ratio and the run-up length. The location of the transition is at 15.4 m (50.5 ft) from the point of ignition, which is the same location determined in the previous test series. This is undoubtedly caused by the fact that the same data obtained at an initial velocity of 4.6 m/s (15.0 ft/s) and an equivalence ratio of 1.1 are used in both plots. It is these data that produce the maximum levels of flame velocity and peak pressure, which are the criterion used to identify the point of transition. Data at other test conditions, with the one exception, do not show any consistent results that influence a change in the apparent location of transition. A detonation run-up length of 11.2 m (36.7 ft) for the turbulent lined 15.2-cm- (6.0-in.-) diameter piping, or an L/D of 74, holds for all conditions tested except at an equivalence ratio of 0.8.

## SECTION XII

### FACILITY PIPING RELATIVE ROUGHNESS DETERMINATION TESTS

The relative roughness of the turbulent liners in the facility piping was required to relate the experimental results of detonation run-up distance to standard commercial pipe. A series of air-flow tests was made to measure the pressure loss through the 15.2-cm- (6.0-in.-) diameter facility run-up piping with varying lengths of turbulent liners and without the liners. The measured data were used in the Darcy equation to determine the pipe wall friction factor (f) as follows:

- (1) Darcy equation,

$$\Delta P = f \left( \frac{L}{A^2 D} \right) \left( \frac{\dot{m}^2}{2 g_c \rho} \right)$$

- (2) Solving for friction factor,

$$f = 2 g_c \left( \frac{A^2 D}{L} \right) \left( \frac{\rho \Delta P}{\dot{m}^2} \right)$$

where  $g_c$  = gravitational conversion constant relating force and mass

A = internal cross-sectional area of pipe

D = inside diameter of pipe

L = length of pipe

$\rho$  = fluid density

P = pressure loss through pipe

$\dot{m}$  = fluid mass flow

The friction factor is a dimensionless quantity, and at normally encountered pipe flows is a function of two other dimensionless quantities, the relative roughness ( $\epsilon/D$ ) and the Reynolds number ( $R_e$ ), which are defined as follows:

- (1) Relative roughness =  $\epsilon/D$

where:  $\epsilon$  = height of absolute roughness

- (2) Reynolds number,  $R_e = \frac{4 \dot{m}}{\pi D \mu}$

where  $\mu$  = absolute viscosity of fluid

In Reference 12-1, L. F. Moody has presented two charts; one gives the functional relationship between  $f$ ,  $Re$ , and  $\epsilon/D$ , and the second relates  $f$ ,  $\epsilon/D$ , and  $\epsilon$  to those values typical of commercial pipe and tubing.

The first set of experimental pressure loss data, which was obtained with test configurations (No. 157 to No. 164) using the installed pressure transducers and steady-state recorders, proved to be unreliable. The total pressure and differential pressure measurements encountered were below the linear, repeatable range of the transducers employed. They were replaced by a visually read micromanometer to measure upstream pressure and an inclined manometer to measure pressure loss. The data obtained using these instruments were considered to be acceptable.

The air-flow tests were made at velocities of 1.5, 3.0, 4.6, and 6.1 m/s (5, 10, 15, and 20 ft/s) in both increasing and decreasing steps. The test configurations (No. 168 to No. 175) included lined pipe lengths of 12.6, 8.0, and 3.4 m (41.3, 26.2, and 11.2 ft), and an unlined pipe length of 10.6 m (34.9 ft). Pressure loss through each length was measured for the conditions of both an open outlet and for the orifice plate installed on the outlet. At the lowest air-flow velocity, 1.5 m/s, and the shortest pipe length, 3.4 m, the pressure measurements obtained were questionable because of their very low values. However, the measurements made at the other test conditions appeared good and produced the following results:

| Pipe Condition | Length, m          | $Re$                                     | $f$            | $\epsilon/D$   |
|----------------|--------------------|------------------------------------------|----------------|----------------|
| Lined          | 12.6, 8.0, and 3.4 | $2 \times 10^{-4}$ to $5 \times 10^{-4}$ | 0.040 to 0.047 | 0.010 to 0.015 |
| Unlined        | 10.6               | $2 \times 10^{-4}$ to $5 \times 10^{-4}$ | 0.016 to 0.020 | $< 10^{-6}$    |

The lined pipe had a friction factor and relative roughness comparable to riveted steel pipe 15.2 cm (6.0 in.) in diameter. The unlined, honed, and polished shock-tube pipe had a friction factor and relative roughness less than any commercial grade smooth pipe.

## SECTION XIII

### PARAMETRIC TESTS OF DETONATION-FLAME ARRESTERS

#### A. DOWNSTREAM PRESSURE PULSE

A low-level pressure pulse that penetrated through the test arrester was measured in the witness section on two of the four generic types of flame control devices found to be effective in arresting a detonation. The pressure pulse level ranged from 250 to 470 kN/m<sup>2</sup> (36 to 68 psia) for the spiral-wound, crimped aluminum ribbon arrester and the foamed nickel-chrome metal arrester. The pressure pulse, if present, was below the lower sensitivity level of 207 kN/m<sup>2</sup> (30 psia) for the high-pressure, quartz-crystal-type pressure transducers installed in the witness section of the vertical bed of aluminum Ballast rings arrester, the water-trap arrester, and the Linde hydraulic back-pressure valve arrester. The existence of this low-level pressure pulse passing through the arrester caused some concern as to the possibility of a reignition occurring in the combustible fuel and air mixture in the piping at some distance beyond the arrester. Although reignition was not observed in the initial evaluation tests, it was not known whether this was due to the short length of piping in the witness section, which was only 1.5 m (5 ft), or due to the fact that operational procedures terminated the flow of gasoline into the induction section just prior to ignition. Both of these conditions were later evaluated by additional testing. A long length of extension piping was installed downstream of the arrester test section and a change in the operating procedure was made to allow gasoline and air mixture to flow continuously through the piping system for periods up to 120 seconds following ignition and detonation.

Before proceeding with continuous-flow detonation testing, two of the more applicable arrester configurations were further evaluated with a series of parametric tests designed to identify any existing relationships between the measured levels of downstream pressure pulse and the arrester size, inlet configuration, or rupture disc pressure rating. The two configurations selected were (1) The Shand and Jurs spiral-wound, crimped metal ribbon arrester and (2) the vertical bed of Ballast rings arrester. Both of these devices are considered to be readily adaptable to either shipboard or shore-based tank installations, and could be made compatible with a marine environment.

During the initial testing of Shand and Jurs spiral-wound, crimped aluminum ribbon arrester, a pressure pulse of about 290 kN/m<sup>2</sup> (42 psia) was measured on the downstream side (Figure 8-7). The detonation pressure wave on the upstream side was on the order of 1900 kN/m<sup>2</sup> (276 psia). Only 15% of the detonation wave pressure was transmitted through the 15.2-cm- (6-in.-) long arrester core element. An increase in core length would be expected to reduce the downstream pressure pulse even lower. The measured air-flow pressure loss across this core element averaged only 0.152 kN/m<sup>2</sup> (0.022 psid) at an average air velocity of 4.68 m/s (15.35 ft/s) (Table 1-1). It was apparent that the core length could be increased considerably and still operate at an acceptable pressure loss.

Testing of the vertical bed of aluminum Ballast rings arrester produced no measurable pressure pulse in the downstream piping. This original configuration was very large and heavy compared to the Shand and Jurs arrester assembly. The size of the bed of packed rings was designed to assure its flame arresting capability. This large size also resulted in the lowest measured air-flow pressure loss of all the arrester configurations tested. It was apparent that the packed bed of rings could be reduced in size without developing an unacceptable high-pressure loss, providing the detonation arresting capability was not lost. However, a significant reduction in bed size would undoubtedly be accompanied by an increase in the level of a pressure pulse that would pass through the arrester. A more sensitive lower-range pressure transducer had to be employed in the witness section to monitor any measurable variations in downstream pressure pulse.

A series of parametric tests were conducted to evaluate the following variations on the two selected types of detonation-flame arresters:

- (1) The Shand and Jurs arrester was tested with the spiral-wound, crimped stainless-steel ribbon core elements having the same crimp height and diameter as the original aluminum core element, but with three different core lengths. The inlet configuration was eventually changed from the indirect pipe tee, rupture-disc and pipe-elbow assembly to a directly connected in-line pipe tee and rupture-disc assembly where the rupture-disc pressure rating was increased in four steps up to a blanked-off condition.
- (2) The vertical bed of aluminum Ballast rings arrester was tested with four bed diameters, three bed depths, three Ballast ring sizes, and increasing rupture-disc pressure rating in four steps up to a blanked-off condition. The inlet and outlet configuration were the indirectly connected pipe tee, rupture-disc and pipe-elbow assemblies used with the existing pressure vessel housing.

#### B. SHAND AND JURs SPIRAL-WOUND, CRIMPED STAINLESS-STEEL RIBBON ARRESTER TEST ASSEMBLIES

New spiral-wound, crimped stainless-steel ribbon core elements for the Shand and Jurs arrester test assemblies were obtained from G.P.E. Controls. They are manufactured in only two core lengths, 15.2 cm (6 in.) and 20.3 cm (8 in.), so the third experimental length was made by assembling two 15.2-cm- (6-in.-) long units in series in a single 30.5-cm- (12-in.-) long high-pressure housing. The new 20.3-cm (8-in.) and 30.5-cm (12-in.) arrester housings were identical, except in length, to the existing 15.2-cm (6-in.) housing, and could interchangeably use the two existing mounting rings with the grid retainers.

All three lengths of the stainless-steel Shand and Jurs arresters were initially tested using the same test assembly shown in the schematic drawing, Figure 8-6. This configuration used the indirect inlet connection consisting of a pipe tee, rupture disc not in line, and a pipe elbow on

the upstream side of a pair of 30.5- to 15.2-cm- (12- to 6-in.-) diameter concentric and eccentric flanged pipe reducers. A photograph of the 20.3-cm- (8-in.-) long arrester test assembly is shown in Figure 13-1. A rupture disc with a pressure rating of  $690 \text{ kN/m}^2$  (100 psid) was installed on all these tests. The two  $20,685 \text{ kN/m}^2$  (3000 psia) quartz-crystal-type pressure transducers were relocated from the witness section (No. 10) upstream to the verification section (No. 7) instrumentation pressure ports (P71 and P72). Two  $345 \text{ kN/m}^2$  (50 psia) strain-gage-type pressure transducers were installed into the witness section instrumentation pressure ports (P101 and P104). All test firings were made using gasoline and air mixtures at the established standard conditions with the upstream ignition location.

Figure 13-1. Shand and Jurs Spiral-Wound, Crimped Stainless-Steel Ribbon Arrester Test Installation

The 15.2-cm- (6-in.-) long stainless-steel Shand and Jurs arrester configuration (No. 176 and No. 177) was subjected to five stable detonations. The rupture disc was blown out on all tests. Detonation was arrested on the first four test firings, but on the fifth, the passage of a flame traveling at  $570 \text{ m/s}$  ( $1870 \text{ ft/s}$ ) was recorded in the witness section. When the detonation was arrested, the peak-pressure pulse downstream of the arrester averaged  $344 \text{ kN/m}^2$  (50 psia). This same pressure increased to  $460 \text{ kN/m}^2$  (67 psia) when the flame penetrated the arrester. A plot of these test results are shown in Figure 13-2.

Pre- and posttest pressure loss across the arrester averaged  $0.151 \text{ kN/m}^2$  ( $0.022 \text{ psid}$ ) at an average air-flow velocity of  $4.78 \text{ m/s}$  ( $15.68 \text{ ft/s}$ ). These are about the same values recorded for the 15.2-cm-(6-in.-) long aluminum core arrester (Table 1-1). Posttest inspection of the stainless-steel core element revealed that a circumferential displacement had occurred in an overlap joint at the middle of the spiral-wound, crimped ribbon windings. This produced a double-width gap in the windings, approximately 6.35-cm (2.5-in.) long, that extended through the full depth of the core. A photograph showing an enlarged view of this displacement is presented in Figure 13-3. It is believed that this was the path for flame passage through the arrester on the last test, since there was no other evidence of distortion or damage. Inspection of the other stainless-steel core elements disclosed that this particular unit was the only one that had been manufactured with an overlap joint in the crimped ribbon windings.

The 20.3-cm- (8-in.-) long stainless-steel Shand and Jurs arrester configuration (No. 178) was subjected to six stable detonations. The rupture disc was blown out and the detonation was arrested on all test firings. A low-level peak-pressure pulse, which averaged  $320 \text{ kN/m}^2$  ( $46 \text{ psia}$ ), was measured in the witness section. A plot of these test results are shown in Figure 13-4. Pre- and posttest pressure lost across the arrester averaged  $0.152 \text{ kN/m}^2$  ( $0.022 \text{ psid}$ ) at an average air-flow velocity of  $4.58 \text{ m/s}$  ( $15.89 \text{ ft/s}$ ).

The 30.5-cm- (12-in.-) long stainless-steel Shand and Jurs arrester configuration (No. 179) was subjected to six stable detonations. The rupture disc was blown out and the detonation was arrested on all test firings. A low-level peak-pressure pulse, which averaged  $260 \text{ kN/m}^2$  ( $38 \text{ psia}$ ), was measured in the witness section. A plot of these test results are shown in Figure 13-5. Pre- and posttest pressure loss across the arrester averaged  $0.230 \text{ kN/m}^2$  ( $0.033 \text{ psid}$ ) at an average air-flow velocity of  $4.48 \text{ m/s}$  ( $14.70 \text{ ft/s}$ ).

The results of the parametric tests are summarized in Table 1-2. A plot of the arrester core length versus the downstream peak-pressure pulse is shown in Figure 13-6. If the apparent linear relationship between core length and peak-pressure pulse on this graph were to be extrapolated down to the atmosphere, (zero peak-pressure pulse) the corresponding arrester core length would be 58.5 cm (23 in.). It was impractical to verify this result by further testing since the required arrester core element was not commercially available. The 20.5-cm- (8-in.-) long Shand and Jurs arrester assembly was selected to be evaluated using a directly connected inlet pipe configuration.

The indirect inlet connection to all detonation-flame arresters was initially employed to reduce the severity of the impacting shock wave. The rupture-disc assembly was used to release the hot combustion gas from the pipeline detonation rather than allowing it to flow through the arrester. If this gas retained enough heat, it could cause a reignition of the flammable mixtures downstream of the arrester. The first assumption proved to be wrong, in that there was no evidence that the combustion-

FLAME VELOCITY AND PEAK PRESSURE VERSUS PIPE LENGTH  
TEST CONFIGURATION NO. 176 AND NO. 177

Figure 13-2. Shand and Jurs Spiral-Wound, Crimped Stainless-Steel Ribbon Arrester Assembly Test Results, Size: 30.5-cm Diameter by 15.2-cm Length

Figure 13-3. Spiral-Wound, Crimped Stainless-Steel Ribbon Core Element, 30.5-cm Diameter by 15.2-cm Length, Posttest

driven detonation wave was in any way diminished by combinations of pipe tees and pipe elbows. The second assumption on combustion gasses causing a reignition remained to be evaluated.

A direct connect inlet was made by rearranging the test assembly inlet pipe tee to an in-line position with the arrester test assembly and removing the inlet pipe elbow. The branch line of the pipe tee, containing the rupture-disc assembly, was directed vertically up as shown in Figure 13-7. A photograph of this installation containing the 20.3-cm- (8-in.-) long stainless-steel Shand and Jurs arrester test assembly is presented in Figure 13-8. This configuration (No. 180 to No. 183) was subjected to six stable detonations. In the first three tests, the rupture-disc pressure rating was increased in steps through 690, 2068, and 4137  $\text{kN/m}^2$  (100, 300, and 600 psid). On the last three tests, the rupture-disc assembly was blanked off with a blind flange. The detonation was arrested on all test firings. A low-level peak-pressure pulse that averaged 325  $\text{kN/m}^2$  (47 psia) was measured in the witness section. The level of this pressure pulse was not noticeably influenced by the rupture-disc pressure rating or when the blow-out port was blanked off. Pre- and posttest pressure loss across the arrester averaged 0.138  $\text{kN/m}^2$  (0.020 psid) at an average air-flow velocity of 4.44 m/s (14.58 ft/s). A plot of the test results is shown in Figure 13-9 and summarized in Table 1-2.

Posttest inspection of the arrester core element showed no distortion or damage to the spiral-wound, crimped stainless-steel ribbon windings. A photograph of the upstream side of the core element showing a flame imprint of the retainer grid, caused by carbon deposit, is presented in Figure 13-10. By contrast, the downstream side of the same element shown in Figure 13-11 appears very clean. The downstream retainer grid was bowed slightly at the axial center line as shown in Figure 13-12.

#### C. VERTICAL BED OF ALUMINUM BALLAST RINGS ARRESTER TEST ASSEMBLIES

The vertical bed of Ballast rings arrester test assembly was installed into the test section in the same configuration used earlier as shown in Figure 8-18. New aluminum Ballast rings were obtained from Glitsch, Inc. in three sizes: (1) 2.54 cm (1.0 in.) in diameter by 2.54 cm (1.0 in.) long, (2) 3.81 cm (1.5 in.) in diameter by 3.81 cm (1.5 in.) long, and (3) 5.08 cm (2.0 in.) in diameter by 5.08 cm (2.0 in.) long. Figure 13-13 shows the three different sizes of Ballast rings used. The lower support grid ring covered with heavy wire mesh was installed into the arrester housing assembly just above the inlet port. This was followed by a welded spacer assembly made from two 2.54-cm (10-in.) diameter pipe rings and four 3.81-cm (1.5-in.) steel 90-deg angle bars. The spacer established the packed bed depth. A second support grid ring, also covered with heavy wire mesh, was placed on top of the first spacer and held down by a second spacer, which built the stack height up to the vessel cover. This stacked assembly is shown in Figure 13-14. The internal volume between the two grid support rings was packed with the selected size of aluminum Ballast rings. The spacers rigidly controlled the established bed depth by maintaining the position of the support grid rings against the displacing forces of the incoming detonation wave. Three sets of spacers, two in each set, provided the three variations in bed depth: (1) 63.5 cm (25 in.), (2) 45.7 cm (18 in.), and (3) 22.9 cm (9.0 in.), all at a constant bed diameter of 43.2 cm (17 in.).

The variations in bed diameters were accomplished with cylindrical pipe inserts that were flanged on the lower end to close-off the annular area between the inner wall of the housing vessel and the outer wall of the pipe insert. Internal diameter of the pipe insert controlled the packed bed flow path. The insert was lowered into the vessel housing on top of the lower support grid ring. The second support grid ring was then placed on top of the insert and held in place by a spacer, which built the stack height up to the vessel cover. This stacked assembly is shown in Figure 13-15. The volume between the two support grid rings were packed with the selected size of Ballast rings, both inside the cylindrical insert and in the surrounding annulus. The flow path is restricted to the internal diameter of the pipe insert. Including the unrestricted vessel housing and three sets of cylindrical inserts and spacers, the four variations in bed diameter are (1) 43.2 cm (17 in.), (2) 33.7 cm (13.25 in.), (3) 30.5 cm (12 in.), and (4) 25.4 cm (10 in.), all at a constant bed depth of 63.5 cm (25 in.).

The inlet and outlet piping connections to the vertical bed of Ballast rings arrester were the same combination of pipe tees, rupture-disc not in line, and pipe-elbow assemblies as previously used. It would have required a major modification to the facility piping and support structures to accomplish a direct in-line inlet and outlet connections to the arrester vessel housing. Rupture-disc assemblies with a  $690 \text{ kN/m}^2$  (100 psid) pressure rating were installed on the inlet pipe tee, the vessel cover, and the outlet pipe tee. All test firings were made using gasoline and air mixtures at the standard test conditions with the upstream ignition location.

Figure 13-11. Spiral-Wound, Crimped Stainless-Steel Ribbon Core Element, 30.5-cm Diameter by 20.3-cm Length, Posttest Downstream Side

The first three bed depth parametric test configurations (No. 184, No. 185, and No. 186) were all packed with the 2.54-cm- (1.0-in.-) diameter by 2.54-cm- (1.0-in.-) long aluminum Ballast rings. A new bed of rings was installed at the start of each test series because of the deformation that occurred in the rings. Starting with the full-size bed that was 43.2 cm (17 in.) in diameter, the bed depth was reduced in steps through 63.5 cm (25 in.), 45.7 cm (18 in.), and 22.9 cm (9 in.). Each configuration was subjected to six stable detonations. Only the inlet rupture disc was blown out and the detonation was arrested on all but two test firings. On the fourth and sixth test firings, with the 22.9-cm (9-in.) bed depth, the detonation passed through the arrester, blowing out all three rupture discs. Flame velocity in the witness section on these tests was measured at around 660 m/s (2166 ft/s). When the detonation was arrested, the downstream peak pressure pulse ranged from 181 to 236 kN/m<sup>2</sup> (26.3 to 34.2 psia), and showed an increase in pressure level with the reduction

in bed depth. On the test firings where the detonation passed through the arrester, the peak pressure pulse exceeded the  $450 \text{ kN/m}^2$  (65 psia) upper range of the pressure sensors installed. Plots of the test data results for these tests are shown in Figures 13-16, 13-17, and 13-18. Table 1-3 is a summary of the test results.

Figure 13-18. Vertical Bed of Ballast Rings Arrestor Assembly Parametric Test Results, Bed Size: 43.2-cm Diameter by 22.9-cm Depth, Ring Size: 2.54-cm Diameter by 2.54-cm Length

The pre- and posttest pressure loss across the arresters ranged from 0.052 to 0.075 kN/m<sup>2</sup> (0.007 to 0.011 psid) at an average air velocity of 4.58 m/s (15.03 ft/s). Pressure loss decreased with the reduction in bed depth, and generally increased slightly after the first test firing in a series. Posttest inspection of the packed bed of rings showed about a 35% compaction due to distortion of the Ballast rings. A posttest photograph of a compacted bed of rings is shown in Figure 13-19. Since the support grid rings were restrained from motion, the compaction had to be caused by the force of the detonation wave acting on the frontal area of the Ballast rings alone.

A full-size arrester bed was used in the parametric tests with different-size Ballast rings. The 2.54-cm (1.0-in.) rings were replaced by new 3.81-cm- (1.5-in.-) diameter by 3.81-cm- (1.5-in.-) long aluminum Ballast rings in a bed depth of 63.5 cm (25 in.). All other parameters remained the same. This new arrester configuration (No. 187) was subjected to four stable detonations. On the first two firings, only the inlet rupture disc was blown out and the detonation was arrested. On the last two firings, all three rupture discs were blown out and flame was recorded in the witness section with a velocity of around 770 m/s (2530 ft/s). When the detonation was arrested, the downstream peak pressure pulse averaged 290 kN/m<sup>2</sup> (42.1 psia) and then exceeded 450 kN/m<sup>2</sup> (65 psia) when flame penetrated the arrester. Pre and posttest pressure loss across the arrester averaged 0.067 kN/m<sup>2</sup> (0.010 psid) at an average air-flow velocity 4.73 m/s (15.52 ft/s). The arrester bed was repacked

Figure 13-19. Posttest Compacted Bed of Aluminum Ballast Rings

with new 5.08-cm- (2.0-in.-) diameter by 5.08-cm- (2.0-in.-) long aluminum Ballast rings at the same bed depth of 63.5 cm (25 in.). All other parameters remained the same. This arrester configuration (No. 188) was subjected to three stable detonations. The detonation was arrested on only the first test firing. On the last two test firings, all rupture discs were blown out and flame was recorded in the witness section with a velocity of around 733 m/s (2406 ft/s). When the detonation was arrested, the downstream peak pressure pulse was 304 kN/m<sup>2</sup> (44.1 psia) and exceeded 450 kN/m<sup>2</sup> (65 psia) when flame penetrated the arrester. Pre- and posttest pressure loss across the arrester averaged 0.056 kN/m<sup>2</sup> (0.008 psid) at an average air-flow velocity of 4.68 m/s (15.35 ft/s). Posttest inspection showed a 28% compaction of the bed from distortion of the Ballast rings. The results of this test are plotted in Figure 13-21 and summarized in Table 1-3.

The next three parametric test configurations (No. 189, No. 190 and No. 191) for variations in bed diameter were all made with new 2.54-cm (1.0-in.) aluminum Ballast rings. A full 43.2-cm- (17-in.-) diameter bed was demonstrated in the first test series, so this test series started with the largest cylindrical insert and in three steps reduced the bed diameter through 33.7 cm (13.25 in.), 30.5 cm (12 in.), and 25.4 cm (10 in.), all at a constant bed depth of 63.5 cm (25 in.). Ballast rings were packed into both the central flow passage of the insert and the nonflowing annular space between the inner wall of the housing vessel and the outer wall of the insert. Figure 13-22 is a pretest photograph showing the ring packing of the 33.7-cm (13.25-in.) diameter bed. Each configuration was subjected to six or more stable detonations. The detonation was arrested on all test firings and only the inlet rupture disc was blown out. The downstream peak pressure pulse ranged from 181 to 132 kN/m<sup>2</sup> (26.3 to 19.1 psia) and showed a slight reduction in pressure level as the bed diameter was reduced in size. Pre- and posttest averaged pressure loss across the arresters increased from 0.075 to 0.278 kN/m<sup>2</sup> (0.011 to 0.040 psid) as the bed diameter was reduced. The averaged air-flow velocity was 4.55 m/s (14.93 ft/s). Posttest inspections showed that each bed had compacted about 30% from distortion of the Ballast rings. The results of these tests are plotted in Figures 13-23, 13-24, and 13-25, and summarized in Table 1-3.

The vertical bed of Ballast rings arrester test assembly used to evaluate the inlet rupture-disc pressure rating parameter combined the results of the previous parametric tests. The selected bed size was 25.4-cm (10-in.) diameter by 45.7-cm (18-in.) deep, packed with 2.54-cm- (1.0-in.-) diameter by 2.54-cm- (1.0-in.-) long aluminum Ballast Rings. The bed depth was obtained by cutting 17.8 cm (7 in.) off the upper end of the 25.4-cm- (10-in.-) diameter cylindrical insert and employing the appropriate length spacer to complete the stack height. This test configuration (No. 192 to No. 195) was subjected to six stable detonations. In the first three tests, the inlet rupture-disc pressure rating was increased in steps through 690, 2068, and 4137 kN/m<sup>2</sup> (100, 300, and 600 psid). On the last three tests, the rupture-disc assembly was blanked-off with a blind flange. The detonation was arrested on all test firings. Where the inlet rupture disc was blown out, the downstream peak pressure pulse measured about 141 kN/m<sup>2</sup> (20.4 psia).

When the rupture disc was blanked-off, this same pressure increased slightly to average  $164 \text{ kN/m}^2$  (23.8 psia). Pre- and posttest pressure loss across the arrester ranged from  $0.162$  to  $0.220 \text{ kN/m}^2$  (0.023 to 0.032 psid) at an averaged air-flow velocity of  $4.56 \text{ m/s}$  (14.97 ft/s). Posttest inspection showed that the bed had compacted 28% from distortion of the Ballast rings. The results of this test are plotted in Figure 13-26, and summarized in Table 1-3.

This last test completed the parametric testing of detonation-flame arresters. From these tests, two arrester configurations were defined that were used in the continuous-flow testing described in the next section.

## SECTION XIV

### CONTINUOUS-FLOW TESTING OF DETONATION-FLAME ARRESTERS

#### A. TEST FACILITY MODIFICATION

Continuous-flow testing, as referred to in this report, is defined as a type of test where the gasoline and air mixture, used to generate a stable detonation in the facility piping, continues to flow into the piping for a finite time period following ignition and detonation. At the end of the specified time period, the gasoline vapor is manually diverted into the fuel condenser. This differs from the normal detonation test where the vaporized gasoline flowing into the induction piping is automatically diverted into the fuel condenser 1.0 second before ignition. In both procedures, air continues to flow through the piping until a posttest inspection verifies that the facility is clear of residual gasoline and combustion by-products.

There was a high probability that continuous flow testing would cause a flame to flash back from the detonation test piping into the induction system piping. The rarefaction wave or the reflected detonation wave could be expected to drive any lingering flame in the ignition section upstream through the flow straightener and into the induction piping. This flame would undoubtedly persist in the mechanical mixer, a region of high turbulence, and burn out the hardware. The flow straightener, which was made from a spiral-wound, crimped stainless-steel ribbon core, 15.2 cm (6 in.) in diameter by 3.8 cm (1.5 in.) long with a flow passage hydraulic diameter of 0.269 cm (0.106 in.), was not considered to be an adequate arrester for high-velocity flames. Installed in its place was a larger Shand and Jurs spiral-wound, crimped aluminum ribbon arrester assembly, 25.4 cm (10 in.) in diameter by 15.2 cm (6 in.) long with a smaller flow passage hydraulic diameter of 0.114 cm (0.045 in.). The arrester assembly was mounted between two 25.4- to 15.2-cm- (10- to 6-in.-) diameter flanged-pipe reducer assemblies, as shown in Figure 14-1.

To explore the possibility of reignition occurring at some distance downstream of the experimental detonation-flame arrester, two lengths of standard steel pipe 15.2 cm (6.0 in.) in diameter, and each 6.7 m (22 ft) long, were installed at the exit of the witness section (No. 10). The upstream instrumented verification section (No. 6) was removed and replaced by the uninstrumented extension section (No. 11). The instrumented verification section (No. 6) was reversed 180 deg and installed at the exit of the new 13.4-m- (44-ft-) long extension sections (No. 12 and No. 13). By reversing the verification section, the instrumentation ports were placed at the upstream end of this pipe section, thus allowing some protection for the flame sensors from ambient sunlight. A schematic diagram of the continuous-flow testing arrangement of facility piping is shown in Figure 14-2. This new assembly provided sufficient run-up piping and instrumented sections to verify whether or not the low-level peak-pressure pulse passing through the experimental detonation arrester had sufficient energy to cause an ignition of the combustible gasoline and air mixture downstream. A photograph of the facility piping, showing the new extension sections, is presented in Figure 14-3.

Figure 14-1. Shand and Jurs Spiral-Wound, Crimped Aluminum Ribbon Arrester Assembly Installed in the Inlet Flow Straightener Location, Size: 25.4-cm Diameter by 15.2-cm Length

The preprogrammed ignition and fuel diversion procedure, provided by the automatic sequence timer, was modified to reduce the igniter "on-time" from 500 milliseconds to 180 milliseconds and the fuel diversion command changed from an automatic to a manual input. The reduction in igniter "on-time" removed the source of ignition from the upstream test piping by the time the detonation rarefaction and reflection waves retrogressed back to the ignition section. The only source then available for ignition of the continuing flow of combustible gasoline and air mixture in the test piping would have to be a lingering flame or residual wave energy from the initial detonation. Fast responding bare-wire thermocouples were installed into the induction piping, run-up piping, test section, and witness section to monitor the presence of any continuous flame.

Figure 14-3. Facility Piping Assembly with the 13.4-m-Long Extension Sections Installed

#### B. VERTICAL BED OF ALUMINUM BALLAST RINGS ARRESTER TEST ASSEMBLY

The test configuration for the vertical bed of aluminum Ballast rings arrester used in the continuous-flow tests was identical to the last one used in the parametric test series. Bed size was 25.4-cm (10-in.) diameter by 45.7-cm (18-in.) depth, packed with new 2.54-cm- (1.0-in.-) diameter by 2.54-cm- (1.0 in.-) long aluminum Ballast rings. The inlet rupture-disc assembly was blanked-off, but the rupture-disc assemblies on the vessel cover and the outlet pipe tee both contained discs with the 690  $\text{kN/m}^2$  (100 psid) pressure rating. Using a gasoline and air mixture at the standard test conditions and the upstream ignition location, four stable detonation firings were made on this test configuration (No. 196). The first two firings were followed by a continuous flow of the gasoline and air mixture for a period of 30 seconds. On the last two firings, the flow period was extended to 60 seconds. The detonation was arrested on all tests and was completely contained between the inlet and test section arresters. None of the induction piping rupture discs

or the downstream piping rupture discs were blown out. There was no evidence of reignition in the witness or extension sections, and no lingering flames in the test run-up sections. The thermocouple in the ignition section (T12) registered the short-lived flame and the thermocouple in the witness section (T102) recorded only a few degrees rise in temperature due to the passage of the combustion gas products as they exhausted through the downstream piping. Most of the heat of combustion was apparently absorbed by the pipe wall or the heat sink capability within the arrester bed. The pre- and posttest pressure loss across the arrester bed averaged  $0.30 \text{ kN/m}^2$  ( $0.044 \text{ psid}$ ) at an averaged air-flow velocity of  $4.68 \text{ m/s}$  ( $15.35 \text{ ft/s}$ ). Posttest inspection of the bed showed a 25% compaction due to distortion of the Ballast rings.

The arrester bed was repacked with new 2.54-cm- (1.0-in.-) size aluminum Ballast rings. Four more detonation test firings were made on this test configuration (No. 197). In this series, the first two firings were followed by 90 seconds of continuous gasoline-and-air-mixture flow, and the last two firings by 120 seconds of continuous mixture flow. Again, the detonation was arrested on all test firings and was completely contained between the inlet and test section arresters. No rupture discs were blown out. There was no evidence of reignition in the witness or extension sections and no lingering flame in the test run-up section. Pre- and posttest pressure loss measurements averaged about the same as the previous test series. Posttest inspection showed a 27% bed compaction. Test data from these two test series are plotted in Figure 14-4 and summarized in Table 1-4. The peak pressure pulse measured in both the witness section and the downstream verification section averaged around  $146 \text{ kN/m}^2$  ( $21.1 \text{ psia}$ ) and was traveling at an average velocity of  $398 \text{ m/s}$  ( $1306 \text{ ft/s}$ ). There was no evidence of increasing wave velocity or pressure in the extension section, as would have been the case had ignition and combustion been present.

#### C. SHAND AND JURS SPIRAL-WOUND, CRIMPED STAINLESS-STEEL RIBBON ARRESTER TEST ASSEMBLY

The Shand and Jurs spiral-wound, crimped stainless-steel ribbon arrester test assembly was installed into the test section using the last test configuration developed during the parametric testing. It contained the 30.5-cm- (12-in.-) diameter by 20.3-cm- (8-in.-) long arrester assembly with the directly connected inline pipe tee and the blanked-off rupture-disc assembly shown in Figure 13-7. This test configuration (No. 198) was subjected to four stable detonations using the gasoline and air at the standard test condition and the upstream ignition location. The first two test firings were followed by the continuous mixture flow for a period of 30 seconds and the second two test firings by 60 seconds of continuous mixture flow. The detonation was arrested on all test firings and was completely contained between the inlet and test section arresters. There was no evidence of reignition in the witness or extension sections and no lingering flame in the test run-up section. Pre- and posttest pressure loss measurements showed no change from the parametric tests. A posttest inspection of the arrester assembly revealed a slight bowing of the downstream retainer grid as previously described and a few cracked welds in the

grid. The damage was repaired and the arrester was reinstalled into the test assembly.

Four more stable detonation test firings were made on the repaired arrester configuration (No. 200). The first two test firings were followed by 90 seconds of continuous mixture flow, and on the last two test firings the flow period was extended to 120 seconds. The results were the same as those of the previous test series. There was no evidence of reignition or lingering flames. Test data from these two test series are plotted in Figure 14-5 and summarized in Table 1-4. The low-level peak-pressure pulse measured in the witness section averaged  $335 \text{ kN/m}^2$  (48.6 psia), and decayed to an average  $240 \text{ kN/m}^2$  (34.8 psia) at the exit of the extension section. The velocity of this pressure pulse likewise decayed from an average of 640 m/s (2100 ft/s) in the witness section to 480 m/s (1575 ft/s) at the exit of the extension section. With both the intensity and velocity decreasing in this downstream pressure wave, there was no evidence of reignition or combustion taking place. Posttest inspection revealed no unusual damage or distortion to the crimped ribbon arrester test assembly.

The arrester core was removed from the test assembly and the two 30.5-cm- (12-in.-) diameter flanges were bolted together. Also, the low-pressure transducers were removed from the witness and extension sections. One last test firing was made where a stable detonation was recorded passing through the entire 13.4-m- (44-ft-) long extension piping.

## SECTION XV

### CONCLUSIONS

The following conclusions have been reached from the results of this experimental evaluation of flame-control devices in a simulated vapor recovery system using 15.2-cm- (6.0-in.-) diameter piping where combustible mixtures of gasoline and air flowed at pressures slightly above one atmosphere and temperatures ranged from 23 to 65°C (74 to 149°F).

- (1) The deflagration-to-detonation run-up distance is 11.2 m (36.7 ft), or an L/D of 74 for 15.2-cm- (6.0-in.-) diameter piping artificially roughened to a Darcy friction factor ranging from 0.040 to 0.047, or a relative roughness ranging from 0.010 to 0.015.
- (2) The deflagration-to-detonation run-up distance does not change significantly for gasoline-and-air equivalence ratios ranging from 0.9 to 1.4, or for initial flow velocities ranging from 0 to 6.1 m/s (0 to 20 ft/s).
- (3) The stable detonation after transition has a measured flame velocity of 1800 m/s (5906 ft/s) and a peak pressure of 1900 kN/m<sup>2</sup> (276 psia).
- (4) During the transition from deflagration to detonation, flame velocity reaches 2700 m/s (8860 ft/s) and peak pressure exceeds 4000 kN/m<sup>2</sup> (580 psia).
- (5) A reflected detonation wave had a measured peak pressure of 3300 kN/m<sup>2</sup> (479 psia), or double the level of the stable propagating detonation wave.
- (6) Four generic types of flame control devices found effective in arresting detonations are:
  - (a) Spiral-wound, crimped metal ribbon.
  - (b) Foamed nickel-chrome metal.
  - (c) Vertical bed of aluminum Ballast rings.
  - (d) Water-trap or hydraulic back-pressure valve.
- (7) Combinations of standard pipe fittings, such as tees and elbows, with rupture-disc assemblies and restrictor orifice plates, are ineffective in arresting detonations.
- (8) Rupture-disc assemblies installed on the inlet side of detonation arresters do not reduce the intensity of the detonation wave pressure, but do provide a controlled release of the hot combustion gases behind the detonation wave.

- (9) The smallest-size vertical bed of metal rings arrester found to be effective in arresting detonations is 25.4 cm (10 in.) in diameter by 45.7 cm (18 in.) in depth and packed with 2.54-cm- (1.0-in.-) diameter by 2.54-cm- (1.0-in.-) long aluminum Ballast rings.
- (10) Aluminum Ballast rings in larger sizes, 3.81 (1.5 in.) and 5.08 cm (2.0 in.), are not effective in repeatedly arresting detonations.
- (11) Increasing the rupture-disc pressure rating from 690 kN/m<sup>2</sup> (100 psid) up to a blanked-off condition on the inlet piping of a vertical bed of aluminum Ballast rings arrester does not affect the arrester's ability to stop a detonation. Also, it has very little influence on the level of peak-pressure pulse passed through the arrester.
- (12) Repeated exposure to the impact of detonation shock waves caused distortion of the aluminum Ballast rings, resulting in compaction of the bed of rings in the arrester. The amount of compaction ranged from 25 to 35% of the starting depth; larger diameter beds experience a higher percentage of compaction. The resulting pressure drop across the bed increases with each succeeding detonation, but reaches an upper limit after three to four detonations.
- (13) The smallest core length of a 30.5-cm- (12-in.-) diameter spiral-wound, crimped metal ribbon arrester found to be effective in arresting detonations is 15.2 cm (6 in.) with a crimp passage hydraulic diameter of 0.114 cm (0.045 in.). Stainless-steel ribbon material is better able to withstand the impact of detonation shock waves without distortion than aluminum ribbon, providing the core windings are made from continuous length ribbons.
- (14) The downstream peak-pressure pulse passing through a spiral-wound, crimped stainless-steel ribbon arrester was reduced from 344 to 260 kN/m<sup>2</sup> (49.9 to 37.7 psia) when the core length was increased from 15.2 to 30.5 cm (6 to 12 in.). Assuming a linear relationship between core length and downstream peak-pressure pulse, the core for a 30.5-cm- (12-in.-) diameter arrester would have to be 58.5 cm (23 in.) long to reduce the downstream pressure pulse to one atmosphere or 101.4 kN/m<sup>2</sup> (14.7 psia).
- (15) Increasing the rupture-disc pressure rating from 690 kN/m<sup>2</sup> (100 psid) up to a blanked-off condition on the inlet piping of a spiral-wound, crimped stainless-steel ribbon arrester does not affect its ability to stop a detonation. Also, it has very little influence on the level of the peak pressure pulse passed through the arrester.

- (16) Both the vertical bed of aluminum Ballast rings arrester and the spiral-wound, crimped stainless-steel ribbon arrester are effective in stopping detonations followed by continuous combustible mixture flow for periods up to 120 seconds. There is no indication that lingering flames remain in the 25 m (80 ft) of run-up piping upstream of the arrester, and no evidence of reignition in the 18 m (60 ft) of exit piping downstream of the arrester. In this limited configuration, a rupture disc upstream of the arrester was not required to relieve the hot combustion gases following the detonation.

## SECTION XVI

### RECOMMENDATIONS

In the design of a closed-loop vapor recovery system for gasoline cargo transfer at a marine terminal, the following recommendations are made regarding the selection and installation of detonation-flame arresters:

- (1) Ranked in order of preference, the selection of an arrester based on the least drop in system pressure is (1) packed bed of Ballast rings, (2) spiral-wound, crimped metal ribbon, (3) 80-grade foamed metal, (4) water trap, and (5) hydraulic back-pressure valve.
- (2) Ranked in order of preference, the selection of an arrester based on the ability to withstand repeated detonation is (1) spiral-wound, crimped metal ribbon, (2) packed bed of Ballast rings, (3) water-trap or hydraulic back-pressure valve, and (4) 80-grade foamed metal.
- (3) Ranked in order of preference, the selection of an arrester based on minimum maintenance, least susceptibility to fouling, and reduced contamination is (1) packed bed of Ballast rings, (2) spiral-wound, crimped metal ribbon, (3) 80-grade foamed metal, and (4) water-trap or hydraulic back-pressure valve.
- (4) The selection of materials used in the construction of arresters should be based on their compatibility with the environment and the fuel vapors to be encountered. However, stainless steel is recommended over aluminum or similar lower-strength metals.
- (5) Because of the short deflagration-to-detonation run-up distance, it would be impractical to install a series of detonation-flame arresters in a vapor transfer line at spacing intervals that would prevent the occurrence of a detonation. The combined arrester pressure losses in such an installation would soon exceed the available operating pressure differential between storage and receiver tanks. It would be better to place the arresters as close to the individual tanks as possible, making sure that they are located between the tanks and any source of ignition.
- (6) To minimize the possibility of a detonation, a flame arrester device should be placed as close as possible to any potential ignition source, at a position well within the detonation run-up distance.
- (7) For operational safety, the arrester, vapor transfer lines, valves, and other components in the vapor recovery system should be designed to withstand the instantaneous pressure spikes ranging from 1900 kN/m<sup>2</sup> (276 psia) to 4000 kN/m<sup>2</sup>.

(580 psia) as associated with stable, transitional, and reflected detonation waves, should they occur.

- (8) Rupture-discs or rupture-disc/relief-valve combination assemblies should be included in vapor transfer lines to vent the hot combustion gases produced by a detonation. This would minimize the danger of over pressurizing the tanks attached to these lines.

The data and experience obtained from these detonation arresting tests is limited to gasoline and air mixtures in 15.2-cm (6.0-in.-) diameter pipe sizes. It is recommended that extrapolation of this data should be limited to the following:

- (1) Application to other fuels should be limited to those hydrocarbons that have flame propagating characteristics similar to gasoline. This does not include such fuels as hydrogen and acetylene or any type of fuel in an oxygen enriched environment.
- (2) Scaled-down applications to pipe sizes smaller than a 15.2-cm (6.0-in.) diameter are considered to be conservative.
- (3) Scaled-up applications should be limited to pipe sizes no larger than a 20.3-cm (8.0-in.) diameter, providing adequate consideration is given to structural strength.

It is recommended that the following experimental work be considered as possible follow-on programs to extend the data base and experience already achieved:

- (1) Using the existing test facility and with a moderate increase in air flow and fuel flow capability, detonation-flame arrester testing could be conducted with enlarged conical transition pipe sections up to and larger than 30.5-cm (12.0-in.) diameter.
- (2) Detonation-flame arrester testing should be made with other fuel/air combinations that would normally require a closed-loop type of vapor recovery system for transfers operations.
- (3) Detonation qualification-type testing should be made on vapor recovery system components other than arresters including: (1) valves, (2) pumps, (3) blowers, (4) filters, (5) condensers, and (6) separators.
- (4) Flame arrester qualification type testing should be conducted at conditions other than detonations including atmospheric flashback from fuel/air vapor plumes and under the heat-up characteristics achieved by sustained burning where fuel/air mixture flow rates are representative of a vapor recovery system or normal tank venting systems.

APPENDIX A

ANALYSIS OF INSTRUMENTATION MEASUREMENT AND CALCULATION UNCERTAINTIES

The following is an analysis of the uncertainties associated with pressure, temperature, and IDAC program calculations. Although these values can be assured with only a 95% ( $2\sigma$ ) probability, this is most likely a conservative estimate. Many of the uncertainty values used are absolute in that the procedures specify a maximum limit. Others are difficult to ascertain precisely, so "safe" estimates must be large. The calibration of pressure transducers, for example, are always subject to the uncertainties of accidental, fixed, or operational errors. However, considerable effort has been expended on procedures, techniques, and training to minimize effects of this type. Certainly encouraging is the fact that data taken on B-Stand as well as other stands supports the conclusions reached by this type of analysis.

In this analysis it will be assumed that:

- (1) All elemental errors are normally distributed and hence are in "statistical control."
- (2) All elemental errors are based on at least 20:1 odds, i.e., 95% probability; hence the overall accuracy determination has that probability.

#### A. PRESSURE MEASUREMENTS

##### 1. Component Errors

Figure A-1 shows the various components of error  $e_1, \dots, e_7$  in a strain-gage instrumentation channel from the sensed parameter to the digitized tape record, and is typical for pressure measurements. These error components are first evaluated by estimating the elemental errors making up each component and then combining them (where appropriate) by the standard "square-root-of-the-sum-of-the-squares" technique.

Figure A1. Typical Strain-Gage-Type Instrumentation Channel

## 2. Tap and/or Coupling Errors $e_1$

These consist of amplitude error when the nature (frequency, amplitude, wave shape) of the fluctuating components of the measurements exceeds the response capabilities of the coupling/transducer system. However, the system will produce a nearly-average electrical analog for small amplitude fluctuations at frequencies beyond the response of the system. It is assumed that this analog is a true average of the noise-like fluctuations during steady-state conditions. Therefore,  $e_1 = \text{nil}$ .

## 3. Environmental Errors $e_2$

Bonded strain gage construction provides low vibration sensitivity for pressure transducers. Noise introduced by mechanical vibration for pressure will be assumed to be of small amplitude and to be effectively averaged at the digital recorder input filter (0 to 10 cps low pass).

Transducers are not exposed to heat radiation from exhaust gases and are normally shielded from the direct rays of the sun. Temperature errors are assumed to result from ambient temperature changes between the time of electrical calibration and run time, and not from nonuniform case temperature. Ambient temperature change is estimated to be within  $\pm 2.8^\circ\text{C}$  ( $\pm 5^\circ\text{F}$ ). Temperature effects on pressure and force transducers are minimized by compensation circuitry and quoted by the manufacturers to be in the range of 0.009% full scale/ $^\circ\text{C}$  (.005% full scale/ $^\circ\text{F}$ ) for the pressure transducers.

$$e_2 = \pm 0.04\% \text{ of run level pressure}$$

## 4. Actual Calibration Error $e_3$

The component error  $e_3$  will be considered as the error in the parameter equivalent.

- |     |                                                                                          |               |
|-----|------------------------------------------------------------------------------------------|---------------|
| (1) | Calibrator combined accuracy (linearity, hysteresis, resolution, repeatability) -----    | $\pm 0.05\%$  |
| (2) | Transducer                                                                               |               |
|     | Linearity (determined for near run level) ----                                           | nil           |
|     | Temperature effects (temperature assumed constant during calibration) -----              | $\pm 0.10\%$  |
|     | Interconnecting wiring (negligible current flow with high-impedance system) -----        | nil           |
|     | Combined hysteresis and repeatability -----                                              | 0.25%         |
|     | Excitation (short-term stability) -----                                                  | $\pm 0.10\%$  |
|     | Readout (digital voltmeter overall accuracy at 30-mV full-scale and 24-mV reading) ----- | $\pm 0.033\%$ |

$$\text{Thus, } e_3 = \pm 0.29\%$$

5. Electrical Calibration Error  $e_4$

(1) Repeatability -----  $\pm 0.10\%$

(2) Thus,  $e_4 = \pm 0.10\%$

6. Electrical Excitation Error  $e_5$

(1) Excitation stability (from prerun electrical calibration through run) -----  $\pm 0.10\%$

(2) Thus,  $e_5 = \pm 0.10\%$

7. Amplifier Error  $e_6$

(1) Amplifier stability (from prerun electrical calibration through run):

Gain stability -----  $\pm 0.01\%$

Nonlinearity -----  $\pm 0.01\%$

Balance -----  $\pm 0.01\%$

(2) Thus,  $e_6 = \pm 0.02\%$

8. Digital Recorder Error  $e_7$

(1) Resolution ( $\pm 16,384$  counts full scale) -----  $\pm 0.006\%$

(2) Short term stability (from prerun calibration through run) -----  $\pm 0.05\%$

(3) Linearity -----  $\pm 0.02\%$

(4) Electrical noise (combined effects of entire system) -----  $\pm 0.10\%$

(5) Conversion error -----  $\pm 0.05\%$

(6) Thus,  $e_7 = \pm 0.13\%$

9. Uncertainty

The uncertainty ( $U_p$ ) in a pressure measurement involves  $e_1$  through  $e_7$  plus the uncertainty ( $U_{CAL}$ ) in the calibration step. The uncertainty in the calibrate step involves  $e_4$ ,  $e_6$ , and  $e_7$ :

$$u_{ch} = [(e_4)^2 + (e_6)^2 + (e_7)^2]^{1/2}$$

$$= [(0.10)^2 + (0.02)^2 + (0.13)^2]^{1/2} = \pm 0.17\%$$

$$u_p = [(e_1)^2 + (e_2)^2 + (e_3)^2 + (e_4)^2 + (e_5)^2 + (e_6)^2 + (e_7)^2]^{1/2}$$

$$= [(0)^2 + (0.04)^2 + (0.29)^2 + (0.10)^2 + (0.10)^2 + (0.02)^2 + (0.13)^2 + (0.17)^2]^{1/2}$$

$$= \pm 0.39\%$$

## B. THERMOCOUPLE MEASUREMENTS

Figure A-2 shows the various components of error  $e_1, \dots, e_5$  in a thermocouple instrumentation channel from the sensed parameter to the digitized tape record. These error components are first evaluated by estimating the elemental errors making up each component and then combining them (where appropriate) by the "square-root-of-the-sum-of-the-squares" technique.

### 1. Thermocouple Errors $e_1$

All thermocouple probes at ETS meet the standard limits of error of premium grade thermocouples recommended by the Instrument Society of America (ISA). All of the thermocouples used were type-K, chromel-alumel, and therefore only this type will be evaluated. The ISA limits of error are given as percentages applied to the temperature being measured. The ISA limits of error for type K thermocouples are:

$\pm 1.1^\circ\text{C}$  ( $\pm 2^\circ\text{F}$ ) from  $-17.8$  to  $276.7^\circ\text{C}$  ( $0$  to  $530^\circ\text{F}$ )

$\pm 0.375\%$  from  $276.7$  to  $1260^\circ\text{C}$  ( $530$  to  $2300^\circ\text{F}$ )

Figure A-2. Typical Thermocouple-Type Instrumentation Channel

## 2. Reference Junction Error $e_2$

The reference junction used at ETS is the Pace Engineering Company 65.6°C (150°F) reference junction. The manufacturer lumps its total inaccuracy as  $\pm 0.28^\circ\text{C}$  ( $\pm 0.5^\circ\text{F}$ ).

Temperature  $^\circ\text{C}$  ( $^\circ\text{F}$ ):

|         | 10.0 to 37.8<br>(50 to 100)    | 37.8 to 93.3<br>(100 to 200)   | 93.3 to 148.9<br>(200 to 300)  |
|---------|--------------------------------|--------------------------------|--------------------------------|
| $e_2$ : | 0.67%                          | 0.33%                          | 0.20%                          |
|         | 148.9 to 204.4<br>(300 to 400) | 204.4 to 276.7<br>(400 to 530) | 276.7 to 1260<br>(530 to 2300) |
| $e_2$ : | 0.14%                          | 0.11%                          | 0.03%                          |

## 3. Calibration Voltage Error $e_3$

The thermocouple systems at ETS calibrate the records by voltage substitution using a Video Power Supply Model 200. The power supply stability is  $\pm 0.05\%$ . The voltage divider resistors are  $\pm 0.05\%$ .

$$e_3 = \pm 0.07\%$$

## 4. Amplifier Error $e_4$

- (1) Amplifier stability (from prerun electrical calibration through run):

Gain stability -----  $\pm 0.01\%$

Non linearity -----  $\pm 0.02\%$

Balance -----  $\pm 0.01\%$

- (2) Thus,  $e_4 = \pm 0.02\%$

## 5. Digital Recorder Error $e_5$

- (1) Resolution ( $\pm 16,384$  counts full scale) -----  $\pm 0.006\%$

- (2) Short-term stability (from prerun calibration through run) -----  $\pm 0.05\%$

- (3) Linearity -----  $0.02\%$

- (4) Electrical noise (combined effects of entire system) -----  $\pm 0.10\%$
- (5) Conversion error -----  $\pm 0.05\%$
- (6) Thus,  $e_5 = \pm 0.13\%$

## 6. Uncertainty

The uncertainty ( $U_{TC}$ ) in a thermocouple measurement involves  $e_1$  through  $e_5$  plus the uncertainty ( $U_{CAL}$ ) in the calibrate step. The uncertainty in the calibrate step involves  $e_3$ ,  $e_4$  and  $e_5$ :

$$\begin{aligned} U_{CAL} &= [(e_3)^2 + (e_4)^2 + (e_5)^2]^{1/2} \\ &= [(0.07)^2 + (0.02)^2 + (0.13)^2]^{1/2} \\ &= 0.15\% \end{aligned}$$

$U_{TC}$  for type K (CR-AL) thermocouples for the range 10.0 to 37.8°C (50°F to 100°F):

$$\begin{aligned} U_{TC} &= [(e_1)^2 + (e_2)^2 + (e_3)^2 + (e_4)^2 + (e_5)^2 + (U_{CAL})^2]^{1/2} \\ &= [(2.6)^2 + (0.67)^2 + (0.07)^2 + (0.02)^2 + (0.13)^2 + (0.15)^2]^{1/2} \\ &= \pm 2.7\% \end{aligned}$$

For range 37.8 to 93.3°C (100 to 200°F):

$$\begin{aligned} U_{TC} &= [(1.3)^2 + (0.33)^2 + (0.07)^2 + (0.02)^2 + (0.13)^2 + (0.15)^2]^{1/2} \\ &= \pm 1.4\% \end{aligned}$$

Uncertainties for other ranges of type K are calculated the same way and are listed below.

| Temperature °C (°F):           |                                |                                |
|--------------------------------|--------------------------------|--------------------------------|
| 10.0 to 37.8<br>(50 to 100)    | 37.8 to 93.3<br>(100 to 200)   | 93.3 to 148.9<br>(200 to 300)  |
| $U_{TC}$ : $\pm 2.7\%$         | $\pm 1.4\%$                    | $\pm 0.85\%$                   |
| 148.9 to 204.4<br>(300 to 400) | 204.4 to 276.7<br>(400 to 530) | 276.7 to 1260<br>(530 to 2300) |
| $U_{TC}$ : $\pm 0.62\%$        | $\pm 0.49\%$                   | $\pm 0.43\%$                   |

### C. CALCULATION PROGRAM UNCERTAINTIES

There are three error sources in an IDAC calculation program: input data exceeding the input range of the program, resolution of the engineering units conversion, and calculation round-off errors. The first error nearly always shows as a major discrepancy in the calculated data. The latter two have a relatively small magnitude and are inherent in the IDAC, so will remain throughout use of the program.

In general, there have been no problems with the calculations in other IDAC programs when the range of the source data is within the general range used for the program verification. Problems may be found if the range of the source data is greatly exceeded. However, such errors typically produce a calculated result that is obviously incorrect, so there is relatively little chance of obtaining invalid data.

Engineering units data displayed for the source channels are obtained by multiplying a digital value proportional to the physical quantity by a parameter equivalent (PE) value. The digital value is referred to as "raw data," and has a range of  $\pm 16,384$  counts. The PE typically has a value in the range of 4000 to 10,000 counts. If the PE has a relatively small magnitude, the engineering units value displayed by the IDAC will stay at the same value while the raw data bits are changed through a range of at least several bits. Typically, the raw data must change on the order of 4 counts before change will be shown in the engineering units data. A small PE may require a change of over 10 raw data counts to cause a change in the engineering units data. The typical engineering units data have a resolution of 4 digits; this does not represent a significant error for real-time data. However, this characteristic will affect the calculated data since several source channels may all have their maximum resolution errors at the same time. The combined resolution error is thus present in the calculated data.

The round-off errors are caused by the limited word length of the IDAC. All calculations are performed in a two-word format; one defines the magnitude and the other the exponent. The magnitude word has 16 bits, so the least significant bit represents 0.006% of the full scale value. Each operation of the calculation sequence can thus lose 0.006%. The air-flow calculation involves about 30 operations, so the round-off error can be on the order of 0.2%.

To verify the calculation program results, source channel data was entered into IDAC, read on the video display, and logged. A Texas Instruments SR51 calculator was used to calculate the air- and fuel-flow rates from the logged data. The calculator result was compared to the IDAC result and the difference noted. The maximum percentage difference of reading is, air flow 0.54% and fuel flow 0.13%. Multiplying the percent difference by 1.5 gives a safe uncertainty number for the IDAC program calculation. The results:

Air flow =  $\pm 0.81\%$  of reading; fuel flow =  $\pm 0.20\%$  of reading

#### D. FUEL FLOW MEASUREMENTS

##### 1. Component Errors

Figure A-3 shows the various components of error  $e_1, \dots, e_5$  in a turbine flowmeter instrumentation channel from the transducer to the digitized tape record. These error components are first evaluated by estimating the elemental errors making up each component and then combining them (where appropriate) by the "square-root-of-the-sum-of-the-squares" technique.

##### 2. Environmental Errors $e_1$

Magnetic coil pickups are receptive to external ac signals. Good instrumentation shielding and grounding techniques virtually eliminate externally induced signals. Thus,  $e_1$  is nil.

##### 3. Actual Calibration Errors $e_2$

The turbine flowmeter used was calibrated at the Jet Propulsion Laboratory where the overall calibration uncertainty is 1.3%. Thus,  $e_2 = \pm 1.3\%$ .

##### 4. Electrical Calibration Errors $e_3$

The electrical calibration is a known frequency substitution and is not used in the flow-rate calculation, and therefore introduces no error in the measurement. Thus,  $e_3 = 0$

##### 5. Electrical Shaping Errors $e_4$

The shaping electronics convert the transducer output to a fast-rise-time pulse. This is straightforward electrical process and the error will be assumed to be nil. Thus,  $e_4 = \text{nil}$ .

Figure A-3. Typical Turbine Flowmeter Instrumentation Channel

## 6. Digital Recorder $e_5$

The turbine flowmeter output is recorded on the IDAC period counters. The inherent uncertainty of the period measurement is  $\pm 0.20\%$ . Thus,  $e_5 = \pm 0.20\%$ .

## 7. Uncertainty

The uncertainty ( $U_F$ ) in a turbine flowmeter measurement involves  $e_1$  through  $e_5$ :

$$\begin{aligned} U_F &= [(e_1)^2 + (e_2)^2 + (e_3)^2 + (e_4)^2 + (e_5)^2]^{1/2} \\ &= [(0)^2 + (1.3)^2 + (0)^2 + (0)^2 + (0.20)^2]^{1/2} \\ &= \pm 1.32\% \end{aligned}$$

The uncertainty ( $U_{MF}$ ) in the mass fuel-flow measurement involves the fuel-flow measurement uncertainty ( $U_F$ ) plus the fuel-temperature measurement uncertainty ( $U_{TC}$ ) plus the calculation program uncertainty ( $U_{CPF}$ ):

$$\begin{aligned} U_{MF} &= [(U_F)^2 + (U_{TC})^2 + (U_{CPF})^2]^{1/2} \\ &= [(1.32)^2 + (1.4)^2 + (0.20)^2]^{1/2} \\ &= \pm 1.93\% \end{aligned}$$

## E. MASS AIR-FLOW MEASUREMENT

### 1. Component Errors

Figure A-4 shows the various components required to make the mass air-flow measurement. The error of each component is combined by the "square-root-of-the sum-of-the-squares" technique to determine the uncertainty for this measurement.

### 2. Laminar Flow Element Errors $e_1$

The laminar flow element (LFE) has no direct output but requires that three measurements be taken on it. The manufacturer lists the LFE measurement uncertainty at  $\pm 0.50\%$ . Thus,  $e_1 = \pm 0.50\%$

Figure A-4. Mass Air-Flow Measurement

### 3. Transducer Measurement Uncertainties

- (1) PAMB,  $e_2 = \pm 0.39\%$
- (2) T01,  $e_3 = \pm 1.4\%$
- (3) PBO,  $e_4 = \pm 0.39\%$
- (4) DP2,  $e_5 = \pm 0.39\%$
- (5) Mass air flow calculation program uncertainties  $e_6 = \pm 0.81\%$

### 4. Uncertainty

The uncertainty ( $U_{MA}$ ) in the mass air-flow measurement involves  $e_1$  through  $e_6$ .

$$\begin{aligned}
 U_{MA} &= [(e_1)^2 + (e_2)^2 + (e_3)^2 + (e_4)^2 + (e_5)^2 + (e_6)^2]^{1/2} \\
 &= [(0.50)^2 + (0.39)^2 + (1.4)^2 + (0.39)^2 + (0.39)^2 + (0.18)^2]^{1/2} \\
 &= \pm 1.82\%
 \end{aligned}$$

### F. MIXTURE RATIO (MR) AND EQUIVALENCE RATIO (ER) CALCULATIONS

The MR and ER calculation uncertainty involves the mass fuel-flow uncertainty ( $U_{MF}$ ), mass air-flow uncertainty ( $U_{MA}$ ), and calculation program uncertainty ( $U_{CP}$ ). In this case, the calculation program involves only 2 operations, so the round-off error is 0.012%.

$$\begin{aligned}
 U_{MR} &= U_{ER} = [(U_{MF})^2 + (U_{MA})^2 + (U_{CP})^2]^{1/2} \\
 &= [(1.93)^2 + (1.82)^2 + (0.012)^2]^{1/2} \\
 &= \pm 2.65\%
 \end{aligned}$$

## G. QUARTZ-CRYSTAL PRESSURE TRANSDUCER MEASUREMENTS

### 1. Component Errors

Figure A-5 shows the various components of error  $e_1, \dots, e_8$  in a quartz-piezoelectric instrumentation channel from the sensed parameter to the recorder. These error components are first evaluated by estimating the elemental errors making up each component and then combined (where appropriate) by the standard "square-root-of-the-sum-of-the-squares" technique.

Figure A-5. Typical Quartz-Piezoelectric Type of Instrumentation Channel

### 2. Tap and/or Coupling Errors $e_1$

These consist of amplitude error when the nature (frequency, amplitude, waveshape) of the fluctuating components of the measurements exceed the response capabilities of the coupling/transducer system. Quartz-crystal pressure transducers are high-frequency (500-kHz) sensors that are normally flush-mounted to eliminate tap and/or coupling errors. Therefore,  $e_1 = \text{nil}$ .

### 3. Environmental Errors $e_2$

The rigid structure of quartz-crystal pressure transducers with an integral compensating accelerometer reduce vibration sensitivity and suppress resonance effects.

Transducers in the flame arrester detonation piping are exposed to flame and heat for milliseconds as the flame moves down the piping.

Heat radiation absorbed by the transducer is minimal due to the short duration and is estimated to be within 5.6°C (10°F). The manufacturers quoted temperature coefficient is 0.054%/°C (0.03%/°F). Thus,  $e_2 = \pm 0.30\%$ .

4. Actual Calibration Error  $e_3$

The component error  $e_3$  will be considered as the error in the parameter equivalent.

(1) Calibrator combined inaccuracy (linearity, hysteresis, resolution, repeatability) -----  $\pm 0.20\%$

(2) Quartz-crystal pressure Transducers:

Linearity (determined for near run level) ----  $\pm 0.10\%$

Temperature effects (temperature assumed constant during calibration) -----  $\pm 0.10\%$

Interconnecting wiring (negligible current flow with high-impedance system) ----- nil

Combined hysteresis and repeatability ----- 0.25%

Excitation (short-term stability) -----  $\pm 0.10\%$

Readout (X-Y plotter combined linearity, hysteresis, resolution, repeatability) -----  $\pm 0.50\%$

(3) Thus,  $e_3 = \pm 0.62\%$

5. Electrical Calibration Error  $e_4$

(1) Repeatability -----  $\pm 0.10\%$

(2) Thus,  $e_4 = \pm 0.10\%$

6. Electrical Excitation Error  $e_5$

(1) Excitation stability (from prerun electrical calibration through run) -----  $\pm 0.10\%$

(2) Thus,  $e_5 = \pm 0.10\%$

7. Amplifier Error  $e_6$

(1) Amplifier stability (from prerun electrical calibration through run):

|                      |              |
|----------------------|--------------|
| Gain stability ----- | $\pm 0.01\%$ |
| Nonlinearity -----   | $\pm 0.01\%$ |
| Balance -----        | $\pm 0.01\%$ |

(2) Thus,  $e_6 = \pm 0.02\%$

#### 8. Oscillograph Recorder Error $e_7$

|                                                                               |              |
|-------------------------------------------------------------------------------|--------------|
| (1) Resolution [ $\pm 10.16$ -cm ( $\pm 4$ -in.) full-scale deflection] ----- | $\pm 0.50\%$ |
| (2) Linearity [ $\pm 10.16$ -cm ( $\pm 4$ -in.) full-scale deflection] -----  | $\pm 2.00\%$ |
| (3) Electrical noise (combined effects of entire system) -----                | $\pm 0.10\%$ |

(4) Thus,  $e_7 = \pm 2.1\%$

#### 9. FM Tape Recorder Error $e_8$

|                                                                        |              |
|------------------------------------------------------------------------|--------------|
| (1) DC Linearity -----                                                 | $\pm 0.50\%$ |
| (2) Short-term stability (from pressure calibration through run) ----- | $\pm 0.05\%$ |
| (3) Electrical noise (combined effects of entire system) -----         | $\pm 0.10\%$ |
| (4) Flutter (instantaneous tape speed errors) ----                     | $\pm 0.10\%$ |
| (5) Resolution -----                                                   | $\pm 0.01\%$ |

Thus,  $e_8 = \pm 0.53\%$

#### 10. Uncertainty

The uncertainty ( $U_{QT}$ ) in a quartz-crystal pressure transducer measurement recorded on FM tape and played back onto an oscillograph involves  $e_1$  through  $e_8$  plus the uncertainty ( $U_{CAL}$ ) in the calibration step. The uncertainty in the calibrate step involves  $e_4$ ,  $e_6$ ,  $e_7$ , and  $e_8$ :

$$\begin{aligned}
 U_{CAL} &= [(e_4)^2 + (e_6)^2 + (e_7)^2 + (e_8)^2]^{1/2} \\
 &= [(0.10)^2 + (0.02)^2 + (2.06)^2 + (0.02)^2 + (0.53)^2]^{1/2} \\
 &= \pm 2.17\%
 \end{aligned}$$

$$\begin{aligned}
 U_{QT} &= [(e_1)^2 + (e_2)^2 + (e_3)^2 + (e_4)^2 + (e_5)^2 + (e_6)^2 + (e_8)^2 \\
 &\quad + (e_6)^2 + (e_7)^2 + U_{CAL}^2]^{1/2} \\
 &= [(0)^2 + (6.30)^2 + (0.62)^2 + (0.10)^2 + (0.10)^2 + (0.02)^2 \\
 &\quad + (0.53)^2 + (0.02)^2 + (2.06)^2 + (2.17)^2]^{1/2} \\
 &= \pm 3.1\%
 \end{aligned}$$

The uncertainty ( $U_{QG}$ ) in a quartz-crystal pressure transducer measurement recorded directly onto an oscillograph involves  $e_1$  through  $e_7$  plus the uncertainty ( $U_{CAL}$ ) in the calibration step. The uncertainty in the calibrate step involves  $e_4$ ,  $e_6$ , and  $e_7$ :

$$\begin{aligned}
 U_{CAL} &= [(e_4)^2 + (e_6)^2 + (e_7)^2]^{1/2} \\
 &= [(0.10)^2 + (0.02)^2 + (2.06)^2]^{1/2} \\
 &= \pm 2.06\%
 \end{aligned}$$

$$\begin{aligned}
 U_{QG} &= [(e_1)^2 + (e_2)^2 + (e_3)^2 + (e_4)^2 + (e_5)^2 + (e_6)^2 + (e_7)^2 \\
 &\quad + (U_{CAL})^2]^{1/2} \\
 &= [(0)^2 + (0.30)^2 + (0.62)^2 + (0.10)^2 + (0.10)^2 + (0.02)^2 \\
 &\quad + (2.06)^2 + (2.06)^2]^{1/2} \\
 &= \pm 3.0\%
 \end{aligned}$$

#### H. QUARTZ-CRYSTAL PRESSURE TRANSDUCER RISE-TIME RESPONSE

##### 1. Component Limitations

Figure A-6 shows the various components for a quartz-piezoelectric instrumentation channel that limit the rise-time response. These components are first evaluation individually for rise-time limiting characteristics; the lowest response component(s) in the system determines the maximum rise-time response capability of the system.

Figure A-6. Typical Quartz-Piezoelectric Type of Instrumentation Channel

2. Tap and/or Rise-Time Response Limitations  $r_1$

These consist of amplitude damping, waveshape distortion or frequency filtering when the nature of the fluctuation components of the measurement exceed the response capabilities of the coupling/transducer system. Quartz-crystal pressure transducers are fast rise-time, high-frequency (500-kHz) sensors that are normally flush-mounted to eliminate tap and/or coupling errors. Therefore,  $r_1 < 1\text{-}\mu\text{s}$  rise time.

3. Transducer In-Line Amplifier Rise-Time Limitations  $r_2$

The manufacturer's quoted rise-time response for a quartz-crystal pressure transducer, in-line amplifier system is  $1\text{ }\mu\text{s}$ . Thus,  $r_2$  is  $1\text{-}\mu\text{s}$  rise time.

4. Transmission Line Rise-Time Limitations  $r_3$

All coaxial lines are used. Thus,  $r_3$  is negligible.

5. Amplifier Rise-Time Limitations  $r_4$

The manufacturer's quoted rise-time response is  $2.5\text{ }\mu\text{s}$ . Thus,  $r_4$  is  $2.5\text{ }\mu\text{s}$  rise time.

6. FM Tape Recorder Rise-Time Limitations  $r_5$

When frequency data and/or rise-time response data is required for a test, the data is recorded at maximum FM tape recorder speed. If more than 13 channels of data are required, two tape recorders are used and they have different capabilities:

| Parameter                      | Recorder No. 1<br>(Ampex FR 3020) | Recorder No. 2<br>(Ampex PR 2200) |
|--------------------------------|-----------------------------------|-----------------------------------|
| Tape speed, cm/s (ips)         | 304.8 (120)                       | 152.4 (60)                        |
| Bandwidth, kHz ( $\pm 1/2$ dB) | DC to 80                          | DC to 40                          |
| Rise Time, $\mu\text{s}$       | 3.5                               | 7.0                               |
| Flutter, %                     | 0.13                              | 0.20                              |
| Dynamic Skew, $\mu\text{s}$    | 0.2                               | 0.4                               |

Dynamic skew is the relative time displacement of an event recorded simultaneously on any two adjacent tracks within the same head stack as observed on playback. The dynamic skew of the recorders can be accounted for by simultaneously recording a square wave on all tape channels and making note of the time displacement between all channels.

A technique used to improve the time resolution between step functions on different tape tracks is to time expand the playback by decreasing the tape speed. A one-step speed reduction [from 304.8 to 152.4 cm/s (120 to 60 ips)] reduces the recorded frequency output by 1/2 and increases the time resolution by a factor of 2. This is very useful when playing back onto an oscillograph recorder whose galvanometers have a limited frequency and rise-time response.

#### 7. Oscillograph Recorder Frequency Limitations $r_6$

The response limitations are dependent on the type of galvanometer used. Included here are galvanometers used for this test program:

| Galvanometer<br>Type | Undamped<br>Natural<br>Frequency, Hz | Rise-Time<br>Response, $\mu s$ |
|----------------------|--------------------------------------|--------------------------------|
| M600                 | DC to 600                            | 757                            |
| 7-362                | DC to 4150                           | 110                            |

#### 8. Results

The quartz-crystal pressure transducer system response limit when recorded directly on the oscillograph is:

757- $\mu s$  rise time response

When recorded on FM tape and playback with a time expansion of 32 onto the oscillograph, the response limits are:

3.5- $\mu s$  rise time on tape recorder No. 1  
7.0- $\mu s$  rise time on tape recorder No. 2

#### I. PHOTODETECTOR RISE-TIME LIMITATIONS

##### 1. Component Limitations

Figure A-7 shows the various components of a photodetection system that limit the rise-time response. These components are first evaluated individually for rise-time response limiting characteristics; the lowest response components in the system determine the maximum rise-time response capability of the system.

Figure A-7. Typical Photodetector Type of Instrumentation Channel

2. Tap and/or Coupling Rise-Time Limitations  $r_1$

With photodetectors, the tap or coupling may decrease the photo intensity and affect the spectral response. These characteristics may result in lower output amplitudes, but have minimum effect on rise-time response. However, the field of vision, reflections, flame-front characteristics, and flame speed will affect rise-time response. These characteristics are unknown and indeterminate at this time. Therefore,  $r_1$  is indeterminate, and the rise-time limitation analysis will begin with  $r_2$ .

3. Photovoltaic Rise-Time Limitations  $r_2$

The manufacturer's quoted rise-time response is 1.5  $\mu$ s.

4. Multiplier Phototubes Rise-Time Limitations  $r_2$

The manufacturer's quoted rise-time response is 0.05  $\mu$ s.

5. Rise-Time Limitations  $r_3$  Through  $r_6$

These rise-time limitations are the same as for quartz-crystal transducer systems.

6. Results

The photodetector system response is limited by the rise-time response limitations of the recorders. Therefore, for real-time recordings, the limit is the 757- $\mu$ s rise-time response of the oscillograph.

For time-expanded data recorded on FM tape and played out onto an oscillograph, the limits are:

| Time<br>Expansion | Rise-Time Response, $\mu$ s |            |
|-------------------|-----------------------------|------------|
|                   | Tape No. 1                  | Tape No. 2 |
| 1:1               | 110                         | 110        |
| 2:1               | 55                          | 55         |
| 4:1               | 28                          | 28         |
| 8:1               | 14                          | 14         |
| 16:1              | 7                           | 7          |
| 32:1              | 3.5                         | 7          |
| 64:1              | 3.5                         | 7          |

APPENDIX B

TEST CONFIGURATION LOG

| Configuration<br>No. | Test<br>No.              | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
|----------------------|--------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 100<br>to<br>117     | 1415<br>to<br>1428       | The first eighteen test configurations were evolved during the facility check-out tests designed to produce a stable detonation with propane and air mixtures. They covered the development of the hydrogen-air-spark igniter, the fuel-and-air-mixture sampling procedure, the increase in pipe run-up length from 8.4 to 31.5-m (25.5 to 103.5-ft), the changes in propane fuel from chemically pure to commercial grade, and the eventual addition of the expanded metal liners to produce turbulence in the fuel-and-air mixture burning in the run-up piping. |
| 118                  | 1429 (A-F)               | This configuration was similar to that shown in Figure 3-1. The only difference was that two 4.6-m (15.0-ft) sections of turbulent liners were installed at this time. The orifice plate was not installed.                                                                                                                                                                                                                                                                                                                                                        |
| 119                  | 1430 (A,B)               | The orifice plate was installed at the outlet of the extension Section No. 11.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
| 120                  | 1431 (A)                 | The third turbulent liner was added to the remaining 4.6-m (15.0-ft) Section No. 5, making the total run-up length of lined piping 13.7-m (45.0-ft).                                                                                                                                                                                                                                                                                                                                                                                                               |
| 121                  | 1431 (B-D)               | Installed orifice plate at the exit of the verification sections; that is, between Sections No. 8 and No. 9.                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| 122                  | 1432 (A-D)<br>1433 (A,B) | Changed fuel in the test supply tank from commercial grade propane to Indolene HO III clear gasoline. Removed the orifice plate.                                                                                                                                                                                                                                                                                                                                                                                                                                   |
| 123                  | 1433 (C-E)               | Installed the orifice plate between Sections No. 8 and No. 9.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |
| 124                  | 1434 (A)                 | Removed the 3.1-m (10.0-ft) test Section No. 9 and installed the two pipe tees and in-line rupture-disc test assembly as shown in Figure 8-1. Two 4137-kN/m <sup>2</sup> (600-psid) pressure-rated rupture discs were installed. Orifice plate was installed at entrance to witness Section No. 10.                                                                                                                                                                                                                                                                |

| Configu-<br>ration<br>No. | Test<br>No.            | Description                                                                                                                                                                                                                                                                                   |
|---------------------------|------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 125                       | 1434 (B)               | Rupture discs with 2068-kN/m <sup>2</sup> (300-psid) pressure rating were installed.                                                                                                                                                                                                          |
| 126                       | 1434 (C)               | Rupture discs with 690-kN/m <sup>2</sup> (100-psid) pressure rating were installed.                                                                                                                                                                                                           |
| 127                       | 1434 (D)               | Rupture discs with 345-kN/m <sup>2</sup> (50-psid) pressure rating were installed.                                                                                                                                                                                                            |
| 128                       | 1435 (A)               | Rearranged the upstream pipe tee and replaced the downstream pipe tee with a pipe elbow as shown in Figure 8-3. Installed a rupture disc with 4137-kN/m <sup>2</sup> (600-psid) pressure rating. Orifice plate remained at the entrance to witness Section No. 10.                            |
| 129                       | 1435 (B)               | Rupture disc with 2068-kN/m <sup>2</sup> (300-psid) pressure rating was installed.                                                                                                                                                                                                            |
| 130                       | 1435 (C)               | Rupture disc with 690-kN/m <sup>2</sup> (100-psid) pressure rating was installed.                                                                                                                                                                                                             |
| 131                       | 1435 (D)               | Rupture disc with 345-kN/m <sup>2</sup> (50-psid) pressure rating was installed.                                                                                                                                                                                                              |
| 132                       | 1436 (A-E)<br>1437 (A) | Removed the orifice plate from the entrance to Section No. 10 and installed the 30.5- to 15.2-cm (12-to 6-in.-) diameter pipe reducer assembly containing the Shand and Jurs arrester as shown in Figure 8-6. Installed a rupture disc with 690-kN/m <sup>2</sup> (100-psid) pressure rating. |
| 133                       | 1437 (B)               | Rupture disc with 1379-kN/m <sup>2</sup> (200-psid) pressure rating was installed.                                                                                                                                                                                                            |
| 134                       | 1437 (C)               | Rupture disc with 2068-kN/m <sup>2</sup> (300-psid) pressure rating was installed.                                                                                                                                                                                                            |
| 135                       | 1437 (D)               | Rupture disc with 4137-kN/m <sup>2</sup> (600-psid) pressure rating was installed.                                                                                                                                                                                                            |
| 136                       | 1437 (E)               | Removed the Shand and Jurs arrester and bolted the 30.5-cm- (12-in.-) diameter flanges back together with only a gasket seal. Rupture disc with 4137-kN/m <sup>2</sup> (600-psid) pressure rating installed.                                                                                  |

| Configu-<br>ration<br>No.                                                                                                             | Test<br>No.            | Description                                                                                                                                                                                                                                                                                         |
|---------------------------------------------------------------------------------------------------------------------------------------|------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 137                                                                                                                                   | 1438 (A-D)             | Replaced the 30.5- to 15.2-cm- (12- to 6-in.-) diameter pipe reducer assembly with a 25.4- to 15.2-cm- (10- to 6-in.-) diameter pipe reducer assembly containing the Amal arrester as shown in Figure 8-10. Installed a rupture disc with a 690-kN/m <sup>2</sup> (100-psid) rating.                |
| NOTE: The rupture-disc pressure rating was 690 kN/m <sup>2</sup> (100-psid) on all subsequent test assemblies unless otherwise noted. |                        |                                                                                                                                                                                                                                                                                                     |
| 138                                                                                                                                   | 1439 (A-C,             | Replaced the Amal arrester with the Whessoe 80-grade foamed metal arrester.                                                                                                                                                                                                                         |
| 139                                                                                                                                   | 1439 (D)               | Replaced the Whessoe 80-grade with a 45-grade foamed metal arrester.                                                                                                                                                                                                                                |
| 140                                                                                                                                   | 1440 (A-E)             | Replaced the 25.4- to 15.2-cm- (10- to 16-in.-) diameter pipe reducer assembly with the water-trap arrester assembly as shown in Figure 8-15.                                                                                                                                                       |
| 141                                                                                                                                   | 1440 (F)               | Removed all the water from the water-trap arrester.                                                                                                                                                                                                                                                 |
| 142                                                                                                                                   | 1441 (A-E)             | Reversed the water-trap inlet and exit ports and installed the vertical-packed bed of aluminum Ballast rings arrester as shown in Figure 8-18.                                                                                                                                                      |
| 143                                                                                                                                   | 1442 (A-E)<br>1433 (C) | Replaced the vertical-packed bed arrester with the Linde hydraulic back-pressure valve arrester as shown in Figure 8-21.                                                                                                                                                                            |
| 144                                                                                                                                   | 1442 (F)               | Removed all the water from the Linde arrester.                                                                                                                                                                                                                                                      |
| 145                                                                                                                                   | 1444 (A-B)             | Reversed all the detonation test piping from the inlet pipe tee Section No. 0 to the exit extension Section No. 11 to arrange the down-stream ignition test assembly. The Linde arrester was installed in the normal flow-through direction. Orifice plate was installed at exit of Section No. 11. |
| 146                                                                                                                                   | 1444 (C)               | Reversed hydrogen-air-spark igniter orientation by 180 degrees.                                                                                                                                                                                                                                     |
| 147                                                                                                                                   | 1444 (D)               | Removed all water from the Linde arrester.                                                                                                                                                                                                                                                          |

| Configuration<br>No. | Test<br>No.              | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         |
|----------------------|--------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 148                  | 1445 (A-F)               | Interchanged ignition Section No. 1 with stabilizer Section No. 2 and installed the orifice plate between Sections No. 1 and No. 2. as shown in Figure 9-1. Refilled the Linde arrester with water up to the gaging port.                                                                                                                                                                                                                                                                                                           |
| 149                  | 1446 (A-E)               | Replaced the Linde arrester with the water-trap arrester and filled with water to the gaging port.                                                                                                                                                                                                                                                                                                                                                                                                                                  |
| 150<br>to<br>156     | 1447<br>to<br>1449       | Removed the water-trap arrester and reassembled all the detonation test piping back to the upstream ignition arrangement so that it was identical to Configuration No. 121. Replaced the gasoline in the test fuel supply tank with chemically pure (CP) propylene.                                                                                                                                                                                                                                                                 |
| 157<br>to<br>164     | 1450<br>to<br>1449       | Various lengths of both lined and unlined piping were used during the unsuccessful measurement of air-flow pressure loss to determine pipe-wall friction factor.                                                                                                                                                                                                                                                                                                                                                                    |
| 165                  | 1458 (A-C)               | Removed the turbulent liner from Section No. 5 and cut it into required lengths for installation into Sections No. 7, No. 8, and No. 10. Provided instrumentation ports in the liners so that the ports were coincident with the flame sensor and pressure sensor locations in these sections. Reassembled all sections in the following order: No. 1, No. 2, No. 3, No. 4, No. 7, No. 8, No. 10, No. 6, No. 5, orifice plate, No. 9, and No. 11. Removed the CP propylene from the fuel supply tank and replaced it with gasoline. |
| 166                  | 1459 (A-G)               | Removed the turbulent liner from Section No. 4, cut it into required length, and installed it into Section No. 6. Reinstalled Section No. 6 between Sections No. 3 and Section No. 7. Reinstalled Section No. 4 between Sections No. 10 and No. 5 as shown in Figure 11-1.                                                                                                                                                                                                                                                          |
| 167                  | 1460 (A-F)<br>1461 (A-I) | Section No. 10 liner broke loose and jammed up into Section No. 8. The damaged liner was removed from Section No. 8 and a new liner installed into Section No. 10.                                                                                                                                                                                                                                                                                                                                                                  |

| Configuration<br>No. | Test<br>No.        | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |

| 168<br>to<br>175     | 1462<br>to<br>1469 | Various lengths of both lined and unlined piping were used during the successful measurement of air-flow pressure loss to determine pipe-wall friction factor.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
| 176                  | 1470 (A-C)         | Reassembled the detonation test shock-tube piping to the upstream ignition configuration shown in Figure 3-1. Two new expanded metal tube liners were installed into the run-up Sections No. 4 and No. 5. The liners were removed from the verification Sections No. 6, No. 7, and No. 8 and the witness Section No. 10. Installed the 30.5-cm- (12- to 6-in.-) diameter pipe reducer assembly into the test Station No. 9 as shown in the arrester test assembly, Figure 8-6. A 30.5-cm- (12-in.-) diameter by 15.2-cm- (6-in.-) long Shand and Jurs spiral-wound, crimped stainless-steel ribbon core element was installed into the arrester assembly. Replaced the two high-pressure quartz-crystal-type pressure transducers in the witness Section No. 10 (P101 and P104) with two lower-range bonded strain-gage-type pressure transducers. |
| 177                  | 1471 (A,B)         | Installed the two high-pressure quartz-crystal-type pressure transducers into verification Section No. 7 (P71 and P72).                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |
| 178                  | 1472 (A-F)         | Replaced the arrester core element with a 30.5-cm- (12-in.-) diameter by 20.3-cm- (8-in.-) long spiral-wound, crimped stainless-steel ribbon core element and high-pressure housing.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               |
| 179                  | 1473 (A-F)         | Replaced the arrester core element with a 30.5-cm- (12-in.-) diameter by 30.5-cm- (12-in.-) long spiral-wound, crimped stainless-steel ribbon core element and high-pressure housing.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
| 180                  | 1474 (A)           | Rearranged the test assembly inlet pipe tee to an in-line position with the branch line containing the rupture-disc assembly directed vertically up and eliminated the inlet pipe elbow as shown in Figure 13-7. Reinstalled the Shand and Jurs arrester test assembly containing the 30.5-cm- (12-in.-) diameter by 20.3-cm- (8-in.-) long core element.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |

| Configu-<br>ration<br>No.                                                                                                                                   | Test<br>No. | Description                                                                                                                                                                                                                                                                                                                                                                                                                      |

| 183                                                                                                                                                         | 1474 (D-F)  | Replaced the rupture-disc assembly on the inlet pipe tee of the test assembly with a blind flange.                                                                                                                                                                                                                                                                                                                               |
| 184                                                                                                                                                         | 1475 (A-F)  | Removed the Shand and Jurs arrester test assembly and installed the vertical bed of Ballast rings arrester test assembly as shown in Figure 8-18. Bed size is 43.2-cm (17-in.) in diameter by 67.5-cm (25-in.) in depth containing 2.54-cm- (1.0-in.-) diameter by 2.54-cm- (1.0-in.-) long aluminum Ballast rings. Bed depth controlled by special spacers between lower and upper grids and between upper grid and dome cover. |
| NOTE: Aluminum Ballast ring size was 2.54-cm (1.0 in.) in diameter by 2.54-cm (1.0 in.) in length on all subsequent test assemblies unless otherwise noted. |             |                                                                                                                                                                                                                                                                                                                                                                                                                                  |

| 191               | 1482 (A-H) | Changed bed size to 25.4 cm (10 in.) in diameter by 63.5 cm (25 in.) in depth containing new Ballast rings.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
| 192               | 1483 (A)   | Changed bed size to 25.4 cm (10 in.) in diameter by 45.7 cm (18 in.) in depth containing new Ballast rings.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
| 193               | 1483 (B)   | Rupture disc with 2068-kN/m <sup>2</sup> (300-psid) pressure rating installed on inlet pipe tee.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |
| 194               | 1483 (C)   | Rupture disc with 4137-kN/m <sup>2</sup> (600-psid) pressure rating installed on inlet pipe tee.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |
| 195               | 1483 (D-F) | Replaced the rupture-disc assembly on the inlet pipe tee with a blind flange.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
| 196               | 1484 (A-D) | Modified the detonation test piping installation for continuous flow as shown in Figure 14-2. Replaced the 15.2-cm- (6-in.-) diameter flow straightener at the exit of the inlet pipe tee Section No. 0 with the 25.4- to 15.2-cm- (10- to 6-in.-) diameter flanged pipe reducer arrester assembly containing a 25.4-cm- (10-in.-) diameter by 15.2-cm- (6-in.-) long Shand and Jurs spiral-wound, crimped aluminum ribbon core element mounted in a high-pressure housing. The instrumented verification Section No. 6 was replaced by the extension Section No. 11. The vertical bed arrester assembly remained installed in test Section No. 9 with a blind flange on the inlet pipe tee. The bed size remained at 25.4 cm (10 in.) in diameter by 45.7 cm (18 in.) in depth containing new Ballast rings. Two flanged 15.2-cm- (6-in.-) diameter standard pipe extension Sections No. 12 and No. 13, each 6.8 -m (22.4-ft) long, were installed at the exit of the witness Section No. 10, downstream of the gas sample rake. The instrumented verification Section No. 6 was reversed 180 degrees and installed at the exit of extension Section No. 13. In reversing Section No. 6, instrument ports |

| Configu-<br>ration<br>No. | Test<br>No. | Description                                                                                                                                                                                                                                                                                                                               |
|---------------------------|-------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                           |             | F63 and P63 are now upstream of instrument ports F62 and P62. This change provided better protection of the flame sensors from ambient light at the pipe exit.                                                                                                                                                                            |
| 197                       | 1485 (A-D)  | Replaced the bed with new Ballast rings.                                                                                                                                                                                                                                                                                                  |
| 198                       | 1486 (A-D)  | Replaced the vertical bed arrester test assembly with the Shand and Jurs 30.5-cm- (12-in.-) diameter by 20.3-cm-(8-in.-) long spiral-wound, crimped stainless-steel ribbon arrester test assembly using the inline pipe tee connection with the rupture-disc assembly replaced by a blind flange in a configuration identical to No. 183. |
| 199                       | 1487 (A-D)  | Removed the Shand and Jurs arrester assembly to straighten and repair cracked welds in the downstream retainer grid ring. Reversed the upstream and downstream retainer grid rings and reinstalled the Shand and Jurs arrester test assembly.                                                                                             |
| 200                       | 1487 (E)    | Removed the Shand and Jurs arrester assembly and bolted the 30.5-cm- (12-in.-) diameter flanges together without an arrester.                                                                                                                                                                                                             |

<sup>a</sup>VA values given in parentheses are the air flow velocities at the time DPA measurements were taken. Flow velocity at the time of ignition was zero.

<sup>b</sup>The dash signifies the lack of an event.

<sup>a</sup>VA values given in parentheses are the air flow velocities at the time DPA measurements were taken. Flow velocity at the time of ignition was zero.

<sup>b</sup>The dash signifies the lack of an event.
