SECURITY CLASSIFICATION OF THIS PAGE(When Data Entered)

The Predetection Combiner (PDC) developed under this effort accepts one to four 70 MHz input diversity signals and provides a combined signal output at three delay values shifted 1/2 QPSK symbol length from each other. These three combined diversity signals are inputs to the MD-918 modem tapped-delay line in the Adaptive Forward Dqualizer. The purpose of the factory tests was to evaluate the PDC operation and its interface with the MD-918 troposcatter modem. Some of the specific measurement objectives of the test program included:

Measurement of the PDC combining performance with no diversity inputs to the MD-918 modem. The PDC performance for up to four diversity inputs was compared with the MD-918 performance. No substantial differences resulted.

Measurement of PDC operation in conjunction with MD-918 diversity combining. Joint operation was compared with MD-918 and PDC operation alone. No substantial differences resulted.

Calibration of the PDC Correlation Coefficient Analyzer.

A field test of the concept of angle diversity as implemented with a vertical splay of beams spaced approximately one beamwidth apart.

SECTION 1

TEST REPORT

1.0 Introduction

This is the test report for the Adaptive Antenna Control Program (Contract No. DAAB07-76-C-8085). The program is under the management of the U.S. Army Communications Systems Command, and monitored by the U.S. Army Communications R&D Command, both of Fort Monmouth, New Jersey. SIGNATRON, Inc. and RF Systems, Inc. (as antenna subcontractor) had the responsibility for executing the program tasks. This report summarizes these tasks and includes the results of the factory and field test phases.

1.1 Background

The Defense Communications Agency (DCA) and the military departments are upgrading the troposcatter links in the Defense Communications System (DCS). Current attention is focused on DCS links in Europe. NATO is also contemplating an upgrade of the troposcatter links in its ACE-High system. Current planning for DCS troposcatter links calls for all digital traffic to meet the criteria set forth in the Defense Communications Engineering Center's Technical Report No. 12-76, "DCS Digital Transmission System Performance". The upgrade effort is complicated by a need to reduce frequency assignments and conserve spectrum bandwidth.

In response to DCA tasking for a solution to the problem, the Depart. of Army sponsored an investigation which chose angle diversity as a promising technique to combat short term fading and alleviate aperture-to-medium coupling loss without expanding current usage of the frequency spectrum. The effort consisted of three phases: the study phase, the equipment development phase, and the link test and data evaluation phase.

1.1.1 Study Phase

The study phase involved the specification of the system parameters, the development of various mathematical models, and prediction of angle diversity performance on various links. Documents describing the study phase are Interim Technical Report [1.1], Second Interim Technical Report [1.2], and Final Report [1.3].

1.1.2 Equipment Development Phase

The equipment developed for the field test phase consist of:

1. Two C-band angle diversity feedhorns.
2. A Pre-Detection Combiner (PDC) to augment one of two MD-918 modems allowing up to 8 diversity operation.

The feedhorns were developed, factory and field tested by RF Systems, Inc. The final report prepared by RF Systems describes the feedhorns and gives the results of those tests. It can be found in Appendix A.

The Pre-Detection Combiner was developed by SIGNATRON, Inc. In order to interface with the PDC, one of the MD-918 modems [1.4] (S/N 008) was modified. The PDC also contains a

correlation coefficient analyzer for measuring the envelope process correlation coefficient between any two diversities. The PDC, the modifications to the MD-918, and the operation of the correlation coefficient analyzer are discussed in the Pre-detection Combiner Operating and Maintenance Manual [1.5].

Factory tests were made to establish the performance of the PDC/MD-918 combination. These tests are described in Section 2.

1.1.3 Link Test Phase

Field testing of the feedhorns was done by RF Systems in July 1977. Field testing by SIGNATRON including channel and bit error rate measurement covered the period from September 1977 to May 1978. The testing was done on the RADC C-band troposcatter link. The link, the test set-up, and the field tests are described in Section 3.

In addition to the field tests from September 1977 to May 1978, resident test site personnel took channel data intermittently from November 1978 to October 1979.

1.2 Reliability Analysis

A reliability analysis for the Pre-Detection Combiner is included as Appendix J.

SECTION 2

PREDETECTION COMBINER - FACTORY TESTS

2.0 Introduction

The Predetection Combiner (PDC) accepts one to four 70 MHz input diversity signals and provides a combined signal output at three delay values shifted $1/2$ QPSK symbol length from each other. These three combined diversity signals are inputs to the MD-918 modem tapped-delay line in the Adaptive Forward Equalizer. The purpose of the factory tests was to evaluate the PDC operation and its interface with the MD-918 tropo-scatter modem. Some of the specific measurement objectives of the test program included:

- Measurement of the PDC combining performance with no diversity inputs to the MD-918 modem. The PDC performance for up to four diversity inputs was compared with MD-918 performance. No substantial differences resulted.
- Measurement of PDC operation in conjunction with MD-918 diversity combining. Joint operation was compared with MD-918 and PDC operation alone. No substantial differences resulted.
- Calibration of the PDC Correlation Coefficient Analyzer.

2.1 Bit Error Rate Testing

Performance tests included measurement of bit error rate on a non-fading channel and measurement of average bit error rate on both flat fading and multipath spread fading channels. The non-fading tests were performed for each diversity vs. the abscissa value of bit energy per noise spectral density, E_b/N_o . This quantity is also expressable as

$$\frac{E_b}{N_o} = \frac{P_{AV}}{N_o R}$$

which represents the ratio of average signal power P_{AV} to the noise power in the bit rate (R) bandwidth. Figure 2.1 shows the ideal non-fading performance, viz.,

$$p = \frac{1}{2} \operatorname{erfc} \sqrt{E_b/N_o} ,$$

and the typical MD-918 non-fading performance. The set-up for all the bit error rate tests is shown in Figure 2.2. The tropo simulator was a SIGNATRON S-139C, which generates four independent diversity channels. This limited testing to four orders of diversity or less.

The type and sequence of tests is outlined in Table 2.1. The sequence of tests shown in Table 2.1 was first performed at 12.6 Mb/s; the data rate was then changed to 6.3 Mb/s, and the test sequence repeated. The selected value of rms Doppler spread for the tests was 5 Hz since this choice reduces

measurement time and is also consistent with maximum expected rms Doppler values for the C-band RADC link. Spot checks of fading performance at 1 Hz were used to verify the absence of any speed dependencies. All fading tests were initiated using the simulator reset button to provide repeatable measurements and to allow system comparisons.

Typical data sheets for non-fading, flat fading, C-Band fading and L-Band fading form Figures 2.3, 2.4, 2.5 and 2.6, respectively. A typical plot of performance is shown in Figure 2.7. The abscissa value, average bit energy divided by noise spectral density for all beams, is equal to the average signal power for all beams divided by the noise power in the bit rate bandwidth.

Two path models were selected for the multipath fading tests at 6.3 and 12.6 Mb/s. A natural first choice was the C-band test link at RADC upon which the field tests were to take place. A DCS L-band link was selected for the other path model. The characteristics of these links are summarized in Table 2.2 and Table 2.3.

The multipath profiles for both the main and elevated beams, the squint loss of the elevated beam, and the normalized correlation coefficient between beams have been calculated for these path models. Because the troposcatter simulator utilizes independent diversity channels, simulation of the angle diversity configurations approximated the actual situation by using independent diversities but with an increased squint loss to account for the correlation. The asymptotic (large signal-to-noise ratio and flat fading) loss due to correlation

between diversities is equivalent to an increase in the squint loss of $1 - \rho^2$ where ρ is the noarmalized correlation coefficient between beams. We defined the equivalent squint loss S_{eq} as the sum in dB of the squint loss S_L and the correlation loss, i.e.,

$$S_{eq} = S_L - 10 \text{ LOG } (1 - \rho^2).$$

In the simulation, S_{eq} was used as the loss factor for the elevated beam diversities. This choice of squint loss to account for correlation between diversities is pessimistic at lower values of SNR but is adequate for purposes of evaluating PDC and MD-918 modem operation.

The 2σ values for the simulated profiles, correlation coefficients, and squint losses for these two path models are summarized in Table 2.3. The simulator attenuator settings given in Table 2.3 do not include the equivalent squint loss in the elevated beam. The power correction factor (PCF) is the additional multipath power which must be included in the computation of average bit energy E_b . We define the noise power at the simulator output measured in the bit rate bandwidth as $N_o R$ and the average signal power for one tap output with an attenuator setting of 0 dB as P_s . The mean SNR expressed as the ratio of average bit energy to noise power in a 1 Hz bandwidth is equal to

$$\text{SNR} = 10 \text{ LOG } (\bar{E}_b / N_o) = 10 \text{ LOG } (P_s / N_o R) + \text{PCF}$$

where the power correction factor accounts for the additional power from other simulator taps. The simulator was calibrated and the noise power at the simulator was checked with a noise-bandwidth calibrated filter.

The predicted performance curves for the MD-918 modem/PDC combination for these two links and the two data rates 6.3 and 12.6 Mb/s are shown in Figures 2.8 through 2.11. The predicted performance includes the correlation effect. The use of S_{eq} to approximate the correlation effect is slightly pessimistic because it represents an asymptotic case. Thus, all other effects being equal, the measured results should be slightly poorer than the predicted results. However the effect of this pessimistic approximation is only a fraction of a dB, which is less than the prediction accuracy (a few dB) and the measurement accuracy (± 1 dB).

Appendix B contains plots of the data taken for the various configurations of Table 2.1.

2.2 Correlation Coefficient Analyzer (CCA)

The test set-up for assessing the performance of the correlation coefficient analyzer of the PDC is shown in Figure 2.1.2. The diversity A output is split. One splitter output feeds CCA input port #1, the other feeds attenuator A. Diversity B is attenuated by 3 dB (to match the loss of the splitter), then feeds attenuator B. The attenuator outputs are summed to form the input to CCA port #2.

By controlling the A and B attenuators, the correlation between A and C (inputs 1 and 2) can be controlled. The calculated correlation coefficient (ρ_{calc}) is generated according to the formula appearing in the figure.

Several runs were then made comparing the actual coefficients obtained with the calculated coefficient. This data is in Appendix C. Figure 2.13 is a plot of ρ_{meas} vs. ρ_{calc} .

2.3 Results of Factory Tests

The data indicated successful operation of the MD-918/PDC combination for up to four diversities. The correlation coefficient analyzer was shown to function.

Fig. 2.13 Measured vs. Calculated Correlation Coefficient

SECTION 3

FIELD TESTS

3.1 Link Description

The RADC troposcatter test link between Youngstown and Verona, N.Y. is a 168 statute mile path operating in a dual space/dual frequency (2S/2F) configuration using 28 foot parabolic reflectors. The radio system has the military designation AN/TRC-132A. Figure 3.1 shows the link path profile. Figure 3.2 shows the link geometry for the angle diversity configuration.

Since all the data collection apparatus is located at Verona, operation was simplex, with Verona as the receive site.

3.1.1 Youngstown

The transmitter at Youngstown, N.Y. is assigned 4500 and 4690 MHz and is capable of transmitting 10 Kw at each of these two frequencies. However, for broadband test purposes, the transmitter has been tuned to a 1 dB bandwidth of approximately 10 MHz and an output power of 2 to 4 Kw. Figure 3.3 shows the frequency responses of the broadbanded reduced power transmitters.

Stable transmit and receive local oscillators are required for RAKE and digital transmission. Figure 3.4 shows the local oscillator chain used for the tests. This method, also employed for the receiver local oscillators, results in a received frequency error on the order of a few Hertz.

Fig. 3.1 Youngstown-Verona Path Profile

Fig. 3.2 Test Link Geometry

Fig. 3.3 AN/TRC-132A Transmitter Frequency Response

Fig. 3.4 Modified Local Oscillator Chain (Youngstown)

3.1.2 Verona Description

As normally configured, the Verona site is set up for 2S/2F reception. Therefore, an additional four receivers, two circulators, one TRC-132A van, and four additional LEL's were obtained and an interconnecting shelter was constructed between the two TRC-132A vans.

Figure 3.5 shows the antennas, vans and shelter. The receivers were modified to have 3 dB bandwidths of approximately 20 MHz. The AN/TRC-132A local oscillators were replaced with the configuration shown in Figure 3.6. Eight receiver output cables are run from the shelter to LAB 2 (where the data collection equipment is located); a 1 MHz reference is run from LAB 2 to the shelter. A telephone line allows communication between the shelter and LAB 2.

Figure 3.7 shows the data collection equipment in LAB 2. Each receiver cable from the shed feeds a splitter. One output of each splitter is filtered (to approximately the bit-rate bandwidth) then drives an LEL. The LEL's convert the 70 MHz IF signals to D-C voltages proportional to the log of the amplitude of the 70 MHz inputs. These D-C voltages are the inputs to the A/D converters in the NOVA computer.

The computer samples this data, comparing the input voltages with voltages corresponding to known received powers, and outputs received signal level (RSL) and fade rate (FR) for each receiver. The output device is a teletype, which is also used to input such parameters as number of receivers and length of test.

Calibration was done daily and almost always in the morning. The procedure required the use of a C-band signal generator, frequency counter, and a power meter.

Fig. 3.5 Modified TRC-132A Receiver Set-up

Fig. 3.6 Modified TRC-132A Local Oscillator Chain (Verona)

Fig. 3.7 Lab 2 Data Acquisition Set-up

The procedure also required two persons: one in the shelter and one in LAB 2 at the calibration console. The signal generator is set for frequency and its output attenuator dial checked for calibration with the power meter.

Tones (4500 and 4690) are then fed into the receivers at the following amplitudes: -110, -105, 100, -95, -90, -85, -80, -75 and -70 dBm. For each tone amplitude, a proportional d-c level is fed to the calibration system. At each level, a d-c voltage is set via a potentiometer, to "store" that voltage for the computer. This is accomplished by seeking a null on a meter that is part of the calibration console. There are 9 test levels per receiver x 8 receivers = 72 separate potentiometers to adjust.

The RAKE is a channel prober, used for making multipath spread measurements of two diversities simultaneously. It also gives the 'mean path delay' for each diversity, useful for assessing the additional delay encountered by the elevated beam. Cables are run to the RAKE from the splitter rack when needed.

The correlation coefficient analyzer was also accessed by connecting cables to the appropriate splitter.

The modems (MD-918 and MD-918/PDC) were also set up for the various configurations by moving cables around. Two modems were used to allow simultaneous testing of different configurations; specifically comparison of conventional systems against systems augmented with angle diversity.

3.1.2.1 Bit Error Rate-Related Changes

In an attempt to equalize the mean path delays of the main and elevated beam signals, delay cables were inserted at the main beam receiver outputs. Original estimates indicated a delay difference of 180 ns. This delay was reconsidered after some channel data was accumulated and the cable was shortened to a delay of 88 ns.

The receivers in the AN/TRC-132A did not have equal or near equal gain. Therefore, attenuators were inserted after the appropriate splitters so that a given input level to any of the receivers resulted in the same power level at the modem inputs.

Gain equalization is required in order to maintain the relationship between received signal power and signal-to-noise ratio. When this relationship is distorted by a sufficient amount (~10 dB) degradations due to limited dynamic range in the equalizer result.

Delay equalization is required to relieve the MD-918 adaptive equalizer of the burden of dealing with the mean delay difference between diversities.

3.1.3 Receiver Noise Figure

The four TRC-132A receivers and the additional four GFE receivers were measured for noise figure at the beginning of the field test and at least twice a month thereafter. Noise figure measurements provide the means to accurately convert received signal level values into signal-to-noise ratio.

The measurements were performed using a filter whose noise bandwidth has been calibrated by SIGNATRON. This filter is used to calibrate the noise sources in the troposcatter simulator. The test set-up for measuring noise figure is shown in Figure 3.8. A calibrated signal generator is connected to the RF receiver under measurement and the frequency tuned to the receiver midband. The input level is set to a high but non-overdriving level. The input and output powers P_{IN} and P_{OUT} in dBm are recorded. The input to the RF receiver is then terminated and the noise power P_N at the calibrated filter output is measured. The SNR at the input is defined as

$$SNR_{IN} = P_{IN} - 174 + 10 \text{ LOG } (B_N) \text{ dB}$$

where B_N is the noise bandwidth of the calibrated filter. The SNR at the filter output is

$$SNR_{OUT} = P_{OUT} - P_N \text{ dB.}$$

The noise figure of the receiver is the loss in signal-to-noise ratio, i.e.,

$$NF = SNR_{IN} - SNR_{OUT} \text{ dB.}$$

STEP 1: $GAIN_{RCVR} = (POWER\ OUT) - (POWER\ IN) - (GAIN\ OF\ TEST\ FIXTURE) + (PADS)$

STEP 2: $INPUT\ NOISE = ((POWER\ OUT) + (RCVR\ GAIN) + (GAIN\ OF\ TEST\ FIXTURE) - (PADS))$

(NORMALLY NO
PADDING DURING
THIS STEP)

$NOISE\ FIGURE = INPUT\ NOISE - NOISE\ FLOOR$

$NOISE\ FLOOR = -174\ dBm/Hz + 60\ Hz/MHz + 10.6\ dBm/MHz = -103.4\ dBm/MHz$

NOISE EQUIV. BANDWIDTH
OF TEST FIXTURE

Fig. 3.8 Noise Figure Measurement Procedure

These measurements and calculations of NF were performed for each of the eight receivers.

3.2 Data Taking

3.2.1 Channel Data

Channel data was taken daily (equipment and weather permitting). Channel data consisted of received signal level, fade rate, multipath spread, and correlation coefficient measurement. The RAKE can run (integrate) for slightly less than 2 minutes, or slightly less than 15 minutes. Initially, 2 minute runs were made, but resolution was poor at low signal-to-noise ratios, so 15 minute runs were instituted. A recalculation procedure was also instituted. This involved subtracting the value of the noise (defined as the level of the smallest of the 10 cells) from all the cells, then recalculating the multipath spread and mean path delays. The calculation also contained an adjustment for terminal filter characteristics.

During these runs, correlation coefficient measurements were made. For each diversity pair, several correlation measurements (each measurement takes 80 seconds) were made, and the results averaged.

A typical channel data (RSL/FR/MS) sheet is shown in Figure 3.9. A typical correlation coefficient sheet is shown in Figure 3.10.

Fig. 3.10 Typical Correlation Coefficient Data Sheet

Since each channel run took ≈ 20 minutes (15 minutes plus input and output time, plus time to change cables to the RAKE), and Youngstown had to be called to change RAKE frequency half-way through the set of runs, channel data usually took 90 minutes to 2 hours. Calibration took an hour typically. Calibration was done daily, channel data was taken twice daily.

3.2.2 Bit Error Rate

The remainder of each test day was devoted to Bit Error Rate measurements. Configurations tested (at 6 Mb/sec) are shown in Table 3.1.

Bit Error Rate data was taken with the set up shown in Figure 3.7. At Youngstown, a PRN sequence is generated, transmitted, received at Verona, recovered by the modem and compared to the original sequence by means of an SDS box (which stands for Source Data Simulator, but it is also used as a Source Data Comparator and Error Detector). This box compares the recovered data with the sequence it knows was sent, outputting an error every time a difference is detected.

A typical BER data sheet is shown in Figure 3.11.

3.3 Antenna Adjustment

The following procedure was used for antenna adjustment. First, alignment in azimuth was performed by a $R\Omega$ maximization procedure. Elevation adjustment was accomplished according to the following criteria: the main beam at Verona is maximized by observing the RSL at Verona. Youngstown is then lowered until earth blockage decreases the RSL's at Verona, then raised slightly. A second or third iteration at Verona and Youngstown is then used to verify that the joint optimum has been found.

Fig. 3.11 Typical Bit Error Rate Data Sheet

A problem with this procedure was observed early on. On any given day inhomogenities in the atmosphere can result in stronger signals from the higher angles than lower angles. Thus main-beam maximization can cause the main beam to be pointed way up in the air. Final elevation adjustment requires the optimization procedure described above to be repeated on different days. The minimum pointing angles determined in this series of experiments are selected as those corresponding to homogenous conditions, would place the beams slightly above the horizon.

It is important to use this iterative procedure to aim the antennas, since operation will normally be duplex and the transmitted beams should be pointed just above the horizon.

3.4 Additional Tests

In quad angle diversity (2S/2A) set-ups, reception is on one frequency. This leaves a power amplifier and dish at the transmit end idle. If a link were to employ angle diversity, both transmitters would be tuned to the same frequency, giving a 3 dB boost in power. In order to check for any problems with two side-by-side dishes transmitting on the same frequency, Youngstown retuned the 4.5 GHz power amplifier to 4.69 GHz and tests of bit error rate, with and without the additional P.A., were made.

Also, the angle diversity feedhorns were tested for isolation by turning on one of the Verona transmitters (only one was operational) and taking bit error rate measurements.

On March 28, 29, 30 channel data was taken for 8 hours each day.

These tests are discussed in Section 4.

3.5 Down Time

Data collection on a daily basis was not possible. Most problems were equipment-related, though operator error made re-calibration necessary on several occasions.

From September thru early October 1977, tests were confined to quad diversity, as the additional four receivers and two circulators had not arrived. The first weeks were used for set-up, provision of sufficient L.O. power, noise figure tests, gain equalization, removal of oscillations in the (previously) broad-banded IF strips, and activation of the RAKE.

Early tests were impaired by two problems at Youngstown. The first was faulty operation of an SDS card, the second was related to the local oscillator scheme. Communication with Youngstown caused several synthesizer changes, to no avail. A trip to Youngstown to deliver an SDS box (related to the first problem) led to an alternate scheme for locking the synthesizers to the 1 MHz standard. This alteratate scheme solved the problem.

There was a failure of a PDC card in mid-October, and failures of the teletype.

Some time was spent investigating receiver 3 (Ant. #2, Main, 4.69 GHz), which had a reduced RSL (relative to the other main beams). No explanation was found.

The link was unavailable during late October. In early November, testing was resumed. The new receivers were installed. Noise figures were taken.

In early November, the first look at the angle diversity beams was available. This led to some confusion, as the statistical nature of the squint loss was not fully recognized. A long series of antenna adjustment exercises ensued, until the adjustment criteria of Section 3.3 was adopted.

During this time period, various methods of determining the proper length of the delay equalization cable were tried. One involved a series of bit error rate measurements with various lengths. The results were not clear, as any variations in the bit error rate were obscured by the changing channel, (also, the MD-918 is capable, within limits, of adjusting to the differential delay). Another method involved running one modem on the main beams, and one modem on elevated beams, then viewing the 'eyes' of the two modems. The relative location of data transitions was viewed, and the elevated beam could be observed to move over a range of ≈ 100 nanoseconds, at a rate comparable to the fading of the channel. It became apparent that an accumulation of rake data, to evaluate the relative delay on a statistical basis, was necessary, as mentioned in Section 3.1.2.1.

By mid-December, testing on a regular basis began. In late December, a metal plate, part of the adjustment mechanism on one of the TRC-132A dishes was broken. This caused no immediate problem, but by late January, it became apparent that this dish (Antenna #1) had moved (down and to the right) due to the broken plate. Reception on this dish was degraded 3 to 5dB. The plate was repaired in mid-February, and the antenna re-aligned.

In early January, a heat exchanger pump failed at Youngstown, causing operation to be limited to 4.69 GHz. The teletype also failed again, reducing operation to SLVTS. Both the teletype and the 4.5 GHz P.A. were down for approximately two weeks.

The high winter path loss resulted in many days of unuse-ably weak signals. Also, the civilian contractor was stranded in Boston during - and after - a blizzard in February, 1978.

There were a few power failures (or deliberate interruptions for repair work) which forced recalibration after power was resumed.

March was a fairly successful month. In early April, the switch to 12 Mb/s was made and data taking became erratic as the civilian operator concentrated on various tests, re-configurations and measurements to attempt to isolate the 12 Mb/s problem. These tests are mentioned in Section 5.

SIGNATRON testing ended in late May.

SECTION 4

TEST DATA

4.1 Channel Data

The data accumulated in this program was entered into computer files for processing. All channel data presented here (except correlation coefficient) was obtained by taking only one sample per 6 hour period.

Figure 4.1 shows the distributions of the composite received signal levels for:

- (1) the main beams (receivers 0,1,2,3)
- (2) the 2S/2A configurations to which 3dB has been added to simulate an additional power amplifier.

This figure is critical in assessing the viability of angle diversity as an alternate to frequency diversity. The implications of these results are discussed more fully in the Final Report [1.3].

Figure 4.2 shows the distributions of the received signal levels for the individual receivers. Figure 4.3 shows the distributions of the squint loss for the four space/angle pairs.

Figures 4.4, 4.5, 4.6, and 4.7 are the multipath spreads and normalized delays for the four space/angle pairs. Note that the median of the path delays indicate that 88 n sec was a good estimate of the length of the delay equalization cable. Also note that the elevated beams have larger multipath spreads, as is expected with a larger common volume.

Figure 4.8 gives the distributions of the composite fade rates of the main beams (receivers 0,1,2,3) and the elevated beams (receivers 4,5,6,7).

PROBABILITY MULTIPATH SPREAD OR RELATIVE DELAY EXCEEDS ORDINATE

Fig. 4.7 Multipath Spreads and Relative Delay, Space Angle Part 3/7

Fig. 4.8 Composite RMS Doppler Spreads

Figure 4.9 gives the distributions of the correlation coefficients for the space/angle pairs, and the distribution of the correlation coefficients between main beams of the same frequency, or different (crossed) frequencies.

SIGNATRON does not have confidence in the correlation coefficient data. Approximately 30% of the individual measurements had to be discarded as not physically possible (magnitude greater than 1, and/or roots of negative numbers). A test of the correlation coefficient between the noise output from two receivers indicated a correlation coefficient of 1, when it should have been 0. On the basis of 30% bad tests, noise correlation coefficient of 1, and the fact that the calibration of the analyzer was done in the absence of noise, SIGNATRON advises against making conclusions on the basis of this data.

4.2 Bit Error Rates

Due to the degraded data at 12 Mb/s, only the 6 Mb/sec bit error rate data was entered. Figures 4.10, 4.11, 4.12 and 4.13 show the configurations 2S/2F, 2S/2A 4.69 GHz, 2S/2F vs. 2S/2A 4.5 GHz, and 2S/2F vs. 2S/2F/2A respectively, plotted against Mean Diversity $\bar{E}_b/N_o$. Figure 4.14 shows 2S/2F vs. 2S/2F/2A plotted against Mean Main Beam diversity $\bar{E}_b/N_o$. The quad diversity data indicates that the modems have no trouble with the delay difference or increased multipath spread of the elevated beam.

The 2S/2F/2A data is worse than the prediction by 2 - 3 dB. This configuration could not be factory tested, and there may have been some diversity combining loss.

Figure 4.15 shows 2S/2F vs. 2S/2A 4.50 GHz, with 2S/2A 4.69 GHz, all plotted against main beam path loss.

Fig. 4.15 Quad Diversity Configurations Plotted Against Main Beam Path Loss

4.3 Additional Tests

1. Three days continuous data.

This consisted of channel data taken all day for three consecutive days. The dates were March 28, 29 and 30, 1978. This data is included of the RSL and Correlation Coefficient Appendix.

2. Co-located transmitter test.

This test consisted of firing up one of the Verona Power Amplifiers and taking alternate bit error rate measurements with the P.A. on and off. The results are shown in Figure 4.16. No degradation is visible.

3. Two P.A.'s on the same frequency.

For this test, Youngstown retuned one of the P.A.'s to 4690. Bit error rate measurements with (alternately) one P.A. and two P.A.'s were made. Figure 4.17 shows this data.

SECTION 5
DEGRADATION AT 12.6 Mb/sec

Change-over to 12.6 Mb/sec was executed in early March. Problems were immediately evident, as expected error rate performance was not obtained.

During March, the S139B Troposcatter Simulator (100 ns tap spacing) was available for checking modem performance. For a period of about one week at the end of March, the SIGNATRON operator could not get good performance. Personnel from Sylvania arrived at the end of March, and solved the problem. The Sylvania trip report appears in Appendix H.

During April, the tunnel diode amplifier bias voltage for all 8 receivers was adjusted for flat response across C-Band. (Figure 5.1 shows data for one of the tunnel diode amplifiers.) The receivers were also swept (Figure 5.2).

The test set-up of Figure 5.3 was used to pass a pulse through the receivers to look for delay distortion. The pulse was only slightly smeared (this is a subjective judgement).

Delay from receiver input to shelter cable ends was measured for the 8 receivers with the set-up of Figure 5.4. The delays were within 50 n sec of each other.

Numerous tests to verify calibration accuracy were made. The LEL's were checked for response to broad and narrow-band signals.

The circulators were by-passed and tests on one frequency run. Loss in the waveguide was measured. The tunnel diode amplifiers in the receivers were bypassed (resulting

in ≈ 11 dB noise figures). None of these steps alleviated the degradation.

In mid-May 1978 SIGNATRON and Sylvania personnel went to Youngstown to look for degradations at the transmit end. Reports by these personnel is included in Monthly Status Report #23, reproduced in Appendix I. The conclusion of these personnel is that the degradation did not originate at the transmit end, although full power tests could not be run, and inter-symbol interference at full power may exist.

Figures 5.5, 5.6 and 5.7 shows the 12 Mb/sec bit error rate data for various configurations for various time periods. 11 May was the conclusion of the trip to Youngstown.

At the end of the program, a high VSWR in the waveguide feed to one of the horns was measured. This was probably due to lack of pressurization and water leakage. The horn itself was removed and factory tested again, revealing no degraded parameters. Whether or not the high VSWR in the feed was present during the 12 Mb/sec bit error rate testing is not known. The current theories of the source of the source of the degradation are:

- (1) Nonlinear ISI due to full power klystron.
- (2) Horn leakage (between space and angle waveguide).
- (3) High waveguide VSWR.

The high VSWR could have caused some coupling between the space and angle feeds, indicating that (2) and (3) together may have been the source of the degradation.

I. INTRODUCTION

The subject Final Report summarizes the test results from the design, development and installation at the Verona, New York RADC test sites of an angle diversity feed system for the AN/TRA-39A Tropospheric Scatter Communications antennas. Included herein are pertinent data from the engineering development tests, factory tests of the final devices and test results and conclusions from the sequence of field tests.

Test procedures and the design plan for this program were previously submitted to Signatron, Inc. as part of Line Item E.6 and E.4, respectively. Please refer to these documents for background material.

II. CONCISE STATEMENT TECHNICAL REQUIREMENTS

The intent of the Antenna Feed Development Program was to design, install and test a special angle diversity feed suitable for use in the AN/TRA-39A troposcatter reflectors which would exhibit the following technical characteristics:

Frequency Range	4.4-5.0 GHz
Type	Dual aperture, high and low elevation beam
Polarization	Dual linear
Power Level	10 KW, CW
VSWR	1.3, max.
Crossover Level	3 to 4 dB nominal
Reflector Size	28 feet diameter
Reflector Focal Length	142.2 inches
Nominal Antenna Gain	49 dB at 4.4 GHz
Half-Power Beamwidth	0.6 degrees maximum
Loss of Gain in Lower Beam Compared to Existing Antenna	1 dB, maximum

III. SUMMARY OF RESULTS

The program has been successfully concluded and the test results detailed herein demonstrate that the angle diversity feed does meet the technical requirements summarized above.

IV. FINAL FEED DESIGN

Figures 1-3 show photographs of the final angle diversity feed. The physical design utilizes two dual-mode, two-port feeds arranged one above the other. The vertical spacing is 1.85 inches, center-to-center. Each aperture is 1.600 inches square.

Close spacing of simple square radiating apertures does not result in useable primary feed patterns; therefore, compensating devices near the aperture are required. In the present example these devices take the form of a slow-wave structure consisting of a set of metal fins or corrugations adjacent to the aperture edge. These are supported by a circular metal plate.

In addition, a pair of U-shaped metal straps are added to further shape the primary pattern. The corrugations and the straps reduce the current density outside the aperture, thereby reducing the excessive amplitude ripple and improving the symmetry and reducing the spillover of the patterns.

Tuning screws are added to the feeds and are located just inside each aperture. They improve the VSWR and reduce the coupling from one aperture to the other. Four screws are used per aperture; they are located at different distances from the aperture to optimize the isolation for the two different polarizations.

The four ports on the feed are designated S_h , S_v , A_v and A_h , respectively, from the top to the bottom of the feed. (The A_v and A_h ports are the ones with the integral waveguide bends attached.)

The feed is constructed of aluminum alloy; the fabricated circular plate and fins are dip brazed to investment cast horns with formed waveguide sections attached.

A radome constructed of epoxy fiberglass laminate is added to seal the aperture. It is a thin wall spherical shell, and the entire assembly is pressure tight to 5 psig pressure. Input waveguide flanges are standard UG-507/U cover flanges.

The development of the feed also required that a new set of supporting struts be fabricated to replace existing struts on the AN/TRA-39A antenna. These were fabricated of aluminum alloy and are pinned in place using existing attachment hardware.

IV. FINAL FEED DESIGN (Continued)

New WR187 waveguide was also supplied to replace the existing waveguide on the AN/TRA-39A reflector, and new waveguide was added for a third transmission line connecting additional microwave receivers located near the existing ones. Test data for these waveguides is included in this report.

Per instructions by Signatron personnel, this third waveguide run was connected to the A_v port. The A_h port was capped with a pressure-tight cover. The waveguide brackets on the lower spar are such, however, that this third waveguide may be attached to the A_h port instead by adjusting the bracket attachment hardware.

The assembly drawing of the final feed (R F Systems #843253) is shown in Figure 68.

V. DISCUSSION OF TEST RESULTS - FACTORY AND DEVELOPMENT TESTS

(a) Feed VSWR

Figures 4-11 show measured swept frequency VSWR measurements of the feed. The data is taken over the 4.4-5.0 GHz frequency range and for all four ports of the two serial numbered feeds. The tabulation of results in Figure 36 shows that the maximum VSWR did not exceed 1.24, thus meeting the requirement for a maximum 1.3 VSWR.

(b) Feed Isolation

Figures 12-23 show the measured swept frequency isolation (coupling) measurements of the feed. This data was swept over the 4.4-5.0 GHz frequency for all combinations of ports. The tabulation of results in Figure 36 shows that the minimum isolation was 19.4 dB for the vertical-vertical ports (A_v-S_v) and 19.5 dB for the horizontal-horizontal ports (A_h-S_h). The remaining ports were all orthogonally polarized and hence exhibited much better isolations (typically better than 35 dB).

The development effort had as one of its tasks the improvement of the vertical-vertical and horizontal-horizontal isolation. It is believed that the values of approximately 20 dB for these ports represent the best attainable results for such a relatively simple four-port angle diversity feed operating over a broad frequency band. In many strategic troposcatter communications systems, however, the frequencies of operation are well established at each site, and tuning the antennas for optimum VSWR and isolation is logistically possible. In this case, the achievable isolation in a relatively narrow operating frequency band (e.g. 50 MHz or 1%) can be as much as 30 dB for the vertical-vertical and horizontal-horizontal ports.

V. DISCUSSION OF TEST RESULTS (Continued)

(c) Primary Feed Patterns

Measured primary feed patterns are shown in Figures 24-35. They were measured at 4.4, 4.7 and 5.0 GHz in the elevation and azimuth planes and for vertical and horizontal polarizations. The pattern summary shown in Figure 36 tabulates the measured reflector edge intensities (including 2.9 dB of "space" attenuation to take into account the longer path length to the edge of the AN/TRA-39A reflector).

The summary shows that the measured edge intensities lie within the range for optimum antenna gain and low sidelobes. Figure 64, "Characteristics of Circular Apertures", demonstrates this. In addition, the lack of significant amplitude ripple on the patterns shows that the illumination of the antenna will be adequate.

(d) Primary Feed Phase Center Measurements

The angle diversity feed was set up on a short antenna test range in such a way that the feed could be translated in three axes about the center of rotation of the antenna positioner. A phase bridge consisting of a local oscillator, two mixers and a Hewlett-Packard Vector Voltmeter was established to measure the relative phase of the signal received by the feed. This phase information was recorded on an X-Y recorder as a function of the angle to the feed. The feed was then translated so as to minimize the deviation from a uniform phase envelope when the feed was rotated through a total of ± 65 degrees. The position of the feed in relation to the center of rotation was then noted; this is the phase center of the feed. This measurement was done in the elevation and azimuth planes and for vertical and horizontal polarizations for 4.4, 4.7 and 5.0 GHz frequencies.

Figure 37 summarizes the phase center data. It shows that the phase is located at the horizontal (x) centerline, as expected. The phase center position in the longitudinal (z) direction varies with polarization and frequency. The variation amounts to +0.5" to -0.4". This variation will result in a quadratic phase error across the aperture of the reflector, which will cause a slight loss in antenna gain.

The magnitude of this loss can be estimated by the use of Figure 12.6 in Silver's "Microwave Antenna Theory and Design" (McGraw Hill, 1949), which computes the gain loss of a circular paraboloid when the feed is translated along the axis. Assuming that the feed is positioned so that the maximum excursion of the phase center is $\pm 0.45''$ about the focus, the resulting phase error (at 5 GHz) is $0.45/\lambda (1 - \cos 61^\circ)$, where 61° is the edge angle of the reflector. This value is 0.098 wavelengths. Figure 12.6 shows that the expected loss in gain due to this feed phase center movement is 0.18 dB.

Of special interest is the phase center position in the vertical direction (y), since this position determines the crossover level and angular spacing of the lower and upper secondary beams.

Measurements show that, for horizontal polarization, the phase center lies close to the center of the square horn aperture. However, for vertical polarization the phase center is displaced a slight distance away from the center of the horn aperture. This effect is due to the relatively tight coupling of the local fields at the common metal wall for this polarization. The horn centers are physically 1.85" apart, and the horizontally polarized phase center is 1.84" apart, while the vertically polarized phase center is 2.06" apart. Later discussion will calculate the effects on the angular spacing of the secondary beams.

(e) VSWR of Waveguide Components

All waveguide components (straight and flexible sections) were checked out for VSWR by sweeping in frequency across the 4.4-5.0 GHz band and plotting the return loss. Figure 38 summarizes the maximum VSWR of each component supplied as part of the feed system. The maximum peak VSWR was 1.07, and the median peak VSWR was 1.04.

VI. DISCUSSION OF TEST RESULTS - TESTS AT VERONA, NEW YORK

The original plan for verifying the performance of the angle diversity feed in the AN/TRA-39A reflectors was described in the Test Plan. The initial test setup utilized an RADC tower for the transmitting source located about one mile from the tropo installation. Initial measurements using this tower, however, showed that the intervening high tree line was causing severe fluctuations in the received signal. Accordingly, a substitute transmitting site was implemented in a corn field about 3500 feet from the tropo installation. This setup is shown in Figure 39.

VI. DISCUSSION OF TEST RESULTS (Continued)

A six-foot diameter transmitting antenna was installed on a pickup truck and aimed at the test antennas. The receiving equipment consisted of a calibrated microwave instrumentation receiver and a display meter. Angular rotations of the antennas were measured by a 5 minute accuracy transit affixed to the hub of each reflector and arranged so as to sight a target on a nearby antenna pedestal.

Before starting the test sequence, the transits were carefully levelled and their scales were locked. The initial angles to the target were noted for future reference as a means of re-aiming the antennas to the Great Circle azimuth and to the elevation angle of the existing units.

Starting with the right-hand antenna, a series of four radiation patterns were plotted at a frequency of 4.7 GHz. These patterns were examined to determine the correlation between the results and the expected radiation patterns described in the Technical Manual for these antennas. The right antenna patterns are shown in Figures 40-43. They indeed indicate that the half-power beamwidth and sidelobes conform closely to the expected values. This measurement also developed confidence in the quality of the 3500 foot test range.

The original AN/TRA-39A feeds were then removed and replaced with the new angle diversity feeds without disturbing the settings of the instrumentation receiver. A set of patterns (Figures 44-52) for all four ports and for both vertical and horizontal planes was then measured and the peak gain levels noted.

This entire sequence was repeated on another day for the left-hand antenna. Refer to Figures 53-63.

The Table of Figure 65 summarizes the test results for the angle diversity feeds. Included in this table is a summary of the calculated parameters resulting from the measured primary patterns and from the phase center data previously recorded. The calculated parameters were taken from the curves in Figure 64. It can be seen from a comparison of the 4.7 GHz data that the half-power beamwidths correlate well with the expected values, keeping in mind the 5 minute accuracy of the transits.

VI. DISCUSSION OF TEST RESULTS (Continued)

The first sidelobe levels are somewhat higher than calculated, although quite satisfactory for troposcatter application. The worse measured sidelobe level was -21 dB for the on-axis feed. The worst computed sidelobe was -23.5 dB. The discrepancy is undoubtedly due to a combination of slight errors in the test range and other effects, such as reflector surface tolerances and feed and feed support member aperture blockage. Neither of these latter effects were allowed for in the theoretical calculations. Since the reflector surface tolerance is not known, no estimate can be made here of this effect.

The sidelobe degradation due to the aperture blockage can be computed roughly. Assuming an 8" diameter feed, a pair of 2" diameter spars and the 2" wide waveguide run, the sidelobe degradation would amount to about 2.6 dB. This is in the order of magnitude of the degradation experienced in the field tests.

The relative beam positions in the elevation plane were examined and summarized in Figure 66. The expected shift from lower to upper beam is different for vertical and horizontal polarizations in keeping with the variation in phase center position previously measured. The expected values are 39' and 44', respectively. The measured beam shift average is 36' and 42.5', respectively. It is felt that this agreement is satisfactory in view of the 5' accuracy of the transit.

The crossover levels resulting from the intersection of the two beams in the elevation plane are summarized in Figure 67. The calculated crossover levels are 4.0 and 5.7 dB for vertical and horizontal polarization, respectively, and the measurements show that they averaged 3.4 and 5.5 dB, respectively. Again, the agreement is felt to be satisfactory.

Accurate record was kept of the received signal level at the peak of the beam during the course of the measurements. A signal monitor was employed at the transmitting site to detect variations in transmitting power during the period of measurement.

Figure 67 summarizes the difference in gain for the elevated and lower beams for the right and left antennas and for both vertical and horizontal polarizations as compared to the gain of the original AN/TRA-39A antenna.

VI. DISCUSSION OF TEST RESULTS (Continued)

The average of the gain differences for the lower beam compared to the original is -0.3 dB. The averages of the gain differences for all beams compared to the original is -0.15 dB.

The conclusion is that the measured gain differences resulting from the installation of the new angle diversity feed did not exceed the specification limit of 1 dB. More probably, the actual gain is unchanged in view of the estimated measurement accuracy of ± 0.5 dB.

Following the radiation pattern tests, the antennas were reset to the original Great Circle azimuths and to the original elevation angles using the transits. The transits were left fixed to the reflectors for future use and were left locked to the original reference positions.

Figure 67 tabulates these reference angles so that, if necessary, the antennas can be re-aimed at a future date.

VII. APPLICATION OF ANGLE DIVERSITY FEED TO OTHER ANTENNAS

In light of the successful design procedure and verification of the 4.4-5.0 GHz feed in the 28 foot diameter reflector, an examination of the feasibility of modifying other tropo reflectors may be productive. Also, the feasibility of accomplishing this in different frequency bands is of interest.

The present feedhorn is designed for illumination of a circularly symmetrical paraboloid having an f/D ratio of 0.42. It can be applied without modification to other reflectors if they have f/D ratios in the range of 0.40 to 0.45. This will preserve the present edge intensities within a tolerance of ± 1 dB and will have a minor effect on far field gain, beamwidth sidelobe levels and crossover levels.

There is a minimum reflector diameter below which the relatively large size of the angle diversity feed presents problems with aperture blockage. To evaluate this, an estimate is made of the size of the feed in various frequency bands by scaling the existing feed. Then an estimate is made of the sizes of the support spars for the feed and the sizes of the waveguide or coaxial transmission line which will be required to carry the RF signal. A criteria is decided upon to limit the total permissible aperture blockage. This criteria is taken to be the requirement for a maximum sidelobe level of -20 dB.

VII. APPLICATION OF ANGLE DIVERSITY FEED TO OTHER ANTENNAS (Continued)

The calculations on Table VII summarize these results. In the lower tropo frequency band, coaxial transmission line is used with waveguide employed in the higher microwave bands.

The conclusions are that the present angle diversity feed will be suitable for reflector diameters down to about 45 feed in the 755-985 MHz frequency band if coaxial line is used as a feeder.

There is no further restriction on the application of this feed other than to limit the CW power incident to the unit to those values estimated in Table VII.

Most existing tropo antennas will require that the feed support assembly be modified, sometimes extensively, to accommodate the new feed. In many instances (such as the AN/TRA-39A), complete replacement of the feed support assembly may be the most effective method.

Table VIII tabulates the expected radiation pattern parameters for a variety of combinations of likely troposcatter antenna size and frequency combinations when equipped with the angle diversity feed.

FIGURE 65

TABLE V
RELATIVE BEAM POSITIONS

CALCULATED

From Silver, p. 488, $\Delta = 60 \text{ (BDF)} \tan^{-1} \left(\frac{2Y}{f} \right)$ minutes arc
where $\text{BDF} \approx 0.88$ for $f/D = 0.42$.

From phase center measurements, $Y = 0.92$ (horizontal polarization),
 $Y = 1.03$ (vertical polarization).

<u>Horizontal Polarization</u>	$\Delta = 60 (0.88) \tan^{-1} (1.84/142.2) = 39'$
<u>Vertical Polarization</u>	$\Delta = 60 (0.88) \tan^{-1} (2.06/142.2) = 44'$

MEASURED

From measured secondary patterns, bisecting half-power points

	<u>RIGHT ANTENNA</u>	<u>LEFT ANTENNA</u>	<u>AVERAGE</u>
<u>Horizontal Polarization</u>	39'	33'	36'
<u>Vertical Polarization</u>	44'	41'	42.5'

Signatron, Inc.

The purpose of this trip was to determine the cause of failure of MDTS Serial Number 003, and return it to service. This modem was set up at 12 MB/Sec and would not synchronize when connected in a back-to-back configuration. Apparently this modem and modem SN 008 had both been set up at 12 MB/Sec and had both been successfully checked out on the RADC Simulator at Verona. Subsequently, SN003 failed. John Eschle of Signatron was the test operator.

Initial examination of SN 003 indicated that the analog eye pattern was completely collapsed. All circuit cards were checked for correct data rate components and Strap Settings. All cables in the back of the nest were checked. An intermittent cable was discovered and repaired. This cable went between the FES and FED. The intermittency only appeared under great stress and was not a contributing factor to the problem at hand. Finally, at the suggestion of Pete Monsen, I performed the "collapsed eye test" and the results indicated that the system phasing was not properly aligned. I immediately suspected that the MBC card, which

contains a length of trimmed cable, had been swapped with another modem. Within a few minutes it was determined which MBC cards belonged where. Two 20 minute data points were taken using each of the 12 MB/Sec modems on the simulator. The resulting bit error rates were very close and they also tracked the data that had been previously taken on these two modems. Both modems were then subjected to on-the-air link tests and, again, the results showed that the modems were tracking each other very well. The on-the-air data points were two orders of magnitude poorer than the desired results. However, as both modems performed well on the simulator, and tracked each other both on the simulator and on the live link, it was decided that the poor on-the-air performance was not related to a malfunctioning modem, but rather to some link parameter. John Eschle was convinced that the modems were operating normally and he would continue the investigation to determine the cause of the degraded performance.

Monthly Status Report #23 A212

ADAPTIVE ANTENNA CONTROL

DAAB07-76-C-8085

Prepared by: P. Monsen, Program Manager

Date: 5 June 1978

Work accomplished during the period from 1 May 1978 through 31 May 1978 is summarized. Also included in this report is the Contractor Cost Correlation Data for the reported period.

The angle diversity test program was completed as of 26 May. An earlier problem resulting in significant degradation in the 2S/2F baseline system was partially resolved early in the month. Enclosures 1 and 2 provide the reports of Dr. Ehrman of Signatron and Mr. Wetmore of Sylvania relative to the problem. Although no problem area was specifically identified during their investigation, the site engineer, Mr. Mangold, discovered a faulty cable connecting to the transmitter shortly after their visit. After cable replacement, the BER measured at Verona no longer exhibited the scatter present in previous baseline tests at 12 Mb/s. A fixed degradation of about 3 dB from previous MDTS tests was still present however. This degradation is consistent with the transmitter degradation measured by Dr. Ehrman, c.f. Fig. 3, enclosure 1. We do not have a satisfactory explanation of why previous 12 Mb/s MDTS tests using the same transmitters were 3 dB better.

Preliminary analysis of the 12 Mb/s shows similar results to the 6 Mb/s tests, viz., approximately equal performance of the 2S/2F and 2S/ZA configurations and no serious sensitivity to delay variations between angle diversity beams. The multipath spread in the elevated beams did not present an intersymbol interference problem for the MDTS equalizer.

A technical briefing of our preliminary angle diversity results took place on 2 May at the SHAPE Technical Center in the Hague, Netherlands. Briefings were provided by Mr. Osterholz of DCEC, Mr. Krause of CORADCOM, and Dr. Monsen of Signatron.

SUBJECT: Radio/Modem Testing at Youngstown
May 10-11, 1978

DATE: May 12, 1978

As requested, I went to Youngstown on May 10/11 to run loopback tests on the MDTS and the AN/TRC-132A. Larry Whetmore of Sylvania accompanied me.

On May 10 we measured the exciter and PA spectra, when driven by a 12 Mbps output from the mini-modulator. Photographs are shown in Figures 1 and 2. The exciter outputs, Figure 1(a) and (b), are identical. The PA outputs, Figure 2(a) and (b), shows that the 4500 MHz radio has a somewhat narrower bandwidth. The modulator outputs were looked at in the time domain, and appeared to be quite good -- nearly flat, and no apparant ripple. An RF loopback test was run from the 4690 MHz exciter output to the 4690 receiver. It was approximately 5 dB degraded from a theoretical CPSK curve, but I don't have too much confidence in the calibration accuracy.

The next morning RF loopback tests were run from the PA output. These tests can be considered accurate, as I have more faith in the calibration and we also, as will be seen, cross-checked against the SNR meter on the MDTS. Three tests were run. In the first two the MDTS was looped back at 4690 MHz and 4500 MHz, using the mini-modulator. In the last, a 4500 MHz loopback was run, using the MDTS modulator. The raw data are shown in Table 1. The "Alfred Attenuator" is a variable attenuator which was used to change the RSL. All tests were run with approximately 1 watt output from the 10 KW klystrons in order to reduce RF leakage to an acceptable level.

TABLE 1
RF LOOPBACK TEST DATA

Alfred Atten(dB)	RSL (dBm)	Test 1 4690 MHz		Test 2 4500 MHz		Test 3 4500 MHz	
		SNR	MDTS	MDTS	MDTS	MDTS	MDTS
		(f=5 dB)	SNR	SNR	SNR	SNR	SNR
0	-80.6	21	-	-	-	20	3.2x10 ⁻¹
2	-82.6	19	-	-	-	20	7.0x10 ⁻¹
4	-84.6	17	18.5	4.8x10 ⁻⁷	19.5	18.0	2.4x10 ⁻¹
6	-86.6	15	16.5	2.0x10 ⁻⁵	17.5	16.5	1.0x10 ⁻¹
8	-88.6	13	13.5	3.0x10 ⁻⁴	13	13.0	6.6x10 ⁻¹
10	-90.6	11	10.5	2.8x10 ⁻³	10	10.0	5.9x10 ⁻¹
12	-92.6	9	8.5	1.3x10 ⁻²	8.0	-	-
14	-94.6	7	6.5	3.8x10 ⁻²	6.0	-	-
16	-96.6	5	4.5	9.5x10 ⁻²	4.0	-	-

NOTE: Tests 1 and 2 used minimodulator

Test 3 used MDTS modulator

All tests run with 1W PA Output

5 dB Noise figure Assumed.

In Table 1 we have converted RSL to SNR assuming a 5 dB noise figure, using the equation

$$\begin{aligned}\text{SNR} &= \text{RSL} + 1.6 (\text{Nf} + 10 \log R_b - 174) \\ &= \text{RSL} + 98.6 @ 12.6 \text{ Mbps, } f = 5 \text{ dB.}\end{aligned}$$

An examination of the "MDTS SNR" column of Table 1 shows that in the 5 to 11 dB range, where the SNR meter is supposed to be most accurate (it is calibrated at 10 dB) the SNR derived from computation using the attenuator setting is in agreement with the MDTS SNR meter to within 1 dB, with the computed SNR being the higher.

The experimental data of Table 1 are plotted in Figure 3. It is seen that the 4500 MHz data are about 1 dB poorer than the 4690 MHz data, which in turn is about 5 dB poorer than theoretical. According to John Eschle, simulator testing of the modem on a non-fading channel showed a 3.5-4 dB degradation from theoretical. Therefore our experimental data indicate the radio further degrades performance by 1-1.5 dB, if a 1 dB calibration error exists, this reduces to 0-0.5 dB. The separation between the 4500 MHz tests using the mini-modulator (Test 2) and the MDTS modulator (Test 3) is real, and appears to be due to a nonlinearity in the MDTS modulator.

To sum up, the Verona link looks good. It is possible that the PA will degrade at high powerlevel. Don Mangold states, however, that he has measured the bandwidth at full output power, and it does not change from the low level value. It is therefore an unlikely source of further degradation.

P. Monsen, Signatron

The purpose of this trip was to attempt to determine the reason for the degraded MDTS system performance at 12MB/S. Dr. Len Ehrman and I arrived at the Youngstown site Wednesday morning. An MDTS modem (SN008) set at 12 MB/S and some miscellaneous test equipment had arrived from the Verona test site, via truck, to enable us to perform IF and RF loop back tests. The Sylvania Minimodulator had been performing as the modulator at Youngstown.

An IF loopback was performed at 70 MHz between the minimodulator and the MDTS. The SDS bit error rate test verified that no errors were generated, hence the minimodulator was not creating any irreducible error rate. RF loop back tests were performed at both 4500 GHz and 4690 GHz using a pair of receivers shipped from Verona. Establishing accurate calibration levels was difficult due to the field environment, however, we were able to show that the E_b/N_0 curve at 4690 was about 1 db better than at 4500 GHz. The curves were about 4 db off the theoretical. Experimental results from Verona had indicated that the 4690 GHz data was noticeably better than 4500 GHz data. A 1 db degradation is not significant enough to cause the differences observed. The MDTS modulator was substituted for the minimodulator and E_b/N_0 data was taken at 4500 GHz. This data was degraded by about 1 db at high SNR but fell in line with previous data at low values of SNR. This delta was verified to be the result of a TSC in the modem and an XSC (improved TSC) in the minimodulator. If the minimodulator had been contributing to any irreducible error rate, the observed results of this test would have indicated the MDTS modulator to be superior to the minimodulator, however, this was not the case.

Photographs of the QPSK spectrum at both exciter outputs and power amplifier outputs, at both frequencies, were taken. Dr. Erhman has the photographs and the recorded Bit Error Rate data.

Our final conclusion ~~was~~ that there was nothing occurring at the Youngstown site that would cause the performance degradation observed in Verona, at 12MB/S.

We departed the site Thursday afternoon, May 11, 1978.

APPENDIX J
AAC RELIABILITY ANALYSIS

APPENDIX

AAC Reliability Analysis

This appendix documents the results for the final reliability assessment consisting of a detailed reliability prediction and mathematical model based on MIL-HDBK-217C, Reliability of Electronic Equipment, 9 April 1979.

The AAC model in the quadruple diversity application consists of two dual polarized double feedhorns, spar modifications for feedhorn mounting, and additional waveguide for the elevated beam received signals. The results of the AAC program show that conversion from frequency diversity systems to the above AAC angle diversity model realizes a 2:1 decrease in bandwidth occupancy with approximately the same or better performance. Because the AAC model for this conversion is non electronic, the impact on reliability on the existing system is negligible. The major failure mode for feedhorns is the probability of pressure loss in the guide accompanied by water leadage and resultant corrosion. Good maintenance practices should make such eventualities much less likely than electronic failure. Furthermore, mathematical models and statistical data for feedhorn failure do not exist at a level for accurate reliability prediction.

An extended angle diversity system has also been included in the AAC model for those applications where conversion from fourth to eighth order diversity is recommended. However, the AAC program results show that the improvement for such conversion a Predetection Combiner (PDC) is used to combine the additional four diversities. The prototype PDC used in the AAC tests is now obsolete as it was designed to operate with the original MD-918 modem. Subsequent simplifications in the MD-918 would now require redesign of the PDC for proper interface. For completeness, however, the reliability calculation for this

equipment has been performed using the SIGNATRON Reliability Prediction model. This model is based on MIL-HDBK-217C. In the model, the reliability of each component is computed using part quality data, use environment data, a failure rate model and thermal considerations. These factors are briefly summarized before presenting the reliability results.

A.1 Part Quality

The quality of a part has a direct effect on the part failure rate and appears in the part models as a factor, π_Q . Many parts are covered by specifications that have several quality levels, hence the part models have values of π_Q that are keyed to these quality levels. Such parts with their quality designators are shown in Table A-1. The detailed requirements for these levels are clearly defined in the applicable specification.

TABLE A-1 PARTS WITH MULTI-LEVEL QUALITY SPECIFICATIONS

PART	QUALITY DESIGNATORS
Microelectronics	S, B, B-1, B-2, C, C-1, D, D-1
Discrete Semiconductors	JANTXV, JANTX, JAN
Capacitors, Established Reliability (ER)	L, M, P, R, S
Resistors, Established Reliability (ER)	M, P, R, S
Coils, Molded, R.F., Established Reliability (ER)	M, P, R, S
Relays, Established Reliability (ER)	L, M, P, R

Some parts are covered by older specifications, usually referred to as Non-ER, that do not have multi-levels of quality. These part models generally have two quality levels designated as "MIL Spec.", and "Lower". If the part is procured in complete accordance with the applicable specification, π_Q value for Mil Spec.

should be used. If any requirements are waived, or if a commercial part is procured, the π_Q value for Lower should be used.

A.2 Use Environment

All part reliability models include the effects of environmental stresses through the factor, π_E . The definitions of these environments are shown in Table A.2. The π_E factor is quantified within each part failure rate model. These environments encompass the major areas of equipment use. Some equipment may experience more than one environment during its normal use, e.g., equipment in spacecraft. In such a case, the reliability analysis should be segmented, namely, missile launch (M_L) conditions during boost and return from orbit, and space flight (S_F) while in orbit.

TABLE A-2

ENVIRONMENTAL SYMBOL IDENTIFICATION AND DESCRIPTION

ENVIRONMENT	π_E SYMBOL	NOMINAL ENVIRONMENTAL CONDITIONS
Ground, Benign	G_B	Nearly zero environmental stress with optimum engineering operation and maintenance.
Space, Flight	S_F	Earth orbital. Approaches Ground, Benign conditions without access for maintenance. Vehicle neither under powered flight nor in atmospheric re-entry.
Ground, Fixed	G_F	Conditions less than ideal to include installation in permanent racks with adequate cooling air, maintenance by military personnel and possible installation in unheated buildings.
Ground, Mobile	G_M	Conditions more severe than those for G_F , mostly for vibration and shock. Cooling air supply may also be more limited, and maintenance less uniform.

ENVIRONMENT	π_E SYMBOL	NOMINAL ENVIRONMENTAL CONDITIONS
Naval, Sheltered	N_S	Surface ship conditions similar to G_F but subject to occasional high shock and vibration.
Naval, Un- sheltered	N_U	Nominal surface shipborne conditions but with repetitive high levels of shock and vibration.
Airborne, Inhabited, Transport	A_{IT}	Typical conditions in transport or bomber compartments occupied by aircrew without environmental extremes of pressure, temperature, shock and vibration, and installed on long mission aircraft such as transports and bombers.
Airborne, Inhabited Fighter	A_{IF}	Same as A_{IT} but installed on high performance aircraft such as fighters and interceptors.
Airborne, Uninhabited, Transport	A_{UT}	Bomb bay, equipment bay, tail, or wing installations where extreme pressure, vibration, and temperature cycling may be aggravated by contamination from oil, hydraulic fluid and engine exhaust. Installed on long mission aircraft such as transports and bombers.
Airborne, Uninhabited, Fighter	A_{UF}	Same as A_{UT} but installed on high performance aircraft such as fighters and interceptors.
Missile, Launch	M_L	Severe conditions of noise, vibration, and other environments related to missile launch, and space vehicle boost into orbit, vehicle re-entry and landing by parachute. Conditions may also apply to installation near main rocket engines during launch operations.

A.3 Part Failure Rate Models

Part failure rate models for microelectronic parts are significantly different from those for other parts and require a special model. Another type of model is used on most other parts; a typical example is the following one for discrete semiconductors:

$$\lambda_p = \lambda_b (\pi_E \times \pi_A \times \pi_{S2} \times \pi_C \times \pi_Q)$$

where λ_p is the part failure rate,

λ_b is the base failure rate usually expressed by a model relating the influence of electrical and temperature stresses on the part,

π_E and the other π factors modify the base failure rate for the category of environmental application and other parameters that affect the part reliability.

The base failure rate (λ_b) models are based on MIL-HDBK-217C. The model equations have been incorporated into our computer program for machine processing. The tabulated values of λ_b are cut off at the part ratings with regard to temperature and stress, hence, use of parts beyond these cut off points will overstress the part. The use of the λ_b models in the computer program takes the part rating limits into account. The λ_b equations are mathematically continuous beyond the part ratings but such failure rate values are invalid in the overstressed regions.

A.4 Thermal Aspects

The use of this prediction method requires the determination of the temperatures to which the parts are subjected. Since parts reliability is sensitive to temperature, the thermal analysis of any design should fairly accurately provide the ambient temperatures needed in using the part models.

The ambient temperature T_A in $^{\circ}\text{C}$ is used by the model in this calculation.

A.5 PDC Reliability

The reliability analysis for each card of the PDC is presented in the following tables. These tables include cost data on individual components. The part reliability (LAMDA) and the group failure rate (GFR) are expressed as the average number of failures in 10^6 hours. At the end of the individual card summaries, the failure rate for the entire system is computed.
