20. ABSTRACT (Continue on reverse side if necessary and identify by block number)

Information is provided in this report on the interlevel correlations of the east/west and north/south wind components for altitudes between the surface and 60 km, with special emphasis on levels between 25 km and 60 km. Mean monthly wind speeds and day-to-day variations due to synoptic changes in weather patterns are included. Estimates are also given of the probability of extreme wind speeds at specific locations and altitudes up to 60 km. A statistical technique that can be used to obtain estimates of the integrated effect of wind on the trajectories and impact points of reentry vehicles is presented.

and an example of its application is given. These effects due to the winds must be considered, along with the density effects, in the design and operation of guidance systems for reentry vehicles and for targeting ballistic missiles.

Preface

The authors wish to thank Mr. Karekin Agazarian who developed the computer program for the computation of the statistical arrays. He provided them in "camera-ready" format, eliminating the time-consuming, manual preparation of Appendix A of this report. We also appreciate the work of Mr. Eugene A. Bertoni who prepared many of the figures for final drafting.

Wind Distributions and Interlevel Correlations, Surface to 60 km

1. INTRODUCTION

The winds that are encountered during passage through the atmosphere must be considered in the design and operation of missiles and other aerospace vehicles. In horizontal flight, information on the direction and speed of the wind at a specific altitude is needed to determine the range and ground speed of aircraft and the trajectory of constant level balloons. Variations in the vertical distribution of the winds are important factors in the launching as well as reentry of aerospace vehicles which rise or descend vertically through the atmosphere. During launch, wind shear resulting from changes in wind speed and direction with altitude can create a continuous torque on a vertically rising vehicle, forcing it off course and out of control. Deviations in the assumed vertical wind profile over a target or reentry point affect the range and cross-range of a ballistic missile. These effects must be considered, along with density effects,[1] in the design of guidance systems for reentry vehicles and for targeting ballistic missiles.

The data presented in this report indicate the frequency of extreme wind speeds at altitudes up to 60 km and provide information on the interlevel correlations of the east/west (zonal) and north/south (meridional) wind components for altitudes

between the surface and 60 km over specific locations. Special emphasis is placed on winds in the region between 25 and 60 km. A statistical technique which can be used to integrate the influence of the wind on the trajectories and impact points of reentry vehicles is presented and an example of its application is given in Appendix B. The technique can be also used for estimating the dispersion of balloons released from the surface and of chaff released in the upper atmosphere.

2. OBSERVATIONS AND LIMITATIONS

Wind data used in this report consist of rawinsonde and Meteorological Rocket Network (MRN) observations taken at the ten locations shown in Table 1.

Table 1. Observational Sites

Station	Location	Altitudes	Period of Record
Ascension Island	8°S, 14°W	Surface to 60 km	1969-1976
Kwajalein	9°N, 168°E	Surface to 60 km	1969-1976
Wallops Island	38°N, 75°W	Surface to 60 km	1969-1976
Churchill	59°N 94°W	Surface to 60 km	1969-1976
Fort Sherman	9°N, 80°W	26 to 60 km	1969-1976
Barking Sands	22°N, 160°W	26 to 60 km	1969-1976
Cape Kennedy	28°N, 80°W	26 to 60 km	1969-1976
White Sands	32°N, 106°W	26 to 60 km	1969-1976
Primrose Lake	55°N, 110°W	26 to 60 km	1969-1976
Poker Flats	64°N, 146°W	26 to 60 km	1969-1976

At the first four stations, rawinsonde and rocketsonde observations taken within a few hours of each other were combined to provide individual wind profiles from the surface to 60 km. Rocketsondes without accompanying rawinsondes were used at the six remaining sites to develop statistical properties of the wind distributions between 26 km and 60 km. Only observations that were taken at least 72 hr apart were used for this study in order to minimize the effects of persistence on the statistical properties of the wind. Durst[2] has shown that, at altitudes between 5 km and 20 km, the time rate of decay of the correlation coefficient (R) for wind follows the rule $R = e^{-aT}$, where "a" equals 6.9×10^{-6} sec^{-1} and T is measured in seconds.

2. Durst, B. A. (1954) Variation of Wind with Time and Distance, Geophysical Memoirs No. 93, British Meteorological Office.

The calculated correlation coefficient between observations taken three days apart is 0.17. This is in agreement with observed 72-hr correlations which are generally near zero (< 0.2).

The winds for altitudes up to 26 km, were extracted from rawinsonde observations. The Root Mean Square (RMS) observational errors in rawinsonde wind measurements using FPS-16, T-9, or similar radar for altitudes up to 26 km are 1 m sec^{-1} plus 2 percent of the vector wind.[3] For geometric altitudes between 26 km and 60 km, winds are obtained at 2-km intervals directly from MRN observations.[4] The estimated RMS observational errors in rocketsonde wind measurements at these levels are 2 m sec^{-1} plus 3 percent of the vector wind.[3]

Statistical arrays of the mean monthly winds for the midseason months of January, April, July, and October are presented in Appendix A for the ten locations shown in Table 1. They include mean monthly values of the zonal and meridional components at 2-km increments of altitude, standard deviations around the means, and interlevel correlation coefficients for each component for altitudes up to 60 km. The observed RMS variations (σ_o) around the monthly means include the true RMS variability (σ_t) due to changes in synoptic conditions and the RMS observation error (σ_e). If the true variability and observational errors are independent, the observed RMS variability is given by Eq. (1):

$$\sigma_o = \sqrt{\sigma_t^2 + \sigma_e^2}. \tag{1}$$

As a result, the effect of observational errors should be carefully evaluated to determine how much of the variability indicated by the uncorrected soundings is due to synoptic changes in weather patterns. These errors have a relatively small effect on the mean monthly wind components given in Appendix A because the RMS error of the mean monthly wind is equal to the RMS value of the error of an observation divided by the square root of the number of independent observations used in computing the monthly means.

3. TECHNIQUE

3.1 The Effect of Wind on Aerospace Vehicles

The average effect (E) of mean monthly winds on the range and cross range of a missile can be determined for a particular location by computer-simulated flights

3. Meteorological Group, Range Commanders Council (1977) Meteorological Data Error Estimates, Document 110-77, White Sands Missile Range, NM.

4. World Data Center A (1969-1976) Data Report Meteorological Rocket Network Firings, Ashville, NC.

through mean monthly component wind profiles if the appropriate influence coefficients for the missile at the various levels are given:

$$E = c_i v_i \tag{2}$$

where c_i is the influence coefficient at the ith level that describes the portion of the total response of a missile assignable to that level, and v_i represents the mean of the component wind speed for that level. The variation around this average effect, that is, the integrated standard deviation of the range due to day-to-day deviations from the mean monthly component wind profile, can be obtained from:

$$\sigma = \sqrt{\sum_{ij} c_i c_j R_{ij} \sigma_i \sigma_j} \tag{3}$$

where σ is the integrated standard deviation, c_i and c_j are the influence coefficients at levels i and j, σ_i and σ_j are the standard deviations of the component wind at levels i and j, and R_{ij} is the correlation coefficient between the component wind at level i with that at level j.[5] If it is assumed that the cross-component correlations are zero at any given level as well as between levels, the standard deviations for each component of the wind [Eq. (3)] can be readily combined and used to determine the probability of occurrence of deviations of any desired magnitude from the planned trajectory or, conversely, any probability of occurrence for the means, standard deviations, and correlation coefficients given in Appendix A. The arithmetic example in Appendix B illustrates how to use Eqs. (2) and (3) along with the statistical arrays in Appendix A to estimate the effect of the wind on the trajectory (and impact point) of a reentry vehicle.

3.2 Extreme Winds

Extreme wind speeds also can be estimated from the mean monthly wind components and standard deviations given in Appendix A. Based on the observations described in Section 2 above, mean monthly wind vectors and vector standard deviations were determined from the means and standard deviations of the zonal and meridional winds. Extreme scalar speeds were then calculated using the vector means and associated vector standard deviations and assuming a circular normal distribution.[6] A circular normal distribution requires an assumption that the zonal and meridional

5. Valley, S. L., Sci. Ed. (1965) Handbook of Geophysics and Space Environments, AFCRL.

6. Crutcher, H. L. (1959) Upper Wind Statistics Charts of the Northern Hemisphere, NAVAER 50-1C-535, Vol. I and II.

wind components are uncorrelated (independent) and that their standard deviations are equal. Since the standard deviations around the mean monthly zonal winds are generally somewhat larger than the standard deviations around the mean monthly meridional winds, an elliptical normal rather than a circular normal assumption applies. The effect of this inequality in the standard deviations can be estimated. For example, when the standard deviation of one component is twice that of the other, a circle of radius equal to one vector standard deviation contains about 65 percent of the total probability rather than 63.2 percent when the standard deviations are equal (circular normal).[7] Because of this small difference, a circular normal approximation has been used in this report as it provides reasonably accurate estimates and simplifies the calculations that must be made to determine extreme winds in the stratosphere and lower mesosphere.

4. WIND PROFILES

Profiles of mean zonal and meridional winds (m sec^{-1}) for each of the midseason months at Ascension Island, Wallops Island, and Churchill are plotted in Figures 1 and 2. These profiles describe variations in the vertical distributions of the monthly winds with geographic location. The most obvious feature of the zonal winds (Figure 1) in the stratosphere and lower mesosphere is that the strongest zonal winds occur near 60 km at Wallops Island in three of the four seasons. A west-to-east reversal in the zonal component above 20 km occurs between January and July at both Wallops Island and Churchill. In the troposphere the zonal winds generally increase with altitude from the surface, reaching a maximum near the tropopause where the mean zonal winds are westerly at all latitudes and seasons. This is the level where the wind shear is likely to be the most critical during the launching of missiles and other aerospace vehicles. The mean monthly meridional winds (Figure 2) are relatively light, less than 10 or 12 m sec^{-1} at all levels and locations except above 24 km at Wallops Island and Churchill in January.

Seasonal differences in the component wind profiles at each of the three stations are apparent in Figures 3 and 4. The middle and high latitude west-to-east reversal between winter and summer is clearly shown in Figure 3 for altitudes above 20 km at both Wallops Island and Churchill. Mean monthly differences between the winter westerlies and summer easterlies reach 136 m sec^{-1} at Wallops Island at 60 km. Somewhat larger differences occur between 60 and 70 km, the region of maximum winds in the mesosphere at midlatitude locations, and they gradually

7. Court, A. (1957) Maximum Variability Level of Winds, Scientific Report No. 2, Contract AF19(604)-2060, AFCRC TN-57-478.

decrease at altitudes above 70 km. Below 20 km monthly zonal winds at Wallops Island and Churchill are light to moderate westerly (< 34 m sec^{-1}) during all seasons. The mean meridional components (Figure 4) are generally small during most seasons. Southerly winds approach 18 m sec^{-1} only in January above 44 km at Wallops Island, and northerly winds reach about the same speed, also in January, between 32 and 44 km at Churchill.

5. VARIABILITY

Standard deviations of the day-to-day fluctuations around the mean monthly component winds for altitudes between the surface and 60 km are tabulated in Appendix A and are shown in Figures 5 and 6 for January, April, July, and October at Ascension Island, Wallops Island, and Churchill. These variations are a result of day-to-day changes in synoptic weather patterns. The variations of the zonal winds (Figure 5) are generally largest in January and at high latitudes, and smallest in July. Above the trosphere in July the variations are somewhat larger in the tropics than in middle and high latitudes. In addition, the seasonal differences between January and July increase with both latitude and altitude at levels above 20 km. The variations of the meridional winds (Figure 6) display similar characteristics, but are generally somewhat smaller above the troposphere than variations of the zonal winds.

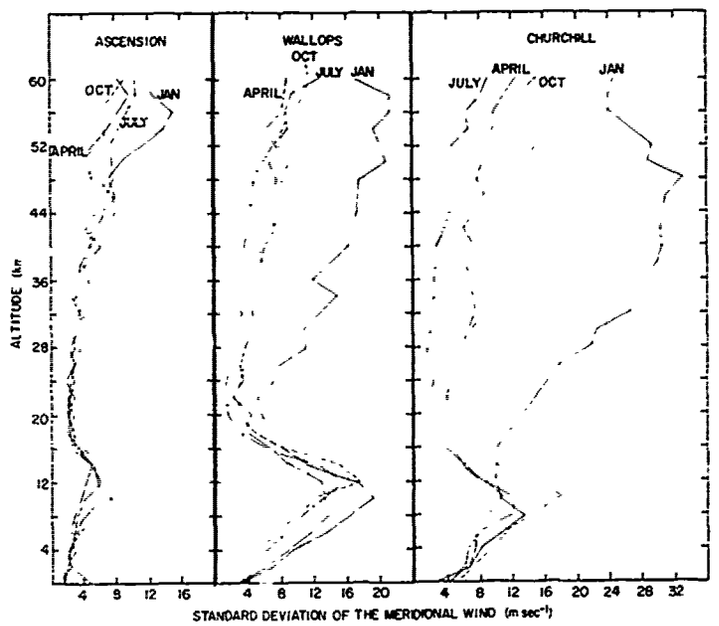

Figure 6. Day-to-day Variability Around Mean Monthly Meridional Winds for the Midseason Months at Ascension Island, Wallops Island, and Churchill

6. INTERLEVEL CORRELATIONS

The rate of decay of the correlations with an increase of either the horizontal or vertical distance between the points of observation, or the time interval between observations, is similar for most meteorological elements such as density, temperature, and wind. As yet, no one fundamental mathematical expression has been found to completely describe this correlation decay. Accordingly, a number of empirical models which are valid for specific meteorological elements over only limited ranges have been developed and used.

Profiles of correlation coefficients (R) of surface wind components with wind components at other altitudes up to 60 km are shown in Figures 7 and 8 for each of the midseason months at Ascension Island, Wallops Island, and Churchill. Correlations between the surface components and those at other altitudes decrease quickly as the vertical distance between levels increases; they generally approach zero and maintain relatively low values during all seasons at the three locations between the surface and all levels above the tropopause (> 8 to 16 km). This indicates that not much information on day-to-day variability around the mean monthly component wind profiles above the tropopause can be obtained from surface wind observations. The decay of the interlevel correlations with increasing separation varies considerably with starting level and season, as can be seen in the tabulations within the statistical arrays in Appendix A.

Profiles of correlation coefficients of the component winds at 26 km with component winds at higher altitudes up to 60 km are shown for each of the midseason months at locations in the tropics (Figures 9 and 10), middle latitudes (Figures 11 and 12), and high latitudes (Figures 13 and 14). The July profiles at Primrose Lake are not shown in Figures 13 and 14 because only 10 or 11 observations were available in July for the development of the interlevel correlations.

Interlevel correlations between zonal components decay most rapidly in the tropics, becoming negative within 6 to 12 km above 26 km. In middle and high latitudes the correlations decay more slowly, remaining positive or near zero at most locations and months. In January, however, correlations at most midlatitude stations become negative above roughly 40 km. The profiles for locations within the same latitude band indicate that the correlations are fairly stable for large areas of the Northern Hemisphere. Consequently, more reliable estimates of the profiles of R for altitudes above 26 km can be derived by using average values for low, middle, and high latitude locations, respectively, obtained either from the plots shown in Figures 9, 11, and 13 or from the statistical arrays in Appendix A.

The meridional components are relatively unimportant since correlations are generally between ± 0.3 at all levels, months, and stations in the tropics; during April, July, and October in the middle latitudes; and during July in high latitudes. The high-latitude correlations decay to near zero or slightly less than zero during the other months at levels above roughly 50 km.

7. EXTREME WINDS

Vertical cross sections of mean monthly zonal and meridional winds have revealed that the strongest monthly vector winds occur in the middle latitudes, generally during November and December. Resulting hemispheric 1-percent extremes have been estimated to reach 215 m sec^{-1} near 55 km.[8] Envelopes of estimated global extreme winds for altitudes from the surface to 80 km can be found in MIL-STD-210B.[9]

Mean monthly vector winds for this report were calculated from monthly component winds for altitudes above 26 km and were found to be largest during winter between latitudes 35°N and 60°N. The 90, 95, and 99 percentile scalar speeds were estimated for Ascension Island, Wallops Island, and Churchill, using the statistical technique outlined in Section 3 of this report. Ascension Island, Wallops Island, and Churchill were selected as locations typical of wind regimes in low, middle, and high latitudes, respectively. Medians and 90, 95, and 99 percentile scalar speeds for the midseason months at these locations are shown in Tables 2, 3, and 4 for altitudes between 26 and 60 km. The largest 1-percent extremes (155 m sec^{-1}) are shown at Wallops Island in January at 50 km, with the maximum apparently occurring at or slightly above 60 km. The 1-percent extreme at Churchill (152 m sec^{-1}), also in January, occurs near 30 km, more typical of a high-latitude location. Extremes are usually smaller in the tropics, as indicated in Table 2 for Ascension Island.

These estimates provide envelopes of the 90, 95, and 99 percentile wind speeds at specific locations for levels between 26 and 60 km. They will not occur simultaneously at all levels; consequently, they cannot be used to represent an extreme wind profile. Because they were determined statistically at all altitudes, assuming independence between levels, they should not be used to determine the effect of wind on a vertically rising or descending vehicle. They are applicable, however, to a vehicle traveling horizontally through the atmosphere such as a constant level balloon or aircraft.

Appendix B

Sample Calculations for Estimating the Effects of Winds on a Reentry Vehicle

The computations given in this Appendix illustrate how to estimate the effect of mean monthly zonal and meridional winds, and the day-to-day variations around their means, on the trajectory of a reentry vehicle passing through the region between 11 km and 5 km near Wallops Island in January.

For the purpose of this simplified example, the following influence coefficients for the vehicle have been assumed such that a wind of 1 m sec^{-1} at a specific altitude will have the indicated effect through a 2-km layer of the atmosphere:

Layer (km)	Influence [m(m sec^{-1})$^{-1}$]
11 — 9	0.7
9 — 7	0.4
7 — 5	0.2

The average departure from a no-wind condition is the sum of the effects due to the mean monthly wind speed at each level as determined from Eq. (2) in Section 3 of the text:

Level (km)	Wallops Zonal Wind (m sec^{-1})		Influence [m(m sec^{-1})$^{-1}$]		Distance (m)
10	31	×	0.7	=	22
8	34	×	0.4	=	14
6	28	×	0.2	=	6
	Average departure due to zonal wind			=	42 m

Level (km)	Wallops Merid. Wind (m sec^{-1})		Influence [m(m sec^{-1})$^{-1}$]		Distance (m)
10	2	×	0.7	=	1
8	2	×	0.4	=	1
6	1	×	0.2	=	0
	Average departure due to merid. wind				2 m

Consequently, the average range and cross-range distance from a no-wind condition is 42* meters to the east and 2* meters to the north.

The integrated standard deviation of the departure due to day-to-day variations in the component wind profiles is determined from Eq. (3) in Section 3 using the standard deviations of the component winds at levels 10, 8, and 6 km and the correlation coefficients between these levels as indicated in the zonal and meridional arrays for Wallops Island, January, in Appendix A:

Zonal Wind

Corr Coeff		Std Dev (m sec^{-1})	Influence [m(m sec^{-1})$^{-1}$]	Std Dev (m sec^{-1})		Influence [m(m sec^{-1})$^{-1}$]		Distance^2 (m^2)
		$(12.0 \times 0.7)^2$					=	71
		$(15.0 \times 0.4)^2$					=	36
		$(12.3 \times 0.2)^2$					=	6
2×0.91	×	12.0×0.7	×	15.0	×	0.4	=	92
2×0.77	×	12.0×0.7	×	12.3	×	0.2	=	32
2×0.94	×	15.0×0.4	×	12.3	×	0.2	=	28
						Total (σ_2^2)	=	265 m^2

Meridional Wind

Corr Coeff		Std Dev (m sec^{-1})		Influence [m(m sec^{-1})$^{-1}$]	Std Dev (m sec^{-1})		Influence [m(m sec^{-1})$^{-1}$]		Distance^2 (m^2)
		$(19.2 \times 0.7)^2$						=	181
		$(16.4 \times 0.4)^2$						=	43
		$(13.4 \times 0.2)^2$						=	7
2×0.97	$\times$	19.2×0.7		X	16.4	$\times$	0.4	=	171
2×0.90	$\times$	19.2×0.7		$\times$	13.4	$\times$	0.2	=	37
2×0.95	$\times$	16.4×0.4		$\times$	13.4	$\times$	0.2	=	33
							Total (σ_m^2)	=	472 m^2

Thus, the integrated standard deviation (σ) is

$$\sigma = \sqrt{(\sigma_z^2) + (\sigma_m^2)} = 27 \text{ m} \qquad \text{(B1)}$$

Based on the assumption of circular distribution of winds, the vehicle will impact within 47 meters* (1.73 σ) of the target 95 percent of the time, provided the aim point has been adjusted to compensate for the mean monthly wind. The CEP (the circle within which 50 percent of the missile hits (0.83 σ) will be scattered) is 20 meters.*

*These values reflect both smaller mean monthly effects and variability around the target than would normally be expected because the sample calculations have been made only for altitudes between 11 km and 5 km.
