The technique of linear regression has been applied as a tool for predicting the cost of an item based on its most important characteristics. Often these characteristics (variables) tend to be highly intercorrelated (the data are said to exhibit multicollinearity) causing least squares estimates of the regression coefficients to be unstable and possibly leading to erroneous predictions.

Ridge regression, a possible remedy for the problems caused by multicollinearity proposed by Hoerl and Kennard, is a biased estimation technique which reduces the variance of estimators and provides more precision (as measured by mean square error of the coefficients) than ordinary least squares (OLS) estimators.

A comparison was made between these techniques to determine when ridge regression provides better cost equation coefficient estimates than OLS as a function of the degree of multicollinearity in the data, the number of predictor variables in the model, the degree of model fit (R^2), and the amount of bias (k) of the estimate.

Monte Carlo simulation was used to generate data for linear and log-linear model forms. A regression analysis of both sets showed that the degree of multicollinearity and amount of bias interact in explaining the major part of the improvement (degradation) in the mean square coefficient error.

Estimates of $k < 0.04$ limit the degradation and allow slight improvements in the MSE for low levels of multicollinearity and enable large improvements to be made for higher levels of multicollinearity.

Abstract

The technique of linear regression has been applied as a tool for predicting the cost of an item based on its most important characteristics. Often these characteristics (variables) tend to be highly intercorrelated (the data are said to exhibit multicollinearity) causing least squares estimates of the regression coefficients to be unstable and possibly leading to erroneous predictions.

Ridge regression, a possible remedy for the problems caused by multicollinearity proposed by Hoerl and Kennard, is a biased estimation technique which reduces the variance of estimators and provides more precision (as measured by mean square error of the coefficients) than ordinary least squares (OLS) estimators.

A comparison was made between these techniques to determine when ridge regression provides better cost equation coefficient estimates than OLS as a function of the degree of multicollinearity in the data, the number of predictor variables in the model, the degree of model fit (R^2), and the amount of bias (k) of the estimate.

Monte Carlo simulation was used to generate data for linear and log-linear model forms. A regression analysis of both sets showed that the degree of multicollinearity and amount of bias interact in explaining the

major part of the improvement (degradation) in the mean square coefficient error.

Estimates of $k \leq 0.04$ limit the degradation and allow slight improvements in the MSE for low levels of multicollinearity and enable large improvements to be made for higher levels of multicollinearity.

AN EVALUATION OF RIDGE REGRESSION IN COST ESTIMATION

I. Introduction

Background

Cost estimation of military and civilian hardware systems based on a limited amount of information has been an integral part of development and acquisition processes for many years. The technique of linear regression has been applied as a tool for predicting the overall cost of an item based on characteristics the system possesses.

During the early stages in the life-cycle of a system, only a limited knowledge of the system characteristics is available. This is especially true for new systems which have no existing counterpart. Here, there is no past experience or data to draw upon to aid in the analysis. Later, as the system takes shape, predictions must be made using only essential data to insure that the predictions are timely and are made at the minimum cost. Thus, it is necessary to identify and collect data for the most important characteristics of the system, identify the appropriate model for making the cost prediction, determine the parameters of the model and, finally, make a prediction (point or interval) of the cost of each item.

In cost estimation, only one (or in unusual circumstances, a few) prediction(s) of the cost of a system will be made. Obviously, it is desired that the prediction be as close to the actual cost incurred as possible. Often the most important characteristics used to predict the cost (predictor/independent variables) tend to be intercorrelated. When this intercorrelation is very high, the data are said to exhibit multicollinearity.

When multicollinearity is present, a tradeoff must be made between models such as ordinary least squares (OLS), which produce unbiased estimates of the cost, and biased techniques such as ridge regression which introduce some bias but reduce the variance of the estimate. The least squares estimates of the individual regression coefficients tend to be unstable. This can lead to erroneous predictions, especially if the degree of multicollinearity is very high.

A possible remedy to the estimation problems caused by multicollinearity was introduced by Hoerl and Kennard (Ref 11). Although biased, the estimates of the regression coefficients tend to have more precision (as measured by mean square error) than the ordinary least squares estimators (Kendall (Ref 18:37-43) and McCallum (Ref 23: 110-113)). The ridge technique is directly applicable to cost estimation because it has the potential of significantly reducing the chance of making a truly bad estimate for a single or small number of trials.

The regression model is $Y=X\beta+u$ where Y is an $n \times 1$ vector of observations on the response variable (cost), X is an $n \times p$ matrix of observations on p explanatory variables (characteristics of the system to be cost estimated), β is a $p \times 1$ vector of regression coefficients and u is an $n \times 1$ vector of residuals such that $E(u)=0$ and $E(u u')=\sigma^2 I$. Ordinary least squares estimates of the regression coefficients are $\hat{\beta}=(X'X)^{-1} X'Y$. On the other hand, for the class of ridge regression estimators indexed by the parameter $k>0$, the estimates of the regression coefficients (for a given value of k) are $\hat{\beta}^*(k)=(X'X+kI)^{-1} X'Y$. As k increases from zero, bias of the estimates increases. As k continues to increase without bound, the regression estimates all tend toward zero.

The total variance, the sum of the variances of the parameter estimates, is a decreasing function of k . The idea of ridge regression, as suggested by Hoerl and Kennard (Ref 12:58-63), is to pick a value of k for which the reduction in total variance is not exceeded by the increase in bias. Ultimately, forecasts of the response variable corresponding to values of the explanatory variables which were not included in the set of data used to estimate the regression coefficients tend to be more accurate.

Statement of the Problem

A comparison has not been made to determine when ridge regression provides a better prediction of the cost of a system than the ordinary least squares estimates ($k=0$ for the ridge regression model) as a function of the degree of multicollinearity in the data, the size of the model (number of predictor variables in the model), the degree of model fit (as measured by coefficient of determination, R^2 , of the regression model), and the amount of bias (controlled by selecting values for k) of the estimate. Mean square error of the coefficients is used as the criterion for evaluating the alternative modeling procedures.

Objective

The objective of this thesis is to determine when ridge regression provides a better prediction of the cost of a system compared to ordinary least squares for data simulated by varying the amounts of multicollinearity in the data, the number of variables in the regression model (2-4), the degree of model fit (R^2), and the amount of bias controlled by the ridge regression parameter, k . The investigation considers both linear and log-linear model forms.

Scope and Limitations

The analysis is limited to the comparison of ridge regression and ordinary least squares estimates within the

constructs of cost estimating relationships where linear or log-linear regression models are appropriate.

It is assumed that the correct model form is being used to analyze the data throughout the investigation; that is to say, the investigation will not consider alternative model forms.

Assumptions

It is assumed that the error term of the regression model is normally distributed with mean zero and common variance σ^2 .

II. Theoretical Background

Least Squares Estimation

The solution to the general linear model $Y=X\beta+u$, where the elements are defined as in Chapter I and $E(u)=0$ and $E(u'u)=\sigma^2 I$ is $\hat{\beta}=(X'X)^{-1}X'Y$. It is well known that the vector $\hat{\beta}$ is an unbiased estimate of the coefficient vector β . The variance of $\hat{\beta}_j$ is given by the formula

$$V(\hat{\beta}_j) = c_{jj}\sigma^2 \quad (2.1)$$

where the c_{jj} 's are the diagonal elements of $(X'X)^{-1}$. According to the Gauss-Markov theorem (Theil (Ref 35: 119-120)) no linear unbiased estimator has a smaller sampling variance than the least squares estimator. If the X's have been standardized, so that the $X'X$ matrix is in correlation form, the $(X'X)^{-1}$ matrix (for a two variable model) is

$$C = (X'X)^{-1} = \begin{bmatrix} \frac{1}{(1-r_{12}^2)} & \frac{-r_{12}}{(1-r_{12}^2)} \\ \frac{-r_{12}}{(1-r_{12}^2)} & \frac{1}{(1-r_{12}^2)} \end{bmatrix} \quad (2.2)$$

and the estimators of the parameters are

$$\hat{\beta}_1 = \frac{X_1'Y - r_{12}X_2'Y}{1 - r_{12}^2} \quad (2.3a)$$

$$\hat{\beta}_2 = \frac{X_2'Y - r_{12}X_1'Y}{1 - r_{12}^2} \quad (2.3b)$$

where r_{12} is the simple correlation between X_1 and X_2 and $X_1'Y$ and $X_2'Y$ are elements of the $X'Y$ vector.

If multicollinearity is present, X_1 and X_2 are highly correlated and $|r_{12}| \rightarrow 1$. It can be seen that the variances and covariances of the regression coefficients become very large, since $V(\hat{\beta}_j) = c_{jj}\sigma^2 \rightarrow \infty$ as $|r_{12}| \rightarrow 1$ and $\text{Cov}(\hat{\beta}_1, \hat{\beta}_2) = c_{12}\sigma^2 \rightarrow \pm\infty$ depending on whether $r_{12} \rightarrow \pm 1$ (Ref 10: 428-429). The large variances for $\hat{\beta}$ imply that the regression coefficients are very poorly estimated; they are very likely to change significantly for small changes in the data.

The constants of proportionality along the diagonal of the inverse of the correlation matrix (c_{jj} 's) are referred to as variance inflation factors, VIF's. In general, $\text{VIF}(\hat{\beta}_j) = \frac{1}{1-R_j^2}$ where R_j^2 is the coefficient of multiple determination resulting from regressing X_j on the other $k-1$ regressor variables. As R_j^2 tends toward 1 indicating the presence of a linear relationship in the X 's, the VIF for the estimated coefficient of X_j tends to infinity. On the other hand, if the explanatory variables are orthogonal, the VIF's will all equal 1 (Ref 10:429-430).

The average of the variance inflation factors for a given set of data is denoted as R_L where

$$R_L = \frac{\sum_{i=1}^p \text{VIF}_i}{p} . \quad (2.4)$$

This ratio measures the squared error in the OLS estimators relative to the size of that error if the data were orthogonal; it is called an "index of multicollinearity."

Ridge Regression Estimation

In ridge regression, the parameter estimates are obtained by solving $\hat{\beta}^*(k) = (X'X + kI)^{-1} X'Y$ where k is a non-negative constant. One approach for selecting the value of k for the problem, as suggested by Hoerl and Kennard (Ref 12:64-65), is examination of the ridge trace, a plot of the estimated values of the parameters as a function of k . The value of k is selected as soon as the coefficients stabilize in magnitude. Other methods of selecting the value of k are discussed in the literature review in Chapter III.

Properties of the Ridge Regression Estimator

Ridge estimation produces biased estimates since the expected value of $\hat{\beta}^*(k)$ is

$$E[\hat{\beta}^*(k)] = (X'X + kI)^{-1} X'X\beta . \quad (2.5)$$

The variance-covariance matrix is

$$\text{VAR}[\hat{\beta}^*(k)] = (X'X + kI)^{-1} X'X(X'X + kI)^{-1} \sigma^2 . \quad (2.6)$$

The ridge solution requires some increase in the residual sum of squares above the least squares sum of squares as is shown in

$$\begin{aligned} [Y - X\hat{\beta}^*(k)]' [Y - X\hat{\beta}^*(k)] &= (Y - X\hat{\beta})' (Y - X\hat{\beta}) \\ &+ (\hat{\beta}^*(k) - \hat{\beta})' X'X (\hat{\beta}^*(k) - \hat{\beta}) \end{aligned} \quad (2.7)$$

where $(Y - X\hat{\beta})' (Y - X\hat{\beta})$ is the OLS residual sum of squares.

The mean square error function of $\hat{\beta}^*$ is

$$\begin{aligned} E[L^2(k)] &= E[(\hat{\beta}^* - \beta)' (\hat{\beta}^* - \beta)] \\ &= \sigma^2 \sum_{i=1}^p \lambda_i / (\lambda_i + k)^2 + k^2 \beta' (X'X + kI)^{-2} \beta \\ &= \sum_{i=1}^p \text{Var}(\hat{\beta}_i^*) + \text{Bias}^2(\hat{\beta}^*) . \end{aligned} \quad (2.8)$$

The first element is the sum of the variances (total variance) of the parameter estimates while the second is the square of the bias introduced when $\hat{\beta}^*$ is used instead of $\hat{\beta}$.

The total variance is a continuous, monotonically decreasing function of k and the squared bias is a continuous, monotonically increasing function of k .

Figure 1 shows the qualitative form of the relationships between the variances, the squared bias, and the parameter k . As is indicated by the dotted line, the sum of the variance and squared bias, the possibility exists that there are values of k (admissible values) for which the mean square error is less for $\hat{\beta}^*$ than it is for $\hat{\beta}$.

Fig. 1. Mean Square Error Functions

Mathematically, it can be shown that $E[L_1^2(k)]$ will go through a minimum and that the squared bias approaches $\beta'\beta$ as an upper limit. As the magnitude of $\beta'\beta$ increases, the minimum will move toward $k=0$. Because $\beta'\beta$ is not boundless in practice, there should be a value (or values) of k that will put $\hat{\beta}^*$ closer to β than $\hat{\beta}$. See Hoerl and Kennard (Ref 12) for proofs and complete development of the theory.

The Ridge Trace

The ridge trace is a two-dimensional plot of the ridge coefficient estimates, $\hat{\beta}^*(k)$, against k . It helps

provide an insight into the structure of the problem and the sensitivity of the results to the particular set of data at hand. For nearly orthogonal data, the ridge trace provides little additional information. However, as multicollinearity in the data increases, the ridge trace stabilizes more rapidly (the rate of change of the standardized coefficients gets rapidly smaller) providing a significant contribution in the analysis of the problem (for example, see Hoerl and Kennard (Ref 13)).

The ridge trace is a characterization of a constrained optimization problem. The residual sum of squares of an estimator B of the vector β is

$$\begin{aligned}\phi &= (Y - XB)'(Y - XB) \\ &= (Y - X\hat{\beta})'(Y - X\hat{\beta}) + (B - \hat{\beta})'X'X(B - \hat{\beta}) \\ &= \phi_{LS} + \phi(B)\end{aligned}\tag{2.9}$$

which is the minimum found by the least squares solution plus the value of the quadratic form. A move from the minimum sum of squares point (ϕ_{LS}) might be reasonable if the length of regression vector (B) could be shortened.

The ridge trace follows a path through the sum of squares surface so that for a fixed value of ϕ , a minimum value of B is chosen. Stated mathematically, the optimization problem is

$$\begin{aligned}&\text{minimize } B'B \\ &\text{subject to } (B - \hat{\beta})'X'X(B - \hat{\beta}) = \phi_0.\end{aligned}\tag{2.10}$$

Using the Lagrangian approach, the solution to the problem is

$$B = \hat{\beta}^* = (X'X + kI)^{-1} X'Y ,$$

the ridge estimator where k is chosen to satisfy the constraint (equation 2.10). In practice, it is easier to choose $k > 0$. This results in an increase in the residual sum of squares and reduction in the R^2 , however, it allows for minimization of the regression vector.

Monte Carlo Simulation of the Data

The comparison of ridge and least squares estimators requires a large number of trials. Consequently, Monte Carlo simulation was used to generate 1,000 data sets for each of the predictor variable combinations. Several subroutines from the International Mathematical and Statistical Library, IMSL (Ref 15), were used in FORTRAN programs DATA and DATAL to generate the predictor and criterion variable values for the linear and log-linear model forms. The FORTRAN statements in these programs are contained in Appendices A (program DATA) and B (program DATAL).

For the linear model, subroutine GGNSM was used to produce the predictor variable deviate vectors with known correlation matrix from a multivariate normal distribution. Corresponding criterion variable values were generated by adding a mean corrected random error deviate from a univariate normal distribution (subroutine GGNML), adjusted to

variance σ^2 , to a linear combination of the predictor variable deviates and known coefficient parameters (β 's).

For the log-linear model, the predictor variable vectors were produced by mean correcting the natural logarithms of the multivariate normal deviates generated by subroutine GGNSM. The criterion variable values ($\ln(Y)$'s) were generated by adding a random error similar to that described for the linear model to a linear combination of the known coefficient parameters and the predictor variable values ($\ln(X)$'s).

The random error terms of both models were mean corrected so that the X's, Y's, $\ln(X)$'s, and $\ln(Y)$'s would have zero means and the resulting regression models would have no Y-intercept term. The coefficient parameters were chosen as 1's for all trials so that all variables would have equal weighting in the analysis.

The relative magnitude of the random error term, with respect to the value of the linear combination of the known coefficient parameters and predictor variables, was used to control the model fit (R^2). The correlation matrix for the simulated predictor deviates was used to control the size of the variance inflation factors. Separate data was generated for each model size (2, 3, or 4 variable models); however, the same random number seed was used for all data sets.

In keeping within the usual limitations of cost estimating data sets, a sample set of 20 random vectors was

used to perform each least squares and ridge regression analysis. Similar analyses of the 1,000 random sample sets provided the data for comparison of the two estimators.

Predictor Variables

The predictor variables for the model used to compare OLS and ridge estimator performance include the number of variables (NVAR), the value of k (K), the index of multicollinearity (RL), and the model fit under least squares (RSQ). Each variable will be explained in detail in succeeding paragraphs.

To determine the impact of model size on comparison of estimators, the analysis was performed for 2, 3, and 4 variable models. Data for each model size was generated using different correlation matrices. The correlation matrices were chosen so as to have reasonably similar determinants for the three levels of multicollinearity investigated.

The value of k was chosen by analyzing the ridge trace and the variance inflation factors for the first sample set. Once a value of k was selected, it was used for all 1,000 analyses.

The index of multicollinearity was chosen as

$$R_L = \frac{\sigma^2 \sum_{i=1}^p VIF_i}{\sigma^2 p} = \frac{\sum_{i=1}^p VIF_i}{p} . \quad (2.11)$$

It measures the squared error in the OLS estimators relative to the size of that error if the data were orthogonal (Ref 1:183). It is interesting to note that this index can also be thought of as the average variance inflation factor of the $(X'X)^{-1}$ matrix since p is the number of predictor variables. The mean of the average variance inflation factors for the 1,000 trials was treated as the predictor variable RL.

The model fit is measured by coefficient of determination (R^2), the ratio of SSR (sum of squares regression) and SST (sum of squares total) in the regression model. The mean of the least squares R^2 (RSQLS) for the 1,000 trials was treated as the predictor variable RSQ.

Measure of Effectiveness

The criterion for evaluation of the two estimators is the mean square error (MSE) of the regression coefficients. The mean square error for the vector $(\hat{\beta})_i$, least squares solution for trial i , is defined as

$$MSE(\hat{\beta})_i = E \left[\sum_{j=1}^p (\hat{\beta}_j - \beta_j)^2 \right]_i . \quad (2.12)$$

For the 1,000 trials, the average MSE $(\hat{\beta})$ becomes

$$\overline{MSE}(\hat{\beta}) = \frac{\sum_{i=1}^{1000} MSE(\hat{\beta})_i}{1000} . \quad (2.13)$$

Similarly, the mean square error for the vector $(\hat{\beta}^*)_i$, ridge regression solution for trial i , is defined as

$$MSE(\hat{\beta}^*)_i = E\left\{ \sum_{j=1}^p (\hat{\beta}^*_j - \beta_j)^2 \right\}_i . \quad (2.14)$$

For the 1,000 trials, the average MSE $(\hat{\beta}^*)$ becomes

$$\overline{MSE(\hat{\beta}^*)} = \frac{\sum_{i=1}^{1000} MSE(\hat{\beta}^*)_i}{1000} . \quad (2.15)$$

The ratio of these averages,

$$\frac{\overline{MSE(\hat{\beta})}}{\overline{MSE(\hat{\beta}^*)}} , \quad (2.16)$$

indicates the relative improvement or deterioration of the ridge regression model with respect to the least squares model in a mean square error sense. A ratio greater than one indicates an improvement by the ridge regression; the greater the ratio, the greater the relative improvement. A ratio less than one indicates that the ridge regression model provides a worse model in the mean square error sense; the smaller the ratio, the worse the model.

III. Literature Review

Introduction

A considerable amount of research has been done based on the results of Hoerl and Kennard (Ref 12) who proposed and developed a comprehensive theory supporting the argument that it is helpful to augment the diagonal of the normal equations matrix by a small positive quantity in order to prevent "inflation" of the elements of the regression coefficient vector. The most significant portion of the research has been focused in the following areas:

1. Estimation methods for the value of k , the ridge bias parameter.
2. (a) Development of other ridge estimators and the comparison of these estimators with the standard ridge estimator, $\hat{\beta}^* = (X'X + kI)^{-1} X'Y$, and the ordinary least squares estimator.

(b) Development of alternative solutions to the ridge trace and generalized ridge regression procedures presented in Hoerl and Kennard (Ref 12:63-66).
3. (a) Development of the theoretical properties of the ridge regression family of estimators.

(b) Attempts to identify the probability distribution of ridge estimators.

4. Alternative methods to MSE of the coefficients for evaluating the regression estimates.

5. Simulation studies comparing ridge and other biased estimators with unbiased estimators (principally OLS) using Monte Carlo techniques.

6. Studies dealing with the practical application of ridge regression.

Estimation Methods for k

In their original papers (Refs 12; 13), Hoerl and Kennard discussed the use of the ridge trace as the "best method for achieving a better estimate $\hat{\beta}^*$ " with respect to mean square error. This method involves selecting a single value of k (all $k_i = k$) once the system has stabilized and has the general characteristics of an orthogonal system. Although reasonably simple, this method has been criticized by Smith and Campbell (Ref 33), Thisted (Ref 36), Van Nostrand (Ref 37), and others who oppose restricting the parameters of the model and mechanically manipulating the data without knowledge of the phenomena being modeled (using a priori information about the coefficients).

Another approach presented in the original papers to achieve a better estimate $\hat{\beta}^*$ was generalized ridge regression (GRR). The general linear regression model $Y = X\beta + u$ is reduced to canonical form by transformations so that the $X'X$ matrix is diagonal. Iteration is used to find optimal k_i 's which achieve stability in estimates in

the canonical form. The GRR estimates are obtained from the canonical model estimates through an inverse transformation.

As an alternative to the iterative approach of Hoerl and Kennard, Hemmerle (Ref 9) proposed a non-iterative, closed form solution. This solution was shown to depend on certain convergence/divergence conditions which related to the ordinary least squares estimator. When the proper conditions are met, an explicit solution for the optimum canonical model estimates is obtained leading directly to estimates of the k_i 's.

Directed ridge regression, a modification of the procedure of Hoerl and Kennard, was proposed by Guilkey and Murphy (Ref 4). This method alters only diagonal elements corresponding to low eigenvalues in an attempt to produce less bias in the coefficient estimates than methods that alter all the diagonal elements.

Other Ridge Related Estimators and Solution Techniques

To overcome the objections to using a subjective estimate of k (or k_i 's), a number of estimators for k have been suggested. Hoerl, Kennard, and Baldwin (Ref 14) proposed the estimator $k = p\hat{\sigma}^2 / \hat{\beta}'\hat{\beta}$ where $\hat{\beta}$ and p have been defined previously and $\hat{\sigma}^2$ is an unbiased estimate of σ^2 . McDonald and Galarneau (Ref 24) suggested "ridge-type" estimators formed by first estimating the squared length of the unknown coefficient vector and then choosing the

value of k so that the ridge estimator squared length was equal to this estimated quantity.

Since

$$E(\hat{\beta}'\hat{\beta}) = \beta'\beta + \sigma^2 \sum_{i=1}^P (1/\lambda_i) \quad (3.1)$$

the quantity

$$Q = \hat{\beta}'\hat{\beta} - \hat{\sigma}^2 \sum_{i=1}^P (1/\lambda_i) \quad (3.2)$$

is an unbiased estimator of $\beta'\beta$. Therefore, for $Q > 0$ McDonald and Galarneau suggested the estimator $\hat{\beta}_k$, such that $\hat{\beta}_k'\hat{\beta}_k = Q$. For $Q < 0$, they suggested selecting k equal to zero (OLS estimator) or infinity (zero vector estimate). Simulations by both sets of authors have shown that the estimators did well for some selections of the parameters but worse for others as compared to the OLS estimator. McDonald and Galarneau also concluded that the performance of the ridge estimators depended on "the variance of the random error, the correlations among the explanatory variables, and the unknown coefficient vector."

A computer iteration technique for finding the k value associated with the minimum mean square error of estimation was proposed by Kasarda and Shih (Ref 17). This technique is based on the monotonic properties of the total variance and squared bias terms as shown by Hoerl and Kennard (Ref 12:60-63). The MSE is estimated by a variable ($\widehat{MSE}$) which, through computer iteration, converges

on the minimum point, yielding the optimum k value. This technique is also applicable to the directed ridge regression approach discussed earlier.

Another alternative to subjectively selecting a k value, the minimum mean square error estimator, was proposed by Farebrother (Ref 3). This estimator was extended and simulated in Vinod (Ref 39) where it was found to be inferior (in MSE) to a Stein-Rule estimator (see Judge, Bock and Yancey (Ref 16) for a detailed study of Stein-Rule estimators).

Several nonstochastic estimators of k have been proposed by Gunst and Hua (Ref 6) and Vinod (Ref 38). The two methods proposed by Gunst and Hua include one where k is chosen so that $|X'X+kI|=1$ (forcing the ridge system to behave orthogonally) and a second where k is chosen so that the largest variance inflation equals 4. The method proposed by Vinod involves choosing k so that the "multicollinearity allowance"

$$m = p - \sum_{j=1}^p \lambda_j (\lambda_j + k)^{-1} . \quad (3.3)$$

Here, m has the interpretation as the assigned deficiency in the rank of $(X'X)$. The value of k is found iteratively once the rank deficiency has been assigned. Vinod also proposed using a "ridge trace" as a function of the multicollinearity allowance (m) instead of the standard ridge trace (function of k). He proposed the Index of Stability

of Relative Magnitudes (ISRM) to quantify the stable region of m values.

Gunst and Hua (Ref 6:8-21) found that use of the minimum ISRM proposed by Vinod performed erratically and often indicated several local minima, one of which had to be subjectively selected. They also found fault with the nonstochastic rule requiring $|X'X+kI|=1$. In some cases, the determinant of $X'X$ matrix was so small that a large value of k caused the bias of the ridge estimator to overcome the reduction in variance negating the advantage of using ridge regression.

Theoretical Properties of Ridge Estimators

Several theoretical studies were conducted to provide additional information about the properties of ridge estimators. Hawkes and Alam (Ref 8) discussed the theoretical properties of ridge estimators using both classical and Bayesian statistics. They showed that for certain choices of k , depending on Y , the ridge estimator had uniformly smaller mean square error than the least squares estimator, provided that a number of the characteristic roots of the $X'X$ matrix were sufficiently small.

An investigation of the probability distributions of ridge estimators was conducted by Lewis (Ref 20) so that hypothesis tests and computation of confidence bounds could be made for $\hat{\beta}^*$. It was found that the distribution of $\hat{\beta}^*$ depended on the objective rule used to select k .

The objective rules selected by the author did not lead to useful probability distributions.

Alternative Evaluation Methods

The majority of the studies comparing estimators used the concept of mean square error of the coefficients as the criteria for evaluation. Gunst and Mason (Ref 7), on the other hand, used integrated mean square error (IMSE) in evaluating ridge, principal component, and least squares estimators. This method was found to introduce the problem of choosing a weighting function to determine the IMSE in addition to the other estimation problems. Also, the results were not considered conclusive since the determination of the effects of variable selection on the technique and the impact of restrictions on the estimators used in the analysis required more research.

Simulation Studies of Ridge and Other Estimators

Many comparisons have been made between ridge regression and other estimators using the Monte Carlo simulation technique. Newhouse and Oman (Ref 29) performed a study which was restricted to the case of two predictors having two different values of r , the correlation between predictors, and a number of methods for choosing k . They concluded that for the two variable case the ridge estimators did worse than the OLS estimators for at least some of the models. The failures were "by a sufficient margin

and in a 'sufficient' number of cases" that they recommended against use of ridge regression. As was pointed out in Eskew (Ref 2:18), however, Sclove (Ref 32) showed in 1967 that no estimator is better in the total mean square error sense than the least squares estimator when only two parameters are estimated. Therefore, the experimental results of Newhouse and Oman only confirm the theoretical work of Sclove.

Lawless and Wang (Ref 19) found results contrary to Newhouse and Oman in their evaluation of ridge estimators. Further, they concluded that it may not be worthwhile to consider generalized ridge estimators since they were found to have inferior mean square error properties than the ordinary ridge estimators.

Simulation results by Newman (Ref 30) supported the first conclusion of Lawless and Wang. He showed that the ridge estimator $\hat{\beta}^*(k)$, found by selecting the value of k from the ridge trace, outperformed other estimators including least squares.

Mitra and Ling (Ref 27) found several ridge estimators, those proposed by Hoerl, Kennard and Baldwin (Ref 14), Farebrother (Ref 3:128), McDonald and Galarneau (Ref 24:409, rule 2), Hoerl and Kennard (Ref 12:63), Guilkey and Murphy (Ref 4:770), and several others, superior to the OLS estimator (in mean square error) and provided a ranking of these estimators based on parameters of the basic regression model.

Su and Chai (Ref 34) performed a comparison of the ridge estimator proposed by Hoerl, Kennard and Baldwin and the least squares estimator using squared error of estimation ($L^2 = (B - \beta)'(B - \beta)$), squared error of prediction ($SSE = (Y - \hat{Y})'(Y - \hat{Y})$), and cross validity (the Pearson's product moment correlation between the observed values in the second sample and the predictions made for the second sample using the ridge estimator estimated from the first sample). The results showed that the ridge estimator was better for nonorthogonal data and the least squares estimator better for orthogonal data (except in one case).

A study by Lindell (Ref 21) considered ridge (Hoerl, Kennard and Baldwin (Ref 14)), ordinary least squares, and jackknife estimators (Mosteller and Tukey (Ref 28)) evaluated using the criteria of mean square error of the coefficients and the size of the t-statistics associated with these coefficients. The design considered two factors, the sample size to number of predictors ratio (N/p) and the metric quality of the data (dichotomous and polychotomous data were used to assess the sensitivity of the estimators to different levels of violation of the regression assumptions). The results of the study showed that the ridge estimator performed better for smaller N/p ratios and worse for higher levels.

Eskew (Ref 2) and other authors, some of whom include Lindley and Smith (Ref 22), Smith and Campbell (Ref 33), Thisted (Ref 36), and Van Nostrand (Ref 37), have

proposed the use of "a priori" information along with ridge regression in the estimation of the regression coefficients (Bayesian approach). In this approach, if the prior estimate of the coefficients is closer than the origin (zero-prior of the classical ridge estimator) to the true model parameters, then the squared bias of the ridge estimators will be reduced without an increase in variance. This results in an even greater improvement over the OLS estimator (in mean square error). Eskew showed that with "good" or even "fair" prior information that the ridge method was superior to OLS for estimation of the model parameters.

Practical Application Studies

Some practical aspects of ridge regression have been addressed by Marquardt and Snee (Ref 26) and Gunst (Ref 5). Three practical application examples were presented in Marquardt and Snee. They noted that models with no constant term required a smaller value of k (often $\leq .01$) than models with a constant term. Also, they claimed that models with lower R^2 statistics required larger values of k than better fitting models. The study further showed that the ridge regression coefficients performed better for prediction and extrapolation than least squares and were useful for selecting variables. Hocking (Ref 11:11, 23,28-31,37-44) also supported the use of ridge regression for variable selection.

Gunst applied ridge regression and two other biased estimators to a data set of automobile emissions. A number of selection rules for determining k were tried yielding similar estimates from the data. The resulting ridge model generated coefficients with magnitudes and signs inconsistent with a priori beliefs. However, it was judged superior to the OLS model.

Conclusions

The ridge regression technique has been shown to possess valuable theoretical and empirical properties which appear advantageous when the predictor variables are collinear. Many methods have been suggested for determining the amount of bias which is "optimal." The body of research has shown that no one method of choosing k is clearly superior to the others.

In terms of mean square error of the coefficients, improvements can be made for prediction and extrapolation by using ridge regression. The criticisms of several authors have pointed out that ridge regression must be used carefully in order to fulfill two important requirements: the model produced must make sense from the physical nature of the problem, and it must provide predictions close to reality.

IV. Research Methodology

Overall Approach

The overall approach of the investigation involved generating mean square error data for various levels of the independent variables (RSQ, RL, NVAR, and K) and analyzing this data using a linear regression model to determine which factor(s) produced a significant impact on the mean square error improvement (degradation) for the ridge versus OLS models. The regression approach was chosen because the independent variable levels could not be specified as is required for the treatments in an Analysis of Variance (ANOVA). In particular, the variables RL and RSQ were outputs of programs DATA and DATAL controlled by a correlation matrix with varying intercorrelations and dimensions (for RL) and the variance of the random error of the known model (for RSQ).

Model Development

A FORTRAN program, RIDGE, developed by McNichols (Ref 25) from theory presented in Chatterjee and Price (Ref 1:181-187), was used to portray the ridge trace and provide other outputs for the first data set (20 random vectors). The computer code for this program is contained in Appendix C.

The outputs of program RIDGE consisted of the following:

1. Sample means and standard deviations of both dependent and independent variables.
2. Sample covariance matrix of all variables.
3. Values of the standardized coefficient estimates, $\hat{b}^*$, for each value of k .
4. Values of the unnormalized coefficient estimates ($\hat{\beta}$ for $k=0$ and $\hat{\beta}^*$ for $k>0$) for each value of k computed from

$$\hat{\beta}_j^* = \hat{b}^*(s_j/s_y) \quad (4.1)$$

where s_j is the sample standard deviation of the j th variable and s_y is the sample standard deviation of the dependent variable.

5. Values of the Variance Inflation Factors (VIF's) for each coefficient at each value of k . The VIF's are the diagonal elements of the matrix

$$(X'X+kI)^{-1} X'X (X'X+kI)^{-1} \quad (4.2)$$

which when multiplied by σ^2 is the variance/covariance matrix of $\hat{b}^*$.

The values of k were selected at three or more levels including $k=0$ (OLS solution), the k value corresponding to all VIF's less than or equal to 10 (where appropriate), and others selected where the ridge trace

(standardized coefficient estimates) and VIF's appeared to stabilize.

A modified RIDGE program was used to perform 1,000 Monte Carlo trials using the k value selected by reviewing the output from RIDGE. A listing of the program is contained in Appendix D. The program generated the following data for each trial (the variables listed are SPSS variable names used in the CONDESCRIPTIVE analysis discussed below):

1. Unstandardized coefficient estimates (variables BLS1 to BLS4).
2. Ridge coefficient estimates (variables BR1 to BR4).
3. Variance Inflation Factors for the OLS solution ($k=0$) and selected k value (variables VIFLS and VIFR, respectively).
4. Model fit (R^2) for the OLS solution (variable RSQLS) and selected k value (variable RSQR).
5. Index of multicollinearity (variable RL).
6. Mean square error for the OLS solution and selected k value (variables MSELS and MSER, respectively).

Several statistics were computed using subprogram CONDESCRIPTIVE of SPSS (Statistical Package for the Social Sciences) (Ref 31) for the data produced by the Monte Carlo RIDGE program.

The mean, standard deviation, variance, range, and minimum and maximum values for each variable (dependent and

independent) were computed from the 1,000 cases at both the $k=0$ and selected $k>0$ levels.

The independent variables for the regression analysis (RSQ, RL, NVAR, and K) were taken from both the CONDESCRIPTIVE output (RSQ and RL) and the Monte Carlo inputs (NVAR and K). The variable RSQ was the mean of the R^2 values for the 1,000 trials; RL was the mean of the RL's for the trials.

The dependent variable for the regression analysis was the mean square error ratio (MSERATIO) as defined and interpreted in Chapter II. The numerator, MSELs, was computed in the Monte Carlo analysis for $k=0$; the denominator, MSER, for the selected $k>0$ value. The ratio (MSELs/MSER) was computed in the regression analysis through use of a COMPUTE statement (Ref 31:96-97).

Generation of the Data

The levels of the independent variables were chosen to generate data consistent with the usual limitations of cost estimating data sets. Each variable will be discussed separately in the succeeding paragraphs.

Three levels of RL were considered corresponding to low (RL (mean) approximately equal to 1.5 - 2), medium (approximately 10), and high (approximately 100) degrees of multicollinearity. RL values below 1.5 were considered too orthogonal and above 120 excessively collinear. The correlation matrices (dimensions 2-4) used to generate the

independent variable deviates (X's) were chosen from actual data sets by evaluating the determinant of each matrix and grouping matrices with similar determinants together (one from each dimension). Correlation matrices with determinants very close to zero produced data with high multicollinearity; matrices with large determinants produced near-orthogonal data.

Only models with RSQ values between 52 and 99.8 percent were used in the analysis since estimates involving cost would not frequently be made with models of poorer fit.

Separate data were generated for models of each size (NVAR); however, the same random number seed was used to generate each set of data. Three SPSS programs were necessary to analyze the data output from the Monte Carlo RIDGE program due to the three model sizes considered. The computer code for these programs is contained in Appendix E.

Analysis of the Data

The REGRESSION subprogram of SPSS was used as the descriptive tool to identify the structural nature of the relationship between mean square error improvement (degradation) of ridge versus OLS models as a function of linear combinations of the predictor variables. For this problem it was appropriate to isolate the smallest subset of predictor variables that yielded the greatest impact on the model. Therefore, the stepwise solution procedure was selected. This procedure combined forward inclusion, the

entering of independent variables that met pre-established statistical criteria, with deletion of variables that met specified exit criteria at each successive step.

The variables considered by the model included the four predictor variables, all first order cross products (six interaction terms), and squared predictor variable terms.

The principal criteria for evaluating the terms of the model included the following:

1. Comparing the coefficient of determination (R^2) for each model step.
2. Comparing the relative size of the partial F-statistics for all variables within each model step.
3. Comparing the relative size of the partial F-statistic for the variables entered during each model step.

The size of the coefficient of determination was interpreted as the percent of total variation explained by the variables in the regression model. The change in the R^2 for a step indicated the additional percentage of variation explained by the variable entering the model, given the variables already in the model. For this analysis, the R^2 statistic was clearly the most important measure for determining the key variables (terms).

The size of the partial F-statistic for each variable within a model step indicated the significance (relative importance) of that variable with respect to the model

formed for that step. The most significant variable contained the highest partial F-statistic and so on.

The partial F-statistic for each variable entering the model was compared between model steps as a further measure of the relative importance of each additional variable to the model.

The SPSS programs used to perform the regression analysis are contained in Appendix F. The output from these programs will be presented and discussed, along with the results, in Chapter V.

V. Results and Conclusions

Linear Model Data Analysis

The regression analysis of the linear model data produced a seven variable model. This model was based on 115 cases which are presented in Appendix G. A summary of the linear model regression results is contained in Table 1.

Based on the criteria used to evaluate the terms of the model discussed in Chapter IV, the key term in the model was determined to be CROSS4, the cross product of K and RL. This term explained 82.6 percent of the total variation in the data and was much more significant than the other terms entering the model as is shown by the partial F-statistics under the "F to enter or remove" column of Table 1. Also, throughout all of the regression steps, the CROSS4 term remained much more significant than the other variables. This is shown in columns "Partial F of CROSS4" and "Partial F of the Next Most Significant Term."

Because of the high amount of variation explained by the CROSS4 term, the small contributions made in explaining the remaining variation by the other terms, and the relative sizes of the partial F-statistics discussed above, CROSS4 was selected as the key variable explaining nature of the relationship between mean square error improvement (degradation) of the ridge versus OLS models.

TABLE 1
SUMMARY OF REGRESSION ANALYSIS RESULTS--LINEAR MODEL DATA

Step	Variable Entered (Removed)	R ²	R ² Change	F to Enter or Remove	Partial F of CROSS4 Term	Partial F of Next Most Significant Term (Variable)
1	CROSS4	.826	.826	537.65	537.65	14.29 (CROSS3)
2	CROSS3	.846	.020	14.29	612.05	14.29 (CROSS3)
3	CROSS6	.851	.005	3.74	625.25	10.42 (CROSS3)
4	K	.856	.005	3.72	590.78	4.90 (CROSS6)
5	RL	.860	.004	3.25	267.71	6.45 (CROSS6)
6	CROSS5	.885	.025	22.95	343.01	26.75 (RL)
7	CROSS2	.886	.001	1.72	313.56	28.31 (RL)

NOTES:

^aVariables defined: CROSS2 - RSQ x K; CROSS3 - RSQ x NVAR; CROSS4 - RL x K; CROSS5 - RL x NVAR; CROSS6 - K x NVAR.

^bAll variables (terms) with F-statistics less than 1 are omitted from the table.

Graphical Analysis of the Linear Model Data

The interrelationship of the variables in the CROSS4 term is shown in Figure 2. The graph is a plot of MSERATIO (improvement/degradation of the ridge versus OLS model) versus K at fixed levels of RL. For two of the lower values of RL (1.536 and 1.830), the results were mixed. Slight improvements (MSERATIO between 1.0 and 1.60); were shown for 16 cases; however, slight degradations (MSERATIO between 0.19 and 1.0) were shown for 4 cases. For RL levels 2.196 to 13.424, greater improvements (MSERATIO between 1.0 and 4.16) were made while there were no degradations. The size of the improvements increased consistently with k for a given level of RL and with RL for a given level of k. For high levels of RL (50.841 to 119.772), large improvements (MSERATIO between 1.0 and 86.94) were realized, especially for models of poorer fit (R^2 values of 90 percent or lower).

Results of the Linear Model Analysis

For the linear model, ridge regression provided the greatest MSE improvement in situations with high multicollinearity, especially for models with an R^2 value of 90 percent or lower. Only in a few situations did the technique show a degradation in the mean square error. These were due to overestimating the value of k, causing the bias to overcome the reduction in variance of the ridge

Fig. 2. Graphical Analysis--Linear Model Data

estimator. Consequently, conservative estimates of k , less than or equal to 0.04, limit worsening the mean square error for data with low RL values (RL less than 2) and enable larger improvements to be made for more collinear data (RL greater than 2).

Log-Linear Model Data Analysis

The regression analysis for a log-linear model data produced a nine variable model. The model was based on 108 cases which are presented in Appendix H.

Using the same evaluation criteria as the linear model, CROSS4 (cross product of K and RL) was again selected as the key term explaining the improvement (degradation) in the MSE. A summary of the log-linear regression results is contained in Table 2.

For the log-linear model, the CROSS4 term explained 92.4 percent of the total variation in the data; each of the remaining eight terms explained less than 0.9 percent of the variation (contributed less than .009 to the R^2 statistic) as they were added to the model.

As in the linear model, CROSS4 was much more significant (partial F-statistic to enter equal to 1280.23) than any other variable entering the model. The next most significant term was CROSS6 with an F to enter of 15.28. Throughout the iterations of the stepwise regression, CROSS4 remained the most significant term by a wide margin

TABLE 2

SUMMARY OF REGRESSION ANALYSIS RESULTS--LOG-LINEAR MODEL DATA

Step	Variable Entered (Removed)	R ²	R ² Change	F to Enter or Remove	Partial F of CROSS4 Term	Partial F of Next Most Significant Term (Variable)
1	CROSS4	.924	.924	1280.23	1280.23	15.28 (CROSS6)
2	CROSS6	.933	.009	15.28	1320.80	15.28 (CROSS6)
3	CROSS5	.941	.008	14.33	976.55	22.58 (CROSS6)
4	RL	.946	.005	10.24	638.00	22.87 (CROSS5)
5	CROSS1	.950	.004	6.74	677.23	28.84 (CROSS5)
6	NVAR	.951	.001	2.77	690.04	28.70 (CROSS5)

^bAll variables (terms) with F-statistics less than 1 are omitted from the table.

as is shown in the comparison of partial F-statistics of CROSS4 and the next most significant term in Table 2.

Graphical Analysis of the Log-Linear Model Data

The interrelationship for the variables in the CROSS4 term of the log-linear model is shown in Figure 3. The graph shows results very similar to the linear model. Mixed results were obtained for RL values 1.528 and 1.836. As with the linear model, the degradations were due to overestimates of k. Slight improvements (MSERATIO between 1.0 and 1.18) were shown for 21 cases while 3 cases showed a slight degradation (MSERATIO between .25 and 1.0) in the mean square error. Similar improvements (MSERATIO between 1 and 3.66) were shown for RL levels between 3.174 to 12.127 as the 2.196 to 13.424 levels in the linear model. Again, greater improvements (MSERATIO between 1.0 and 64.29) were made for RL levels 50.926 to 120.029 with the largest corresponding to models with poorer fit (R^2 values of 92 percent or lower).

Results of the Log-Linear Model Analysis

The overall results of ridge regression for the log-linear model are the same as those for the linear model. Conservative estimates of k, less than or equal to 0.04, limit the worsening effects of bias in the ridge regression estimates (RL values less than 2) while enabling

Fig. 3. Graphical Analysis--Log-Linear Model Data

more significant improvements to be made for data with higher degrees of multicollinearity (RL values greater than 3).

Conclusions

The regression and graphical analyses showed, within the limitations and assumptions of the investigation, when ridge regression provided a better estimate of the coefficients of a system cost model compared to ordinary least squares for simulated data. From the regression analysis, the interaction of the value of k and the degree of multicollinearity (RL) determined the amount of relative improvement in the mean square error. The graphical analysis showed in detail how the variables interacted and what degree of improvement (degradation) could be expected from the data.

In using the ridge trace to select the value of k , it was important to consider the tradeoff between reduction in variance and increase in bias on the mean square error of the coefficient vector. Conservative estimates ($k \leq 0.04$) allowed for reduction in variance desired in the biased estimate for RL values as low as 1.536 for the linear model and 1.528 for the log-linear model. Further, the ridge trace and variance inflation factors of the $(X'X)^{-1}$ matrix were valuable in choosing the value of k , particularly for RL levels greater than or equal to five.

Recommendations

Based on the results of this investigation, it is recommended that ridge regression be used as a tool to construct cost estimating models for data exhibiting multicollinearity. It is particularly valuable for high levels of multicollinearity (RL levels greater than 50) but also shows moderate improvements in MSE for lower RL levels (RL levels as low as 2).

The ridge trace and variance inflation factors can be used to select k which determines the amount of bias in the regression coefficient estimates. It is recommended that conservative estimates be made so that k is less than or equal to 0.04. However, for data producing one or more of the VIF's greater than or equal to 10, the estimate of k should be large enough to reduce the largest VIF to below 10. A priori information about the signs of the coefficients can also be used, within the boundaries recommended, in constructing the model. The value of k is selected after the standardized coefficients have stabilized to the "correct" sign and magnitude.

Suggested Follow-on Research

Further research could be directed at comparing predictions of the ridge and OLS models using actual data. These comparisons could be made using several existing statistics used by cost analysts.

Further Monte Carlo comparisons could be conducted examining prediction intervals of the two estimators. Selection of the appropriate technique might be based on the smallest prediction interval as an alternative to improvements in mean square error of the coefficient vector.

Finally, continued research could be conducted comparing the different methods for selecting k , using the basic variables considered in this study. Although the ridge trace and variance inflation factors provided valuable information for selecting a value of k , additional guidance concerning non-subjective methods for choosing k could simplify the modeling procedure and lead to expanded use of the ridge technique in the area of cost estimation.

VITA

James Richard Makin was born 30 May 1950 in Washington, D.C. He graduated from high school in Bel Air, Maryland in 1968 and attended Drexel University from which he received the degree of Bachelor of Science in Commerce and Engineering in June 1973. Upon graduation, he received a commission in the United States Army through the ROTC program and was called to active duty in July 1973. He completed the Infantry Officer Basic Course and airborne training prior to being assigned to the 9th Infantry Division, Ft. Lewis, Washington in February 1974. During this assignment he performed duties as platoon leader, executive officer, company commander, maintenance officer and others. He completed the Ordnance Officer Advanced Course in December 1979 and subsequently served as tank/automotive maintenance officer of the 2d Infantry Division, Camp Casey, Korea until entering the School of Engineering, Air Force Institute of Technology, in June 1980.

Present address: 27 Brooks Road
Bel Air, Maryland 21014
