PART A

STUDIES ON INFERENTIAL PROCESSING

F. M. Brown

FOREWORD

This Final Report presents the results of an eight-month project on the design and application of an inferential processor. The work on this project, conducted under Grant AFOSR 81-0115, commenced on 1 April 1981 and was completed on 30 November, 1981.

The research was carried out in the Department of Electrical Engineering at the University of Kentucky. Those principally involved were F. M. Brown (principal investigator), D. K. Taylor, and M. R. Rowlette; the latter two are graduate students who were supported by funds provided by the University of Kentucky.

ABSTRACT

Results are presented concerning the design and application of an inferential processor, a digital machine organized to process logical data at high rates of speed. When coupled to a general-purpose digital computer, the inferential processor would enable reasoning tasks to be carried out rapidly and with little programming effort. Specific research-efforts discussed in this report are (a) mechanized inference in Boolean systems, (b) functional deduction, and (c) inferential analysis of relational databases.

I. INTRODUCTION

The objective of the research described in this report has been to investigate the design and application of an inferential processor, a machine specialized for rapid processing of Boolean (i.e., propositional) data. This research is part of a longer-term effort to mechanize a new approach to reasoning in propositional logic. The basic ideas underlying this approach have been worked out over a period of several years; the practical implementation of those ideas was first undertaken in 1980, however, while the principal investigator was at the Air Force Avionics Laboratory under the sponsorship of the USAF/SCEEE Summer Faculty Research Program.

The proposed inferential processor, which is intended to augment the computational power of a general-purpose computer, is to be a high-speed reasoning system having very general capability within the domain of propositional logic. It may be implemented either by microprogramming a general-purpose computer or by attaching to such a computer a special-purpose processor; the latter implementation [1] is assumed in this report.

Our research during the grant-period has been organized into the following tasks:

1. Mechanized Inference in Boolean Systems (F.M. Brown);
2. Functional Deduction (F.M. Brown);
3. Boolean Analysis of Relational Databases (D.K. Taylor);
4. Simulation of the Inferential Processor (M.R. Rowlette).

The foregoing research-tasks were undertaken as eight-month efforts promising the greatest progress toward the objectives stated in our proposal. We present in this report the results of the first three tasks; the results of the final task are to appear in an M.S. thesis which is currently underway.

The objective of the first task, Mechanized Inference in Boolean Systems, was to develop an organized and coherent theory of Boolean analysis. The basic inferential operations on systems of Boolean equations were studied, terminology was established, and properties fundamental to the operation of the inferential processor were proved. The objects of the first task were principally those of clarification, terminology, and proof. In the second task, Functional Deduction, our object was to investigate a new application of the processor, one which had only been sketched in our previous research [2]. We believe functional deduction to be a fundamental operation in Boolean analysis; it is the inverse, essentially, of the much-studied problem of solving Boolean equations. The results obtained under this task enable functional deduction to be performed rapidly and efficiently by the inferential processor. To study its essential features and illustrate its practical utility, we have applied functional deduction to the design of economical multiple-output combinational circuits.

The objective of the third task, Boolean Analysis of Relational Databases, was to investigate potential applications of the inferential processor to database processing. We began by

studying the problems associated with relational databases. This study showed that the generation of keys for a database is a difficult problem of practical importance. The keys may be determined if the functional dependencies associated with the database are known; we therefore devised an algorithm (the first to our knowledge) for generating the functional dependencies in a given relational database. This algorithm also produces the full set of minimal keys for the database. The algorithm was programmed entirely in the logical language PROLOG [3,4], which was used for two reasons: first, this language is most effective for programming tasks involving logic; second, PROLOG is an "inferential processor" in software, whose operation we wished to study.

This report is organized in two parts. Part A includes general background on logical computers and some discussion of the motivation for our research (Section II), a brief description of the structure of the inferential processor (Section III), and discussions of the results obtained under tasks 1 and 2 above (Sections IV and V). Part B, originally prepared as an M.S. thesis [5], presents the results obtained under task 3.

II. LOGICAL COMPUTERS

We outline in this section the motivation for our research, whose ultimate object is to produce a logical computer, i.e., a machine capable of high-speed inferential processing in propositional (Boolean) logic. Some of the material in the present section is taken from a proposal [1] prepared during the grant-period; it is included in this report for completeness.

Propositional logic may be identified roughly with two-valued Boolean algebra. This form of logic has applications in many areas, a few of which are logical design [2], the diagnosis of failures in digital systems [3,4], and the design of relational databases [5]. It is the basis, moreover, for reasoning in higher-order logics such as the first-order predicate calculus; the latter is required for applications in artificial intelligence [6,7]. The propositional calculus is related to the higher-order logics in somewhat the same way that arithmetic is related to the various fields of mathematical analysis; it is a structure, useful in itself, on which more elaborate structures are built.

The range of application of the propositional calculus was outlined by Ledley [8] as follows: "The propositional calculus can be applied to many phases of military science and related problems as well as to business, industry, science, and government in general. In these applications it serves as an aid to complex reasoning, e.g., in the analysis and evaluation of intelligence reports, the preparation and analysis of tactical

methods and principles, the formulation and interpretation of legal statutes, the planning and evaluation of chemical and biological experiments, the formulation of psychological and intelligence examinations, and the formulation and evaluation of business methods and procedures. All of these and similar 'reasoning' activities and operations can use the propositional calculus in a fundamental way. More well-known are its applications to the design of industrial process-control machines, digital computers, large-scale switching circuitry, and other forms of information-handling systems. However, the computational methods of the propositional calculus present serious and frequently insurmountable difficulties in the solution of actual problems, and this factor has severely limited its practical utilization. Consequently the need arises for a systematic way of formulating, analyzing and solving propositional functions and equations."

Notwithstanding the "logical" nature of its internal operations, a general-purpose computer is ill-suited to logical computation. For this reason, a number of dedicated logical processors have been proposed. For a detailed study of logic-machines, from the Ars Magna of Ramon Lull in the thirteenth century to the relay-machines of the 1950's, see Gardner [9]. The electronic machines relevant to the present project may be put into three classes: argument-verifiers, equation-solvers, and formula-minimizers.

All of the argument-verifiers [10-16] known to this investigator (and none of the other kinds of logical computers) have been designed by logicians. The function of any such machine is to decide the validity of an argument, i.e., a collection of premises together with a conclusion. Equation-solving machines [17-22], on the other hand, have been inspired principally by the need to solve technological problems. Such machines accept some representation of a system of Boolean equations and produce a solution (typically particular rather than general) for a selected subset of the arguments in terms of the remaining arguments.

Formula-minimizing machines [23-27] have the common aim of determining simplified sum-of-products (disjunctive normal form) expressions for propositional functions. The procedures implemented in all of these machines are based on Quine's formulation [28-30] of the minimization problem, the essential feature of which is the generation of the prime implicants of the given propositional function. Formula-minimization may at first glance appear to have little bearing on mechanized inference. It is significant, however, for two reasons. First, formula-minimization is useful in the application of other reasoning processes, improving the economy and perspicuity of the results obtained. Second, the existing designs for formula-minimizing machines represent solutions of a problem that is dominant in the design of the proposed inferential processor, namely, that of generating and storing the prime implicants of a propositional function.

Each of the machines cited above carries out a species of reasoning; each extracts useful information, that is, from a collection of propositional data. None of these machines has emerged from the laboratory of its birth, however, because none is in any sense "general-purpose" within the domain of propositional logic. The element absent in these machines is a central principle of reasoning, readily adaptable to argument-verification, equation-solving, formula-minimization, and any other task involving logical inference. The proposed inferential processor embodies such a principle, viz., that the prime consequences characterize, in a simple and economical way, all conclusions deducible from a collection of propositional data.

The technique of automated inference we are investigating is based on a formulation given by A. Blake in a little-known dissertation [31] published in 1937. The concept of a prime implicant, customarily attributed to a paper published by Quine [28] fourteen years later, as well as all of the presently-known methods for generating prime implicants, were presented in Blake's dissertation. The application of prime implicants to formula-minimization was pointed out by Quine and has since been intensively studied and applied; Blake's application of prime implicants to logical deduction, however, has apparently remained unnoticed. Blake's principal contribution was to show that a single rule of inference, that of Hypothetical Syllogism (if P implies Q and Q implies R , then P implies R), suffices to produce all of the prime consequences of a collection of propositional data. Expressed in terms of Boolean algebra, the single operation

of consensus (which Blake called the "syllogistic result") suffices to produce all of the prime implicants of a Boolean function. This idea is closely related to the "resolution principle" given by Robinson [32] in 1965 and now applied in mechanical theorem-proving [6] and in programming languages, such as PROLOG [33,34], designed to solve problems in the predicate calculus. When compared with Blake's use of consensus, the resolution principle is formulated in a more general structure (the first-order predicate calculus) and is applied to a less general problem (theorem-proving by refutation).

Blake demonstrated the fundamental role of the prime consequences in generating and verifying conclusions. Our research has shown an additional advantage of the prime consequences, namely, that they enable the fundamental operations of propositional inference (e.g., elimination of variables, solution of equations in general and particular form, general of functional antecedents and consequents) to be conveniently mechanized in a high-speed processor. Thus a machine that accepts propositional data and produces their prime consequences can be made general-purpose in the domain of propositional logic.

III. ORGANIZATION OF THE INFERENCE PROCESSOR

We present in this section a brief outline of the organization of the proposed inferential processor; see [1] for a more complete description.

The function of the inferential processor is to accept, store, and process Boolean or propositional data. It is intended to function as a high-speed adjunct to a general-purpose computer, as indicated in Figure 1.

Fig. 1. Total system.

The applications anticipated for the inferential processor fall into two main classes: (a) tasks involving only propositional (Boolean) logic and (b) tasks involving higher-order logic, primarily the first-order predicate calculus. The first class includes such applications as computer-aided design of logic-circuits [2], the design and analysis of databases (see [3], which is included as Part B of this report), and on-line diagnosis of faults in digital systems [4]. In the second class of applications, unlike the first, the inferential processor does not do all of the logical work; instead, it provides high-speed subroutines for use by the general-purpose computer. The employment of the inferential processor in the latter class of applica-

tions is based on the fact that higher-order logics employ propositional logic as their basic "arithmetic." Most applications of this class come under the heading of artificial intelligence, many branches of which depend heavily on the first-order predicate calculus.

Principal Components

The major components of the inferential processor are shown in Figure 2.

Fig. 2. Major components of the inferential processor.

The unit labelled TERM is a register that holds the term (Boolean product) currently under consideration. The Minterm Processor accepts terms from TERM, building from them a Boolean function $F(x_1, \dots, x_n)$ using AND, OR, NOT, EOR, etc. The function F is represented in the Minterm Processor by its minterm canonical form. The Term Processor accepts the minterms of F from the Term Processor and generates the Blake canonical form, i.e., the disjunction of the prime implicants, of F . The Term Processor

carries out the fundamental operations of logical analysis (elimination of variables, solution of equations, etc.) which, arranged in programmed sequences, carry out the processing requested by the general-purpose computer.

Major Phases of Operation

The operation of the inferential processor takes place in three major phases: reduction, development, and analysis. The reduction-phase, carried out in the Minterm Processor, reduces a system of logical equations to a single equation having the form $F = 0$. The development-phase, carried out in the Term Processor, generates a representation of F in Blake canonical form. The analysis-phase, carried out in both processors, executes the sequence of inferential operations requested by the general-purpose computer.

IV. MECHANIZED INFERENCE IN BOOLEAN SYSTEMS

The task of the proposed inferential processor is to accept logical data in the form of a Boolean system and to generate useful inferences (conclusions) from such a system. We have attempted in this project to develop a systematic formulation of (a) the properties of Boolean systems and (b) the principal operations on such systems that are of use in logical inference. We discuss that formulation in this section.

Review of Elementary Properties

The equivalences

$$a \leq b \iff a\bar{b} = 0 \quad (1)$$

$$a = b \iff a \oplus b = 0 \quad (2)$$

$$[a = 0 \text{ and } b = 0] \iff a + b = 0 \quad (3)$$

$$[a = 1 \text{ and } b = 1] \iff ab = 1 \quad (4)$$

are valid for arbitrary elements a and b in a Boolean algebra. Equivalences (3) and (4) have obvious extensions to more than three variables; thus $[a = 0 \text{ and } b = 0 \text{ and } c = 0]$ is equivalent to $[a + b + c = 0]$, etc.

Boolean Systems

An n -variable Boolean system on a Boolean algebra B is a collection

$$\begin{aligned} g_1(\underline{x}) &= h_1(\underline{x}) \\ &\vdots \\ g_k(\underline{x}) &= h_k(\underline{x}) \\ g_{k+1}(\underline{x}) &\leq h_{k+1}(\underline{x}) \\ &\vdots \\ g_m(\underline{x}) &\leq h_m(\underline{x}) \end{aligned} \quad (5)$$

of simultaneously-asserted equations and inclusions in which the g 's and h 's are n -variable Boolean functions on B and $\underline{x}$ denotes the vector $(x_1, \dots, x_n)$.

The number, k , of equations may be zero in a system, as may the number, m , of inclusions; we require, of course, that there be at least one equation or one inclusion in a Boolean system.

Solutions. An element $\underline{b}$ of B^n is a solution of the system (5) if each of the statements in (5) becomes an identity under the substitution $\underline{x} = \underline{b}$. A Boolean system is said to be consistent if it has at least one solution; otherwise, it is said to be inconsistent.

Implication and equivalence. Let S_1 and S_2 be two n -variable Boolean systems on B . We say that S_1 implies S_2 , written $S_1 \Rightarrow S_2$, in case the statement

$$(\forall \underline{b} \in B^n) [\underline{b} \text{ is a solution of } S_1 \Rightarrow \underline{b} \text{ is a solution of } S_2]$$

is true. Note that S_1 implies any n -variable Boolean system if S_1 is inconsistent. We say that two Boolean systems S_1 and S_2 are equivalent, written $S_1 \Leftrightarrow S_2$, if each implies the other, i.e., if each has the same set of solutions. Any two inconsistent systems, in particular, are equivalent.

Reduction

By (1) and (2), the system (5) is equivalent to the system

$$\begin{aligned} g_1(\underline{x}) \oplus h_1(\underline{x}) &= 0 \\ &\vdots \\ g_k(\underline{x}) \oplus h_k(\underline{x}) &= 0 \\ g_{k+1}(\underline{x}) \bar{h}_{k+1}(\underline{x}) &= 0 \\ &\vdots \\ g_m(\underline{x}) \bar{h}_m(\underline{x}) &= 0 \end{aligned} \quad (6)$$

System (6) is equivalent, by (3), to the single equation

$$f(\underline{x}) = 0, \quad (7)$$

where f is a Boolean function defined by

$$f = \sum_{i=1}^k (g_i \oplus h_i) + \sum_{i=k+1}^m g_i \bar{h}_i. \quad (8)$$

By similar reasoning, invoking (4) instead of (3), we deduce that the system (5) is equivalent to the single equation

$$F(\underline{x}) = 1, \quad (9)$$

where F is a Boolean function defined by

$$F = \prod_{i=1}^k (\bar{g}_i \oplus h_i) \cdot \prod_{i=k+1}^m (\bar{g}_i + h_i). \quad (10)$$

Any Boolean system can therefore be "boiled down" to a single equation of the form (7) or of the form (9). We will focus principally on the form (7).

Example 1. The system

$$ax = b + y$$

$$ab \leq a\bar{x} + \bar{y}$$

is equivalent to the system

$$a\bar{b}x\bar{y} + \bar{a}b + \bar{a}y + b\bar{x} + \bar{x}y = 0$$

$$ab(\bar{a}y + xy) = 0,$$

which is equivalent, in turn, to the single equation

$$a\bar{b}x\bar{y} + \bar{a}b + \bar{a}y + b\bar{x} + \bar{x}y + abxy = 0.$$

Example 2. The behavior of an AND-gate,

is described by the three equivalent statements

$$UV = W \quad (11)$$

$$\bar{U}W + \bar{V}W + UV\bar{W} = 0 \quad (12)$$

$$\bar{U}\bar{W} + \bar{V}\bar{W} + UVW = 1 \quad (13)$$

Boolean Relations

Given a Boolean algebra B and a vector $\underline{x} = (x_1, \dots, x_n)$, a relation (or constraint) on $\underline{x}$ is a statement that confines $\underline{x}$ to lie within a subset of B^n . The operation of the AND-gate of Example 2, for instance, is specified by the relation

$$(U, V, W) \in \{(0, 0, 0), (0, 1, 0), (1, 0, 0), (1, 1, 1)\} \quad (14)$$

where $B = \{0, 1\}$ and $\underline{x} = (U, V, W)$. (Strictly speaking, the relation is the subset $\{(0, 0, 0), (0, 1, 0), (1, 0, 0), (1, 1, 1)\}$ itself; it is convenient for our present purposes, however, to call the statement (14) a relation.)

Two relation-statements on $\underline{x} = (x_1, \dots, x_n)$ will be called equivalent if they confine $\underline{x}$ to the same subset of B^n . Thus statement (14) above is equivalent to equation (11), as well as to equations (12) and (13).

An identity on $\underline{x} = (x_1, \dots, x_n)$ is a relation equivalent to the statement

$$\underline{x} \in B^n.$$

An identity, in other words, is a relation on $\underline{x}$ that doesn't really "confine" $\underline{x}$ at all. The relations $\bar{x}_1 x_2 \leq x_2$ and $x_1 + x_2 = x_1 + \bar{x}_1 x_2$, for example, are both identities on (x_1, x_2) .

A relation on $\underline{x} = (x_1, \dots, x_n)$ will be called a Boolean relation if it is equivalent to a Boolean equation, i.e., if it is equivalent to a statement of the form

$$f(\underline{x}) = 0 ,$$

where $f: B^n \rightarrow B$ is a Boolean function. If $B = \{0,1\}$, then every relation on $\underline{x}$ is a Boolean relation. If B is a Boolean algebra larger than $\{0,1\}$, then not all relations are Boolean. Suppose $B = \{0,1,\bar{a},a\}$. Then the relation

$$(x_1, x_2) \in \{(0,0), (a,0)\} \quad (15)$$

is a Boolean relation because it is equivalent to the Boolean equation

$$\bar{a}x_1 + x_2 = 0 . \quad (16)$$

The set $\{(0,0), (a,0)\}$ of solutions of (16), that is, is precisely the set defining the relation (15). The relation

$$(x_1, x_2) \in \{(0,0), (a,1)\} , \quad (17)$$

on the other hand, is not a Boolean relation. It is not equivalent, that is, to a Boolean equation; any Boolean equation $f(x_1, x_2) = 0$ on $B = \{0,1,\bar{a},a\}$ having solutions $(0,0)$ and $(a,1)$ must also have solutions $(0,\bar{a})$ and (a,a) --as we shall be able to show after we discuss the solution of Boolean equations.

Eliminants

Let $f: B^n \rightarrow B$ be a Boolean function expressed in terms of arguments $x_1, \dots, x_n$. We derive from f a set $\{C_T f \mid T \subseteq \{x_1, \dots, x_n\}\}$ of Boolean functions by applying the following rules:

$$(i) \quad C_\emptyset f = f$$

$$C_{\{x_1\}} f = f(0, x_2, \dots, x_n) \cdot f(1, x_2, \dots, x_n)$$

$$(ii) \quad C_{R \cup S} f = C_R(C_S f) .$$

We derive another set, $\{D_T f \mid T \subseteq \{x_1, \dots, x_n\}\}$ of Boolean functions by applying the rules

$$\begin{aligned} (i) \quad D_\emptyset f &= f \\ D_{\{x_1\}} f &= f(0, x_2, \dots, x_n) + f(1, x_2, \dots, x_n) \\ (ii) \quad D_{R \cup S} f &= D_R(D_S f). \end{aligned}$$

We call $C_T f$ the conjunctive eliminant, and $D_T f$ the disjunctive eliminant, of f with respect to the subset T of $\{x_1, \dots, x_n\}$. Note that if x is a single letter, then the conjunctive and disjunctive eliminants of f with respect to x are related to the discriminants $f_{\bar{x}}$ and f_x (discussed in Chapter 4) as follows:

$$C_{\{x\}} f = f_{\bar{x}} \cdot f_x \quad (18a)$$

$$D_{\{x\}} f = f_{\bar{x}} + f_x \quad (18b)$$

It is convenient to omit set-braces in specifying eliminants; thus we write $C_{x_1 x_3} f$ rather than $C_{\{x_1, x_3\}} f$.

Suppose the subset T comprises k elements ($k \leq n$) of $\{x_1, \dots, x_n\}$ (we assume without loss of generality that T comprises the first k elements, i.e., that $T = \{x_1, \dots, x_k\}$). Then $C_T f$ and $D_T f$ are determined as follows:

$$\begin{aligned} C_T f &= \prod_{\underline{b} \in \{0,1\}^k} f(\underline{b}, x_{k+1}, \dots, x_n) \\ D_T f &= \sum_{\underline{b} \in \{0,1\}^k} f(\underline{b}, x_{k+1}, \dots, x_n). \end{aligned}$$

If $k=2$ and $n=4$, for example, then

$$C_{wx} f(w, x, y, z) = f(0, 0, y, z) \cdot f(0, 1, y, z) \cdot f(1, 0, y, z) \cdot f(1, 1, y, z)$$

and

$$D_{wx} f(w, x, y, z) = f(0, 0, y, z) + f(0, 1, y, z) + f(1, 0, y, z) + f(1, 1, y, z).$$

It is clear that the conjunctive and disjunctive eliminants of a Boolean function f with respect to a subset T of the argument-set may be expressed by formulas not involving any of the arguments in T . The process of calculating such formulas may in some cases be greatly simplified by application of the two theorems which follow.

Theorem 1. Let $f: B^n \rightarrow B$ be a Boolean function expressed in terms of arguments $x_1, \dots, x_n$. Then

$$BCF(C_{x_1} f) = \sum (\text{terms of } BCF(f) \text{ not involving } \bar{x}_1 \text{ or } x_1).$$

Proof: The literals $\bar{x}_1$ and x_1 may be factored from the terms of $BCF(f)$ in which they appear, in such a way that f is expressed as

$$f = \sum_{i=1}^L \bar{x}_1 p_i(x_2, \dots, x_n) + \sum_{j=1}^M x_1 q_j(x_2, \dots, x_n) + \sum_{k=1}^N r_k(x_2, \dots, x_n),$$

where $p_1, \dots, p_L, q_1, \dots, q_M, r_1, \dots, r_N$ are terms (products) not involving the argument x_1 . Thus $C_{x_1} f = f(0, x_2, \dots, x_n) f(1, x_2, \dots, x_n)$ may be expressed as $[\sum_{i=1}^L p_i + \sum_{k=1}^N r_k][\sum_{j=1}^M q_j + \sum_{k=1}^N r_k] = \sum_{i=1}^L \sum_{j=1}^M p_i q_j + \sum_{k=1}^N r_k$. Every consensus formed by terms of $BCF(f)$ is absorbed by a term of $BCF(f)$. In particular, every consensus of the form $p_i q_j$ is absorbed by one of the r -terms; thus $\sum_{i=1}^L \sum_{j=1}^M p_i q_j \leq \sum_{k=1}^N r_k$, and we conclude that $C_{x_1} f = \sum_{k=1}^N r_k$. Thus $C_{x_1} f$ may be expressed as the portion of $BCF(f)$ that remains after every term involving $\bar{x}_1$ or x_1 is deleted. It is shown in Chapter 4 that the result of such deletion is in Blake canonical form ■

Corollary 1.1. Let $f: B^n \rightarrow B$ be a Boolean function expressed in terms of arguments $x_1, \dots, x_n$ and let T be a subset of $\{x_1, \dots, x_n\}$. Then

$$BCF(C_T f) = \sum (\text{terms of } BCF(f) \text{ not involving arguments in } T). \quad (19)$$

Proof: By Theorem 1, (19) is valid if $\#T=1$, i.e., if T is a singleton-set.

Suppose (19) to be valid if $\#T=k$, and consider the case $\#T=k+1$, i.e., let

$T = \{x_1\} \cup R$, where $\#R=k$ and $x_1 \notin R$. Then $BCF(C_T f) = BCF(C_{\{x_1\}}(C_R f)) =$
 $\sum(\text{terms of } BCF(C_R f) \text{ not involving } \bar{x}_1 \text{ or } x_1) = \sum(\text{terms of } \sum(\text{terms of } BCF(f)$
 not involving arguments in R) not involving $\bar{x}_1$ or x_1). Thus (19) is valid for
 $T = \{x_1\} \cup R$ ■

Example 3. The system

$$\bar{w} + x = y$$

$$x + \bar{y} = wz$$

is equivalent to the single equation

$$x\bar{y} + w\bar{x}y + w\bar{z} + \bar{w}\bar{y} + \bar{y}\bar{z} + \bar{w}x + x\bar{z} = 0 ,$$

whose left side, f , is expressed in Blake canonical form. The conjunctive eliminants expressed below are constructed by inspection of $BCF(f)$, using Theorem 1 and its corollary.

$$C_x f = w\bar{z} + \bar{w}\bar{y} + \bar{y}\bar{z}$$

$$C_{wx} f = C_w(C_x f) = \bar{y}\bar{z}$$

$$C_w f = x\bar{y} + \bar{y}\bar{z} + x\bar{z}$$

$$C_{wx} f = C_x(C_w f) = \bar{y}\bar{z} .$$

Theorem 2. Let $f: B^n \rightarrow B$ be a Boolean function expressed in terms of arguments $x_1, \dots, x_n$. Then $D_{x_1} f$ is obtained from any SOP formula for f by replacing $\bar{x}_1$ and x_1 , wherever they appear in the formula, by 1.

Proof: By definition, $D_{x_1} f(x_1, x_2, \dots, x_n) = f(0, x_2, \dots, x_n) + f(1, x_2, \dots, x_n)$.

An SOP formula for f may be expanded in the form

$$f(x_1, x_2, \dots, x_n) = \bar{x}_1 p(x_2, \dots, x_n) + x_1 q(x_2, \dots, x_n) + r(x_2, \dots, x_n),$$

where p , q , and r are SOP formulas not involving x_1 ; hence, $f(0, x_2, \dots, x_n) = p(x_2, \dots, x_n) + r(x_2, \dots, x_n)$ and $f(1, x_2, \dots, x_n) = q(x_2, \dots, x_n) + r(x_2, \dots, x_n)$.

We deduce, therefore, that

$$D_{x_1} f(x_1, x_2, \dots, x_n) = p(x_2, \dots, x_n) + q(x_2, \dots, x_n) + r(x_2, \dots, x_n).$$

Thus $D_{x_1} f$ is produced by replacing the literals $\bar{x}_1$ and x_1 by 1 in the original SOP formula for f ■

We refer to the foregoing procedure, which was given first apparently by Mitchell [3], as the "replace-by-1 trick."

Example 4. Let $f(w, x, y, z)$ be given by

$$f = \bar{w}\bar{x}y\bar{z} + \bar{w}xyz + w\bar{y}z.$$

Then

$$D_{wx} f = y\bar{z} + yz + \bar{y}z = y + z$$

$$D_{yz} f = \bar{w}\bar{x} + \bar{w}x + w = 1.$$

Example 5. The following (correct) calculations illustrate potential pitfalls in applying the replace-by-1 trick:

$$(a) D_u(\bar{u} + vw) = 1 + vw = 1$$

$$(b) D_u(\overline{u + v}) = D_u(\bar{u}\bar{v}) = \bar{v}$$

$$(c) D_u(u + v)(\bar{u} + w) = D_u(uw + \bar{u}v + vw) = w + v$$

Calculation (a) illustrates that $D_u f$ is not found simply by deleting $\bar{u}$ and u (which would produce vw rather than 1 in this case), but by replacing $\bar{u}$ and u by 1. Calculations (b) and (c) illustrate the necessity that f be expressed in sum-of-products form before the literals $\bar{u}$ and u are replaced by 1. If the replacements are made in the original formulas, then the erroneous results would be $D_u(\overline{u + v}) = \overline{(1 + v)} = 0$ for (b) and $D_u(u + v)(\bar{u} + w) = (1 + v)(1 + w) = 1$ for (c).

Elimination

A Boolean relation constrains the vector $\underline{x} = (x_1, \dots, x_n)$ to lie within a subset of B^n . It also constrains any k -element subvector of $\underline{x}$ ($1 \leq k \leq n$) to lie within a subset of B^k . The Boolean relation (14) describing an AND-gate, for example, constrains (U, V, W) to lie within the subset $\{(0,0,0), (0,1,0), (1,0,0), (1,1,1)\}$ of the 8-element set $\{0,1\}^3$. Suppose we wish to find the implied relation on the subvector (U, W) . To do so, we simply delete the middle element of each triple in (14), and keep the set of pairs that remains. The resulting relation on (U, W) is

$$(U, W) \in \{(0,0), (1,0), (1,1)\}. \quad (20)$$

We say in this case that V has been eliminated from the relation (14) to produce the relation (20), and we call (20) the resultant of elimination of V from (14). Relation (20), it should be emphasized, limits (U, W) to the same subset of $\{0,1\}^2$ as does the original relation (14).

If R is a Boolean relation, i.e., one equivalent to a Boolean equation

$$f(x_1, x_2, \dots, x_n) = 0, \quad (21)$$

then the resultant of elimination of any argument from R is also a Boolean relation. Thus, the resultant of elimination of x_1 from the equation (21) may be expressed by an equation of the form

$$g(x_2, \dots, x_n) = 0. \quad (22)$$

To determine the resultant (22) from equation (21), we may proceed by (i) expressing (21) as an equivalent explicit subset of B^n , (ii) deleting the first element of each n-tuple in the subset, and (iii) expressing the resulting subset of B^{n-1} as an equation of the form (22). The following result enables us, however, to generate (22) directly from (21).

Theorem 3. The equation $g(x_2, \dots, x_n) = 0$ expresses the resultant of elimination of x_1 from the equation $f(x_1, x_2, \dots, x_n) = 0$ if and only if the identity

$$g = C_{x_1} f \quad (23)$$

is fulfilled.

Proof: The fundamental theorem of Boolean algebra, together with properties (1) through (3), gives rise to the following chain of equivalences:

$$\begin{aligned}
 & f(x_1, x_2, \dots, x_n) = 0 \\
 & \quad \updownarrow \\
 & \bar{x}_1 f(0, x_2, \dots, x_n) + x_1 f(1, x_2, \dots, x_n) = 0 \\
 & \quad \updownarrow \\
 & \begin{cases} \bar{x}_1 f(0, x_2, \dots, x_n) = 0 \\ x_1 f(1, x_2, \dots, x_n) = 0 \end{cases} \\
 & \quad \updownarrow \\
 & \begin{cases} f(0, x_2, \dots, x_n) \leq x_1 \\ x_1 \leq \bar{f}(1, x_2, \dots, x_n) \end{cases} \\
 & \quad \updownarrow \\
 & f(0, x_2, \dots, x_n) \leq x_1 \leq \bar{f}(1, x_2, \dots, x_n) . \quad (24)
 \end{aligned}$$

The constraint imposed by (10) on the subvector $(x_2, \dots, x_n)$ is

$$f(0, x_2, \dots, x_n) \leq \bar{f}(1, x_2, \dots, x_n) ,$$

which may be re-expressed as

$$f(0, x_2, \dots, x_n) \cdot f(1, x_2, \dots, x_n) = 0.$$

Thus $g=0$ is the resultant of elimination of x_1 from $f=0$ if and only if the condition (23) is satisfied

Corollary 3.1. The equation $G(x_2, \dots, x_n) = 1$ expresses the resultant of elimination of x_1 from the equation $F(x_1, x_2, \dots, x_n) = 1$ if and only if the identity

$$G = D_{x_1} F \quad (25)$$

is fulfilled.

Example 6. The AND-gate discussed in Example 2 is characterized by either of the equations $f(U, V, W) = 0$ or $F(U, V, W) = 1$, where the functions f and F are defined by

$$\begin{aligned} f &= \bar{U}W + \bar{V}W + UV\bar{W} \\ F &= \bar{U}\bar{W} + \bar{V}\bar{W} + UVW \end{aligned} \quad (26)$$

Applying Theorem 1 and its corollary, the resultant of elimination of V is expressed by either of the equations $g(U, W) = 0$ or $G(U, W) = 1$, where

$$\begin{aligned} g = C_V f &= f(U, 0, W) \cdot f(U, 1, W) \\ &= (\bar{U}W + W) \cdot (\bar{U}W + U\bar{W}) \\ &= \bar{U}W \end{aligned}$$

$$\begin{aligned} G = D_V F &= F(U, 0, W) + F(U, 1, W) \\ &= (\bar{U}\bar{W} + \bar{W}) + (\bar{U}\bar{W} + UW) \\ &= U + \bar{W} \end{aligned}$$

The resultant is expressed, therefore, either by $\overline{U}W = 0$ or by $U + \overline{W} = 1$; either of these equations, or the equivalent inclusion $W \leq U$, is equivalent to the relation (20). These relations express all that is known concerning U and W , in the absence of knowledge concerning V .

If we eliminate W from (12), the resultant is $(UV)(\overline{U} + \overline{V}) = 0$, i.e., $0 = 0$. The latter relation on (U, V) is an identity; it allows (U, V) to be chosen freely, that is, from $\{0, 1\}^2$ --which confirms our expectation that the inputs to an AND-gate should be unconstrained in value if nothing is known concerning the value of the output.

The Extended Verification Theorem

We discuss in this section a result, due to Löwenheim [2] and Müller [4], which enables an implication between two Boolean equations to be translated into an equivalent Boolean inclusion. The presentation in this section is adapted from that of Rudeanu [6].

Let s be a single element of B and let $\underline{v} = (v_1, v_2, \dots, v_n)$ be a vector on B , i.e., $s \in B$ and $\underline{v} \in B^n$. Then $s\underline{v}$ and $\underline{v}s$ are defined by

$$s\underline{v} = \underline{v}s = (sv_1, sv_2, \dots, sv_n) .$$

Lemma 1. Let $f: B^n \rightarrow B$ be a Boolean function and let $\underline{b}$ be an element of B^n such that $f(\underline{b}) = 0$. Then

$$f(\underline{b}f(\underline{x}) + \underline{x}\overline{f}(\underline{x})) = 0 \quad \forall \underline{x} \in B^n . \quad (27)$$

Proof: By the fundamental theorem of Boolean algebra,

$$f(\underline{b}f(\underline{x}) + \underline{x}\overline{f}(\underline{x})) = \overline{f}(\underline{x})f(\underline{x}) + f(\underline{x})f(\underline{b}) .$$

Each term on the right-hand side of the foregoing equation has the value zero, for any $\underline{x} \in B^n$, proving (27). ■

Theorem 4 (Extended Verification Theorem). Let $f: B^n \rightarrow B$ and $g: B^n \rightarrow B$ be Boolean functions, and assume that the equation $f(\underline{x}) = 0$ is consistent. Then the following statements are equivalent:

- (i) $(\forall \underline{x} \in B^n) [f(\underline{x}) = 0 \Rightarrow g(\underline{x}) = 0]$
- (ii) $(\forall \underline{x} \in B^n) [g(\underline{x}) \leq f(\underline{x})]$
- (iii) $(\forall \underline{x} \in \{0,1\}^n) [g(\underline{x}) \leq f(\underline{x})]$.

Proof:

(i) $\Rightarrow$ (ii): Let $\underline{b} \in B^n$ be a solution of $f(\underline{x}) = 0$, i.e., let $f(\underline{b}) = 0$. Then $g(\underline{b}) = 0$. For any $\underline{x} \in B^n$, $f(\underline{x})\bar{f}(\underline{x}) + \underline{b}f(\underline{x}) = 0$ by Lemma 1; hence, $g(\underline{x})\bar{f}(\underline{x}) + \underline{b}f(\underline{x}) = 0$. Thus, for all $\underline{x} \in B^n$, $\bar{f}(\underline{x})g(\underline{x}) + f(\underline{x})g(\underline{b}) = \bar{f}(\underline{x})g(\underline{x}) = 0$, i.e., $g(\underline{x}) \leq f(\underline{x})$, proving (ii).

(ii) $\Rightarrow$ (iii): Trivial.

(iii) $\Rightarrow$ (i): The functions f and g are Boolean; hence, they may be written in minterm canonical form, i.e., $f(\underline{x}) = \sum_{i=0}^{2^n-1} f_i m_i(\underline{x})$ and $g(\underline{x}) = \sum_{i=0}^{2^n-1} g_i m_i(\underline{x})$ for all $\underline{x} \in B^n$. Assume (iii), i.e., assume that $g_i \leq f_i$ ($i=0,1,\dots,2^n-1$), and let $\underline{b} \in B^n$ be a solution of $f(\underline{x}) = 0$. Then $\sum_{i=0}^{2^n-1} f_i m_i(\underline{b}) = 0$, which implies that $f_i m_i(\underline{b}) = 0$, and therefore that $g_i m_i(\underline{b}) = 0$, ($i=0,1,\dots,2^n-1$). Thus $g(\underline{b}) = 0$, proving (i). ■

Corollary 4.1. Let $f: B^n \rightarrow B$ and $g: B^n \rightarrow B$ be Boolean functions and assume that the equation $f(\underline{x}) = 0$ is consistent. Then the following statements are equivalent:

- (i) $(\forall \underline{x} \in B^n) [f(\underline{x}) = 0 \iff g(\underline{x}) = 0]$
- (ii) $(\forall \underline{x} \in B^n) [f(\underline{x}) = g(\underline{x})]$
- (iii) $(\forall \underline{x} \in \{0,1\}^n) [f(\underline{x}) = g(\underline{x})]$.

Proof: Immediate from Theorem 3 and the definition of equivalent systems. ■

Poretsky's Law of Forms

It is useful on some occasions to re-express the information supplied by the Boolean equation $f(\underline{x}) = 0$ in the equivalent form $g(\underline{x}) = h(\underline{x})$, where g is any given Boolean function. The associated Boolean function h is specified by the following theorem.

Theorem 5 (Poretsky's Law of Forms). Let $f, g, h: B^n \rightarrow B$ be Boolean functions and suppose the equation $f(\underline{x}) = 0$ to be consistent. Then the equivalence

$$f(\underline{x}) = 0 \iff g(\underline{x}) = h(\underline{x}) \quad (28)$$

holds for all $\underline{x} \in B^n$ if and only if

$$h = f \oplus g. \quad (29)$$

Proof: Suppose (28) to hold for all $\underline{x}$ in B^n . Then (28) is equivalent, by property (2) and Corollary 3.1, to the equation $f(\underline{x}) = g(\underline{x}) \oplus h(\underline{x})$ ($\forall \underline{x} \in B^n$). Thus $g(\underline{x}) \oplus f(\underline{x}) = g(\underline{x}) \oplus (g(\underline{x}) \oplus h(\underline{x})) = h(\underline{x})$ ($\forall \underline{x} \in B^n$), from which we deduce (29) directly. Suppose on the other hand that the function h is defined by (29). Let $\underline{b} \in B^n$ be one of the solutions of the consistent equation $f(\underline{x}) = 0$. Then $h(\underline{b}) = f(\underline{b}) \oplus g(\underline{b}) = 0 \oplus g(\underline{b}) = g(\underline{b})$, i.e., $\underline{b}$ is also a solution of $g(\underline{x}) = h(\underline{x})$ (and we deduce that $g(\underline{x}) = h(\underline{x})$ is consistent). Thus $f(\underline{x}) = 0 \implies g(\underline{x}) = h(\underline{x})$. To show that $g(\underline{x}) = h(\underline{x}) \implies f(\underline{x}) = 0$, let $\underline{c} \in B^n$ be any solution of $g(\underline{x}) = h(\underline{x})$. Then $g(\underline{c}) \oplus h(\underline{c}) = 0$, whence $g(\underline{c}) \oplus (f(\underline{c}) \oplus g(\underline{c})) = 0$ by (29), from which we deduce that $f(\underline{c}) = 0$, proving (28). ■

Example 7. Suppose a Boolean function h is sought having the property that the equation $x_1 \bar{x}_2 + x_3 = 0$ is equivalent to $x_2 x_3 = h$. The first equation is consistent (a solution, for example, is $x_1 = 0, x_2 = 0, x_3 = 0$); hence, h is

determined uniquely by (29), i.e.,

$$\begin{aligned}h &= (x_1 \bar{x}_2 + x_3) \oplus (x_2 x_3) \\&= \bar{x}_2(x_1 + x_3) .\end{aligned}$$

V. FUNCTIONAL DEDUCTION

An important potential application of the inferential processor is that of generating functional consequences, i.e., conclusions of the form

$$x_1 = f(x_2, \dots, x_n), \quad (30)$$

from a given system of logical equations on the variables $x_1, x_2, \dots, x_n$. If such consequences exist, then we call x_1 functionally deducible from the given equations and we say that $\{x_2, \dots, x_n\}$ is a determining subset for x_1 . Generating functional consequences from a given system of equations is the inverse of solving the system; if (30) is a solution of a system, then the system is a consequence of (30). The problem of solving logical equations was given primary attention in Boole's original work, and has since been studied intensively; there has been no progress to our knowledge, however, on the problem of generating functional consequences.

Some very preliminary work on functional deduction was reported in [1]; we outline in this section the progress we have made in the meantime. A test (Theorem 6) is given to determine, for a given logical database, the functionally deducible variables; this test is well-suited for high-speed execution by the inferential processor, inasmuch as it is based on the basic units of data (prime implicants) stored in the processor. Given that a variable is functionally deducible, the set of functions f for which (30) is a functional consequence is specified by Corollary 6.1. A necessary and sufficient condition for a subset of $\{x_2, \dots, x_n\}$ to be an x_1 -determining subset is given in Theorem 7, and an algorithm is given to generate the class of minimal x_1 -determining subsets. Finally, the theory of functional deduction is applied to the problem of designing economical multiple-output combinational circuits.

The discussion in this section is based on the concepts and terminology introduced in Section II.

Functional Deducibility

Let us suppose a collection of Boolean, i.e., propositional, data to be reduced by the inferential processor to the single equation

$$\phi(x_1, x_2, \dots, x_n) = 1. \quad (31)$$

We say that x_1 is functionally deducible from (31) in case there is a Boolean function $f: B^{n-1} \rightarrow B$ such that equation (30) is a consequence of (31). We call (30) a functional consequence of (31).

Theorem 6. The following statements are equivalent:

- (i) x_1 is functionally deducible from $\phi(x_1, \dots, x_n) = 1$.
- (ii) $D_{x_1} \phi = 1$.
- (iii) $C_{x_1} \phi = 0$.
- (iv) x_1 or $\bar{x}_1$ appears in every term of $BCF(\phi)$.

Proof:

(i) $\Leftrightarrow$ (ii) $\Leftrightarrow$ (iii): The equivalence of the following statements follows directly from the results of Section II. In particular, the equivalence of (a) and (b) follows from the extended verification theorem (Theorem 4) and property (2).

$$(a) \quad (\exists f) [\phi(x_1, \dots, x_n) = 1 \implies x_1 = f(x_2, \dots, x_n)]$$

$$(b) \quad (\exists f) [\phi(x_1, x_2, \dots) \leq \bar{x}_1 \oplus f(x_2, \dots)]$$

$$(c) \quad (\exists f) \left[\begin{array}{l} \phi(0, x_2, \dots) \leq \bar{f}(x_2, \dots) \\ \phi(1, x_2, \dots) \leq f(x_2, \dots) \end{array} \right]$$

$$(d) \quad (\exists f) \quad [\phi(1, x_2, \dots) \leq f \leq \bar{\phi}(0, x_2, \dots)]$$

$$(e) \quad \phi(1, x_2, \dots) \leq \bar{\phi}(0, x_2, \dots)$$

$$(f) \quad \begin{cases} \bar{\phi}(1, x_2, \dots) + \bar{\phi}(0, x_2, \dots) = 1 \\ \phi(1, x_2, \dots) \cdot \phi(0, x_2, \dots) = 0 \end{cases}$$

$$(g) \quad \begin{cases} D_{x_1} \bar{\phi} = 1 \\ C_{x_1} \phi = 0 \end{cases}$$

(iii) $\iff$ (iv): The terms of $BCF(C_{x_1} \phi)$, by Theorem 1, are those of ϕ which do not involve $\bar{x}_1$ or x_1 . Thus $C_{x_1} \phi = 0$ if and only if $\bar{x}_1$ or x_1 appears in every term of $BCF(\phi)$.

Corollary 6.1. Let $f: B^{n-1} \rightarrow B$ be a Boolean function. Then the equation $x_1 = f(x_2, \dots, x_n)$ is a functional consequence of $\phi(x_1, \dots, x_n) = 1$ if and only if the functions f and ϕ satisfy the condition

$$\phi_{x_1} \leq f \leq \bar{\phi}_{\bar{x}_1} \quad . \quad (32)$$

Minimal Determining Subsets

Let $\{\{u\}, V, W\}$ be a partition of $\{x_1, \dots, x_n\}$, where $V = \{v_1, \dots, v_p\}$ and $W = \{w_1, \dots, w_q\}$. We say that V is a u-determining subset of $\{x_1, \dots, x_n\}$, and that W is u-eliminable, if u is deducible from the equation

$$D_W \phi = 1 \quad . \quad (33)$$

Theorem 7 Let $\{\{u\}, V, W\}$ be a partition, as described above, of the set $\{x_1, \dots, x_n\}$. Then V is a u-determining subset if and only if the condition

$$D_W(\phi_u) \cdot D_W(\phi_{\bar{u}}) = 0 \quad (34)$$

is satisfied, in which case a functional consequence is $u = f(\underline{v})$, where f is

any Boolean function in the non-empty interval

$$D_W(\phi_u) \leq f \leq D_W(\phi_u^-). \quad (35)$$

Proof: By Theorem 6, the variable u is deducible from $D_W = 1$ if and only if

$C_u(D_W \phi) = 0$, i.e., $(D_W \phi)_u \cdot (D_W \phi)_u^- = 0$. From the identities

$$(D_W \phi)_u = D_W(\phi_u) \quad (36a)$$

$$(D_W \phi)_u^- = D_W(\phi_u^-), \quad (36b)$$

we conclude that u is deducible from $D_W \phi = 1$ if and only if (34) is satisfied, in which case, by Corollary 6.1, we obtain the equation $u = f(\underline{v})$ as a consequence, where $(D_W \phi)_u \leq f \leq \overline{(D_W \phi)_u^-}$. Identities (36a) and (36b) lead therefore to (35).

Generating minimal determining subsets. The following procedure, based on Theorem 7, generates a convenient representation of the class of minimal u -determining subsets.

Step 1. Express ϕ_u and ϕ_u^- as sum-of-products (disjunctive normal) formulas, viz.,

$$\begin{aligned} \phi_u &= \sum_{i=1}^m p_i \\ \phi_u^- &= \sum_{j=1}^n q_j \end{aligned}$$

Step 2. Associate with each pair (p_i, q_j) of terms an alterm s_{ij} defined by the summation

$$s_{ij} = \sum (\text{letters that appear opposed in } p_i \text{ and } q_j).$$

Step 3. Construct the product-of-sums formula

$$a_u = \prod_{i=1}^m \prod_{j=1}^n s_{ij}.$$

Step 4. Multiply out, to form a sum-of-products formula for a_u , and delete absorbed terms.

Step 5. With each term $xy \dots z$ of a_u associate a minimal u -determining subset $\{x, y, \dots, z\}$.

Example 8. Let us examine for functional deducibility the data given in a problem widely quoted by early logicians (Boole [2], Chapter IX):

"Suppose that an analysis of the properties of a particular class of substances leads to the following statements:

- (1) Whenever properties A and C are missing, then property E is found, together with one of the properties B and D, but not both.
- (2) Whenever the properties A and D are found while E is missing, then both B and C will either both be found or both be missing.
- (3) Whenever property A is found in conjunction with either B or E, or both of them, then C or D will also be found, but not both of them. Conversely, whenever C or D (but not both) is found, then A will be found in conjunction with either B or E or both of them."

The foregoing data are equivalent to the single equation

$$\phi = 1, \quad (37)$$

where ϕ is given in Blake canonical form by

$$BCF(\phi) = \bar{A}CD + ABC\bar{D} + A\bar{C}DE + AC\bar{D}E + \bar{A}B\bar{C}\bar{D}E + A\bar{B}\bar{C}\bar{D}E. \quad (38)$$

The variables appearing in every term of $BCF(\phi)$ are A, C, and D; hence, by Theorem 6, these are the variables functionally deducible from (37).

Let us consider the functionally deducible variable A; in particular, let us determine the minimal A-determining subsets of $\{B, C, D, E\}$.

$$\phi_A = B\bar{C}\bar{D} + \bar{C}DE + C\bar{D}E + \bar{B}\bar{C}\bar{D}\bar{E}$$

$$\phi_{\bar{A}} = CD + B\bar{C}\bar{D}E$$

Thus,

$$\begin{aligned} a_A &= (D)(C)(C)(D)(D)(C)(C+D)(B+E) \\ &= CD(B+E) \\ &= BCD + CDE. \end{aligned}$$

The minimal A-determining subsets, therefore, are $\{B,C,D\}$ and $\{C,D,E\}$. To determine f in the functional consequence $A = f(B,C,D)$, we apply (35) in Theorem 7, viz.,

$$D_{\{E\}}(\phi_A) \leq f \leq \overline{D_{\{E\}}(\phi_{\bar{A}})}.$$

Thus,

$$BC\bar{D} + \bar{C}D + C\bar{D} + \bar{B}\bar{C}\bar{D} \leq f \leq C\bar{D} + \bar{B}\bar{C} + \bar{C}D.$$

Two simplified functional consequences are derived from the foregoing interval, viz.,

$$A = C\bar{D} + \bar{C}D + \bar{B}\bar{C}$$

$$A = C\bar{D} + \bar{C}D + \bar{B}\bar{D}.$$

Similar analysis yields the following functional consequence based on the A-determining subset $V = \{C,D,E\}$:

$$A = C\bar{D} + \bar{C}D + \bar{D}\bar{E}.$$

We noted earlier that the variables functionally deducible from (37), in addition to A , are C and D . The (unique) C -determining and D -determining subsets are $\{A,B,D,E\}$ and $\{A,C,E\}$, respectively; the corresponding functional consequences, in simplified form, are

$$C = \bar{A}D + B\bar{E} + A\bar{D}\bar{E}$$

$$D = \bar{A}C + A\bar{C}E.$$

Circuit Design Based on Functional Deduction

An n-input, k-output combinational circuit is typically specified by a system of equations of the form

$$\begin{aligned} z_1 &= f_1(x_1, \dots, x_n) \\ &\vdots \\ z_k &= f_k(x_1, \dots, x_n) \\ 0 &= f_{k+1}(x_1, \dots, x_n). \end{aligned} \tag{39}$$

The latter equation represents any "don't-care" conditions that may exist on allowable input-combinations.

It was observed as early as 1951 [3] that a system of the form

$$\begin{aligned} z_1 &= g_1(x_1, \dots, x_n) \\ z_2 &= g_2(x_1, \dots, x_n, z_1) \\ z_3 &= g_3(x_1, \dots, x_n, z_1, z_2) \\ &\vdots \\ z_k &= g_k(x_1, \dots, x_n, z_1, \dots, z_{k-1}) \end{aligned} \tag{40}$$

may meet the functional specifications of (39) at reduced logical cost. Outputs, that is, may be used to assist in the generation of other outputs. The recursive structure of (40) guarantees that the resulting circuit is free of closed loops. There are cases, e.g., the end-around carry in a one's-complement adder, in which closed loops may be employed with good effect in combinational design [4,5,6]. Such loops, however, introduce the possibility of oscillations and other problems inherent in the design of asynchronous sequential circuits; we therefore confine our attention to loop-free specifications of the form (40). We call the corresponding realizations recursive circuits.

The logical cost of a recursive circuit depends on which outputs are allowed to depend on which other outputs; the sequence $(1, 2, \dots, k)$ specified by (40) is only one of $k!$ possible sequences. No method has hitherto been known for determining a promising sequence prior to working out the actual functions corresponding to that sequence. Recursive circuits have consequently been regarded as difficult to design, even though their potential economy has been well-recognized; the design of such circuits is stated in [7] to be "practicable for synthesizing a net which has not more than two or three outputs."

Functional deduction provides a way to overcome the foregoing difficulties, enabling recursive circuits to be designed conveniently. The following procedure is based on minimizing the number of arguments upon which the output-functions depend.

Step 1. Reduce the original specification (39) to a single equation of the form $\phi(x_1, \dots, x_n, z_1, \dots, z_k) = 1$.

Step 2. Calculate the z_i -determining subsets ($i=1, 2, \dots, k$).

Step 3. Select a sequence $S_{i_1}, S_{i_2}, \dots, S_{i_k}$ of subsets of $\{x_1, \dots, x_n, z_1, \dots, z_k\}$ having the following properties:

(a) S_r is a z_r -determining subset ($r=1, \dots, k$).

(b) S_{i_1} is a subset of $\{x_1, \dots, x_n\}$;

S_{i_2} is a subset of $\{x_1, \dots, x_n, z_{i_1}\}$;

S_{i_3} is a subset of $\{x_1, \dots, x_n, z_{i_1}, z_{i_2}\}$; etc.

(c) The subsets $S_{i_1}, S_{i_2}, \dots, S_{i_k}$ are as small as possible.

Step 4. Construct simplified consequences of the form $z_r = g_r$

($r=1, \dots, k$), where the arguments of g_r are those appearing in S_r .

Example 9. A multiple-output circuit is specified by the equations

$$z_1 = \bar{a} + bc$$

$$z_2 = a\bar{b} + \bar{c}$$

$$z_3 = \bar{a} + \bar{b} + \bar{c}.$$

Let us apply the procedure given on the previous page, with the object of reducing the logical cost of the foregoing specifications.

Step 1: $\phi = \bar{a}\bar{c}z_1z_2z_3 + \bar{a}cz_1\bar{z}_2z_3 + a\bar{b}\bar{z}_1z_2z_3 + ab\bar{c}\bar{z}_1z_2z_3 + abc z_1\bar{z}_2\bar{z}_3$

Step 2: Calculation of z_1 -determining subsets:

$$\phi_{z_1} = \bar{a}\bar{c}z_2z_3 + \bar{a}c\bar{z}_2z_3 + abc\bar{z}_2\bar{z}_3$$

$$\phi_{\bar{z}_1} = a\bar{b}z_2z_3 + ab\bar{c}z_2z_3$$

$$\begin{aligned} a_{z_1} &= (a)(a)(a + z_2)(a + c + z_2)(b + z_2 + z_3)(c + z_2 + z_3) \\ &= abc + az_2 + az_3. \end{aligned}$$

Similarly,

$$a_{z_2} = abc + cz_1 + acz_3$$

$$a_{z_3} = abc + az_1 + az_2.$$

Step 3: Two subset-sequences are promising:

Sequence # 1

$$S_1 = \{a, b, c\}$$

$$S_2 = \{c, z_1\}$$

$$S_3 = \{a, z_1\} \text{ or } \{a, z_2\}$$

Sequence #2

$$S_3 = \{a, b, c\}$$

$$S_1 = \{a, z_3\}$$

$$S_2 = \{c, z_1\}$$

Step 4: Simplified functional consequences:

Sequence #1

$$z_1 = \bar{a} + bc$$

$$z_2 = \bar{c} + \bar{z}_1$$

$$z_3 = \bar{a} + \bar{z}_1$$

Sequence #2

$$z_3 = \bar{a} + \bar{b} + \bar{c}$$

$$z_1 = \bar{a} + \bar{z}_3$$

$$z_2 = \bar{c} + \bar{z}_1$$

Either of the foregoing realizations is more economical than a direct realization of the original specifications. Each requires a single IC package, sequence #1 a quad 2-input NAND and sequence #2 a triple 3-input NAND.

Example 10. The input-logic for a clocked D-latch is defined by the equations

$$U = \bar{C} + \bar{D} \quad (41a)$$

$$V = \bar{C} + D, \quad (41b)$$

where U and V are excitation-signals for a NAND-latch, C is a clock-input, and D is a data-input. A circuit implementing (41a) requires a single NAND-gate; however, (41b) requires an inverter in addition to a NAND-gate. To simplify (41b), we resort to functional deduction. The system (41) is equivalent to the single equation $\phi = 1$, where

$$BCF(\phi) = \bar{C}UV + C\bar{D}U\bar{V} + CD\bar{U}V. \quad (42)$$

We deduce from (42) that C, U, and V are functionally deducible from $\phi = 1$. The corresponding determining subsets are represented by the functions a_C , a_U , and a_V :

$$a_C = UV$$

$$a_U = CD + CV$$

$$a_V = CD + CU.$$

The function a_V implies that $\{C, U\}$ is a V -determining subset. The corresponding functional consequence is specified by (35) as follows:

$$D_D(\phi_V) \leq V \leq \overline{D_D(\phi_V)},$$

i.e.,

$$\overline{CU} + C\overline{U} \leq V \leq \overline{C} + \overline{U}.$$

A simplified functional consequence specifying V , therefore, is

$$V = \overline{C} + \overline{U}.$$

A circuit implementing the latter relation requires only a single NAND-gate.

Example 11. Let us suppose that we are to design an asynchronous sequential circuit having inputs a_1 and a_0 and output z . The output is to have the value 1 if and only if the present value of the binary number a_1a_0 is greater than the preceding value. We assume that the signals a_1 and a_0 cannot change simultaneously.

By standard processes of asynchronous-circuit design we arrive at the specification

$$\begin{aligned} y &= \text{maj}(a_1, a_0, y) \\ z &= \text{maj}(a_1, a_0, \bar{y}), \end{aligned}$$

where y is an internal state-variable and where the "majority" function maj is defined by $\text{maj}(x, y, z) = xy + xz + yz$. The foregoing specifications are best implemented by full adders (FA's), which generate majority-functions at their carry-outputs; the resulting circuit is shown in Figure 1.

The circuit of Figure 1 requires two packages, a dual full adder and a hex inverter. Only one-sixth of the inverter-package is employed, however, and the upper full adder provides a sum-output,

$$s = a_1 \oplus a_0 \oplus y,$$

Fig. 1. Asynchronous circuit--original design.

which is not employed at all. These observations lead us to apply functional deduction to the expanded system

$$y = \text{maj}(a_1, a_0, y)$$

$$z = \text{maj}(a_1, a_0, \bar{y})$$

$$s = a_1 \oplus a_0 \oplus y.$$

The foregoing specifications are equivalent to the single equation $\phi = 1$, where

$$\phi = \bar{a}_1 \bar{a}_0 \bar{s} \bar{y} \bar{z} + (\bar{a}_1 a_0 + a_1 \bar{a}_0)(\bar{s} \bar{y} z + \bar{s} y \bar{z}) + a_1 a_0 s y z.$$

Thus

$$\phi_z = \bar{a}_1 a_0 s \bar{y} + a_1 \bar{a}_0 s \bar{y} + a_1 a_0 s y$$

$$\phi_{\bar{z}} = \bar{a}_1 \bar{a}_0 \bar{s} \bar{y} + \bar{a}_1 a_0 \bar{s} y + a_1 \bar{a}_0 \bar{s} y,$$

whence

$$a_z = (a_0 + s)(s + y)(a_1 + a_0 + s + y)(a_1 + s)(a_1 + a_0 + s + y) \\ (s + y)(a_1 + a_0 + s + y)(a_1 + s)(a_0 + s),$$

i.e.,

$$a_z = a_1 a_0 y + s.$$

A result (surprising to this investigator) of the function a_z is that one of the z -determining subsets is $\{s\}$. The corresponding z -consequence is specified by the interval

$$D_{\{a_1, a_0, y\}}(\phi_z) \leq z \leq \overline{D_{\{a_1, a_0, y\}}(\phi_z)},$$

i.e.,

$$s \leq z \leq \bar{s}.$$

Thus, z is given by

$$z = s.$$

The corresponding circuit, shown in Figure 2, requires only one-half of a dual full-adder package.

Fig. 2. Asynchronous circuit--modified design.

PART B

INFERENCEAL ANALYSIS OF RELATIONAL DATABASES

Donald Keith Taylor

FOREWORD

Database-processing is an important potential application of the proposed inferential processor. We show in this study that propositional deduction may be used to determine the functional dependencies in a relational database, from which (as is well-known) the keys for the database may be determined. In particular, we have developed and programmed a two-part algorithm: the first part generates the functional dependencies of the relation; the second part uses these dependencies, together with rules for propositional inference, to generate the keys of the relation. The algorithm is programmed in the logical language PROLOG.

CHAPTER I

INTRODUCTION

A major problem in the design and use of computers is that of storing, retrieving, and updating large quantities of non-numerical data. This problem is usually managed by storing these data in a database. Several types of databases exist; however, the relational database has the simplest and most regular structure. This structure makes the relational database attractive for use in large, high-speed data retrieval systems employing associative memories and parallel processors.

The relational model is based on the idea that a database containing information about a particular object (e.g., a university class-schedule) can be viewed as a relation on a set of attributes; the attributes for a class-schedule would be the course number, the room number, the professor's name, and so on. The data of the relational database are stored in a simple tabular form, one row for each record, and one column for each attribute.

The data in each row of the table are accessed by using a key of the database. A key in a relational database is a subset of its attributes which "unlocks"

the database: if the value of each attribute in a key is specified, a unique row of the table can be specified. The keys of a relational database are sometimes very difficult to locate; however, examination of the functional dependencies inherent in a database will generate the desired keys.

The functional dependencies of a database have many uses in modern database theory. However, no clearly defined generation method for these dependencies has been developed. Using the recently proven fact that propositional (Boolean) logic can be used to characterize the functional dependencies inherent in a relational database, an algorithmic procedure to generate these dependencies will be derived. By applying Boolean analysis to these dependencies, an algorithm will be developed to determine the keys of relational database. The two preceding algorithms will be joined together to form the FD-Key algorithm. The FD-Key algorithm has the capability to generate the functional dependencies of a relational database; using these dependencies, the keys of the database may be located. To demonstrate the feasibility of the FD-Key algorithm, the logic programming language, PROLOG, will be used to generate the functional dependencies and keys of a given

relational database.

In Chapter II, the basic concepts of relational databases are discussed, emphasizing the terms, components, and properties of such databases. Also, some associated problems of utilizing relational databases are explored.

Chapter III presents some fundamental rules and properties of propositional logic and Boolean analysis. Also, the equivalence of propositional logic and relational databases is discussed. An algorithm to generate the keys of a database from its functional dependencies is developed. This algorithm is later used as one of the main components of the FD-Key algorithm.

In Chapter IV, the algorithm to generate the functional dependencies from a relational database is developed. As an example, the functional dependencies and keys for a given relation are derived.

Chapter V discusses the basic concepts of the logic programming language PROLOG. Using these concepts, Chapter VI presents the syntax rules and system requirements for correct implementation of the FD-Key algorithm developed in Chapters III and IV.

Suggestions for future work involving the FD-Key

algorithm are presented in Chapter VII. Chapter VIII contains a brief summary of the work and conclusions presented in this thesis. The flowcharts of the FD-Key algorithm presented in this thesis are contained in Appendix A. Appendix B is made up of the actual PROLOG software used to execute the FD-Key algorithms. Finally, Appendix C contains executions of the FD-Key algorithm in PROLOG for several sample relations.

CHAPTER II

INTRODUCTION TO DATABASES

Database Models

A typical database is organized into three different parts: a collection of interrelated data, the hardware necessary to store the data, and the software required to use the data in a real-world application. The database must accurately represent some undertaking in the real world, and it must be at the user's disposal. The currently available hardware imposes a structure upon the data. This structure is called a schema, and it defines the data model used in creating the database. Each model is given a name which represents the way data are viewed by the users. The three currently used structures are the network, hierarchy, and relational models. The database systems that are currently in existence were proposed and studied in many different reports by several authors [1,2,3,4,5,9,12,14,15,17,18,19,21,23].

The network model was first proposed by the Committee on Data System Language, (CODASYL). This model consists of various blocks of data organized in a network. The access time for some blocks of data is very fast, but the user must set up the structure of

the system, which cannot be altered once the data have been stored.

The second data structure is the hierarchical data model. Here, data blocks with similar characteristics are accessed by a common data path. Hence, access time between data blocks with similar information is very small, but access time between blocks with very dissimilar data can be very large.

The third data structure is the relational model developed by E. F. Codd [10]. In a relational database, the data are normalized into a form where the relationships among data items appear in a two-dimensional tabular form. Most users have very little trouble in understanding this data model since the two-dimensional table is a familiar method of conveying information. This thesis will use the relational data model exclusively.

Relational Databases

The previous discussion presented some general concepts of data models, but to fully understand relational databases, the accepted conventions, properties, and formal definitions of a relational database must be explained. Henceforth, the use of the word "database" will refer to a relational database.

In a database, the two-dimensional table is called a relation. The columns of the relation are labeled with unique names called attributes, and the rows are called tuples. The data values in the relation are chosen from several sets of values called domains. Each attribute has a domain and several attributes may share the same domain. For example, if a relation has two attributes, say part number and serial number, the attributes are different, but their domains could be the same set of numbers. A more formal definition of a relation is now given, since some of the basic terminology has been discussed.

Definition. Given a set of domains $D_1, D_2, \dots$, and D_n , R is a relation on these n sets if it is a collection of n -tuples, $\langle d_1, d_2, \dots, d_n \rangle$, such that d_1 is an element of $D_1, \dots$, and d_n is an element of D_n .

The usual method of representing attributes in a relation is to allow letters near the beginning of the alphabet to stand for individual attributes, and letters near the end of the alphabet to stand for sets of attributes. For example, C could represent the attribute COURSE in Fig. 1, and X could represent the set of attributes {NAME, COURSE, TIME, ROOM NUMBER}. The union of two sets of attributes, X and Y , is denoted by the concatenation XY , and ABC

represents the set of attributes $\{A, B, C\}$. The relation R on the set of Attributes X in Fig. 1 is written as $R(X)$. If X is broken into two sets, $Y = \{\text{COURSE}, \text{TIME}\}$ and $Z = \{\text{NAME}, \text{ROOM NUMBER}\}$ where $X = YZ$, then $R(X)$ is the same as $R(Y, Z)$.

NAME	COURSE	TIME	ROOM NUMBER

Smith	Psychology	9:00	104
Johnson	Physics	9:00	210

Fig. 1. Relation $R(X)$.

Database dependencies. In a database, several relationships exist among the attributes. One of the main relationships is that of functional dependency (FD). Before dependencies can be discussed, the representation of a data value in a tuple must be explained. Let r be a tuple in the relation $R(X)$ on the set of attributes X , where the set of attributes Y is contained in X . The tuple of values of r for the set of attributes Y is denoted by $r[Y]$.

DEFINITION. Given a relation R , two sets of attributes X and Y , the functional dependency, $X \rightarrow Y$, holds in R , (or relation R satisfies $X \rightarrow Y$), if and

only if for any two tuples v and w in R , $v[X] = w[X]$ implies $v[Y] = w[Y]$.

DEFINITION. A dependency s is a consequence of a set of dependencies S if for all relations R , s holds in R if all the dependencies of S hold in R .

Functional dependencies are used extensively in designing relations that are free from data storage and retrieval errors. These errors are called insertion, deletion, and rewriting anomalies. The insertion anomaly is the use of undefined or null values in the table of a relation. The removal of a part of a tuple, causing the loss of other information, is called a deletion anomaly. The rewriting anomaly can easily be explained by the following example. Suppose the functional dependency $A \rightarrow B$ holds in the relation $R(X)$, and there exist tuples $t_1 = \langle a_1, b_1, c_1 \rangle$ and $t_2 = \langle a_1, b_1, c_2 \rangle$ in $R(X)$. Then if t_1 is changed to $\langle a_1, b_2, c_1 \rangle$, the tuple t_2 must be rewritten as $\langle a_1, b_2, c_2 \rangle$. If t_2 is not changed, an anomaly will exist in the relation since the dependency $A \rightarrow B$ will no longer hold.

Database schemata and keys. A relation schema is a description of a single relation consisting of the relation name, a set of attributes, and a set of

dependencies. The state (instance or extension) of a relation schema is simply a table of data that conforms to the set of dependencies and uses the attributes contained in the relation schema. A database schema, $\mathcal{D}$, is the set of relation schemata in the database. The state of a database, D , is a mapping of relation states to the schemata of $\mathcal{D}$.

The concept of a set of key attributes (or simply a key) existing in a database is vital to the retrieval of information stored in a database. Once a key has been located, any other information stored in the database can be accessed.

DEFINITION. A subset Y of X is a key for $R(X)$ if and only if $Y \rightarrow X$ and there is no proper subset Z of Y such that $Z \rightarrow X$.

In other words, a key of a relational database is a subset of its attributes that "unlocks" the information stored in the database: if the data values for a key are specified, a unique row of the table is identified.

A notion of a superkey is closely related to the notion of key. A superkey is a set of attributes containing a key as a subset. Consider the relation $R(X)$ shown in Fig. 2, on the set of attributes $X = \{A, B, C, D\}$. The set $Z = \{A, D\}$ is a key of $R(X)$; thus

one of the superkeys of $R(X)$ is the set $Y = \{A, B, D\}$.

a ₂	b ₂	c ₂	d ₁
a ₁	b ₁	c ₁	d ₂
a ₂	b ₃	c ₁	d ₂

Fig. 2. Relation $R(X)$.

An important but difficult task to be completed before a database can be used is that of determining the set of keys for a given relation. To solve this problem, the set of functional dependencies must either be known or found from the relation. A procedure to generate these dependencies and the keys for a relation is presented later in this thesis.

CHAPTER III

PROPOSITIONAL LOGIC AND THE EQUIVALENCE THEOREM

As discussed in Chapter II, the determination of a set of keys for a relation in a database can be a difficult task. However, once a key has been located, the data stored in the database can be easily accessed. It would be very desirable, therefore, to have a method of key generation for a relation. The aim of the following discussion is to present a method to locate the keys of a relation in a database using the functional dependencies of the relation. In later chapters, this algorithm will be used as a major part of the FD-Key generation algorithm. The method of locating the keys will be developed by examining the equivalence between propositional logic and database dependencies. Before this equivalence can be discussed, some basic ideas of propositional logic and Boolean analysis will be presented.

Propositional Logic

Propositional logic deals with statements that are assigned a truth value. Each statement is called a proposition, and it can have only one truth value, either true or false.

These statements are denoted by propositional variables $A, B, C, \dots$. Using the logic operations & (AND) and $\Rightarrow$ (IMPLY), an implication $A_1 \& A_2 \& \dots \& A_n \Rightarrow B_1 \& \dots \& B_k$ can be created. This implication is said to be true if and only if all of the B_j 's are true or at least one of the A_i 's is false. Hence, this implication can be viewed as a statement (proposition). Normally, & is represented by simple juxtaposition of the variables. For example, the above implication may also be written as $A_1 A_2 \dots A_n \Rightarrow B_1 \dots B_k$. It should be noted that in this thesis the symbol $(\Rightarrow)$ is used for conditional implication. Normally, this symbol is used for logical implication, and the symbol $(\rightarrow)$ is used for conditional implication. However, the symbol $(\rightarrow)$ is reserved in this thesis for use with functional dependencies; to avoid notational confusion, therefore, the symbol $(\Rightarrow)$ is used for conditional implication. The following discussion presents some basic ideas of propositional logic [8].

A fundamental inference-rule of propositional logic is that of hypothetical syllogism. This rule states that the conclusion below follows from its premises.

Major Premise: $X \Rightarrow Y$.

Minor Premise: $Y \Rightarrow Z$.

Conclusion: $X \Rightarrow Z$.

The proposition $X \Rightarrow Z$ is said to be a logical consequence of the set of propositions $\{X \Rightarrow Y, Y \Rightarrow Z\}$. In general, we have the following:

Definition. The proposition F is a logical consequence of a set of propositions S , if for every truth assignment P , the proposition F is true under P when all the propositions of S are true under P .

In propositional logic, deduction, (the generation of a conclusion from a set of premises), is performed by invoking various inference rules. These rules state that a specific conclusion can be obtained from a specific set of premises. While these rules work and are useful, a more simplified method of deriving conclusions would be very useful.

Boolean Analysis

Propositions satisfy a set of mathematical laws that are used to define a Boolean algebra. The relation $\Rightarrow$ (conditional implication) of propositions can be translated into the relation $\leq$ (inclusion) of Boolean algebra. In particular, the statement

If X is true, then Y is true

can be represented by the two equivalent expressions

$X \Rightarrow Y$, and

$X \leq Y$.

The information in these expressions can also be presented in two types of equations. These equations can either be in the "equals-zero" or "equals-one" form of Boolean algebra. The equals-one form is found by complementing the left side of the arrow and forming the logic OR of this result with the right side. For example, the equals-one form of the proposition $X \Rightarrow Y$ is given by $X' + Y = 1$. The equals-zero form is found by complementing the right side of the arrow and forming the logic AND of this result with the left side of the arrow. For the previous example, the equals-zero form would be $XY' = 0$. The equals-one form states that "X is false or Y is true" is a true statement. The equals-zero form states that "X is true and Y is false" is a false statement. Hence, the propositions $X \Rightarrow Y$, $Y \Rightarrow Z$, and $X \Rightarrow Z$ can be represented as Boolean equations $XY' = 0$, $YZ' = 0$, and $XZ' = 0$, respectively. It is a property of Boolean algebra that a sum is equal to zero if and only if each of its summands is equal to zero; hence, the above equations can be written as one equation, i.e.,

$XY' + YZ' + XZ' = 0$. Each of the above summands is made up of variables. A single variable, either complemented or uncomplemented, will be called a literal, and the summands in the above equation will be called terms. Each term consists of a single literal or a product of literals in which no literal appears more than once. A term p is included in a term q if all of the literals of q are contained in p . An SOP (sum of products) formula is a single term or a sum of terms. Two important types of terms will now be defined.

Definition. An implicant of a function F is a term p such that p is included in F .

Definition. A prime implicant of a function F is an implicant p of F such that, for any term q , if p is included in q and q is included in F then p and q are equal.

Blake canonical form. In 1937, A. Blake [6] showed that the sum of all prime implicants of a Boolean function G is a canonical form for that function. We shall call this the Blake canonical form for G and denote it by $BCF(G)$.

There are several methods of generating the Blake canonical form of a Boolean function. This thesis will only deal, however, with the method of iterated consensus, which is based upon the following

definitions.

Definition. Two terms p and q are said to have a literal in opposition if

- (i) term p contains a variable A that is uncomplemented, and
- (ii) term q contains the complemented variable A' .

Definition. Let two terms T_1 and T_2 of a Boolean formula F have exactly one literal in opposition, i.e., let $T_1 = X'P$ and $T_2 = XQ$, where P and Q are terms such that PQ is not equal to zero. Then the consensus of T_1 and T_2 is formed from the product PQ by

- (i) deleting the two opposing literals and
- (ii) deleting any repetitions of a literal.

The method of generating the BCF of a Boolean function using iterated consensus is given below.

Definition. Given a Boolean formula F , $BCF(F)$ can be generated by the following procedure.

- (i) Express F as an SOP formula.
- (ii) Persist in the following operations as long as possible:
 - (a) Append to the formula the consensus of two of its terms, unless the consensus is included in a term

already present.

- (b) Delete any term that is included in another term.

Definition. An SOP formula G is said to be formally included in an SOP formula F if every term of G is included in some term of F .

The following two theorems will be presented without proofs. For a more formal presentation, see Blake [6].

Theorem. An equation $F=0$ is a conclusion of the equation $G=0$ if and only if the function F is included in the function G .

Theorem. Let F and G be SOP formulas. Then F is included in G if and only if F is formally included in $BCF(G)$.

To clarify this Theorem, let us examine the following expressions (hypothetical syllogism):

	Propositions	Equations
Major Premise:	$X \Rightarrow Y$	$XY' = 0$
Minor Premise:	$Y \Rightarrow Z$	$YZ' = 0$
Conclusion:	$X \Rightarrow Z$	$XZ' = 0$

After forming the SOP formula $G = XY' + YZ'$, $BCF(G)$ can be found by iterated consensus: $BCF(G) = XY' + YZ' + XZ'$. But, XZ' is formally included in

$BCF(G)$, so $XZ' = 0$ is a conclusion of the equation $G = 0$. This conclusion is equivalent to the proposition $X \Rightarrow Z$, and hence the same result is found by two different but equivalent methods. As mentioned earlier, a simplified method for inferring conclusions was desired. Using the Blake canonical form to generate a conclusion from a given set of propositional premises, stated as equations, is such a method. For a more detailed study of this procedure see [7].

Equivalence Between Propositional Logic And Databases

For a given set of propositions $\{A \Rightarrow B, C \Rightarrow D\}$ and a corresponding set of functional dependencies $\{A \rightarrow B, C \rightarrow D\}$, the syntactical similarity of the sets is very apparent. However, this similarity does not necessarily imply that two corresponding elements of these sets are equivalent. Fortunately, Sagiv, et. al. [21] has proved the following theorem. This theorem states that a set S of functional dependencies is equivalent to a corresponding set of propositions S^* , where S^* is obtained by replacing the dependency symbol $(\rightarrow)$ with the conditional implication symbol $(\Rightarrow)$.

Equivalence Theorem. Let F be a functional dependency and let S be a set of dependencies. Then the following are equivalent:

- (i) The functional dependency F is a consequence of the set S of functional dependencies.
- (ii) The proposition F^* is a logical consequence of the set S^* of propositions.

This theorem states that the set $S = \{A \rightarrow B, B \rightarrow D\}$ of functional dependencies has an equivalent set $S^* = \{A \Rightarrow B, B \Rightarrow D\}$ of propositions, which is generated by replacing the symbol $(\rightarrow)$ with $(\Rightarrow)$. Further, since the proposition $A \Rightarrow D$ is a logical consequence of S^* , the equivalent functional dependency $A \rightarrow D$ is a consequence of S .

This theorem is a very bold statement. It allows any database problem concerning functional dependencies to be solved by the techniques of propositional logic and guarantees the solution to hold for the dependencies of the database. Since the available tools of propositional logic are generally much easier to implement than the inference rules for dependencies, a very difficult database problem may

easily be solved with propositional logic. Hence, the preceding method of iterated consensus may be used to generate the solutions for a given problem concerning the dependencies of a database.

Key generation. As an example of the power of this theorem let us examine the relation $R(X)$ in Fig. 1 of Chapter II. The following functional dependencies exist in this relation. Note that the attributes are replaced by one-letter symbols to make the variable manipulations clearer.

NAME- $\rightarrow$ COURSE	N- $\rightarrow$ C
NAME, TIME- $\rightarrow$ ROOM, COURSE	NT- $\rightarrow$ RC
NAME, ROOM- $\rightarrow$ COURSE	NR- $\rightarrow$ C
COURSE, TIME- $\rightarrow$ NAME, ROOM	CT- $\rightarrow$ NR
COURSE, ROOM- $\rightarrow$ NAME	CR- $\rightarrow$ N
TIME, ROOM- $\rightarrow$ COURSE, NAME	TR- $\rightarrow$ CN

After writing the preceding six dependencies in their equivalent propositional logic forms, the following equations are generated by complementing the right sides of the equivalent propositions and forming the logic AND of this result with the left sides of the propositions.

$$N \Rightarrow C$$

$$C'N = 0$$

$$NT \Rightarrow RC$$

$$R'NT + C'NT = 0$$

$$NR \Rightarrow C$$

$$C'NR = 0$$

$$CT \Rightarrow NR$$

$$CN'T + CR'T = 0$$

$$CR \Rightarrow N$$

$$CN'R = 0$$

$$RT \Rightarrow CN$$

$$C'RT + N'RT = 0$$

Since these equations are in equals zero form, they are equivalent to the single equation $G = 0$, where the function G is the logical sum of their left members, i.e.,

$$G = C'N + R'NT + C'NT + C'NR + CN'T + CR'T + CN'R + C'RT + N'RT.$$

To generate the keys associated with a relation, a method based upon the one developed by Delobel and Casey [13] will be used. For a given relation, the minterm M , which is the juxtaposition of all of the attribute symbols, is always a superkey of the relation. If K is the juxtaposition of all the attributes of a key of the relation and if $G = 0$ is the equation representing the set of dependencies of the relation, then the implication

$$[G = 0] \Rightarrow [K = M]$$

defines all of the keys of the relation.

For the above implication to be true, either $G = 0$

must be false, i.e., $G = 1$, or K must be equal to M , i.e., K and M must both be false, or K and M must both be true. Hence, the above implication can be expressed as the equivalent equation

$$G + KM + K'M' = 1.$$

By applying some generally known properties of propositional logic and Boolean algebra to the above equation, the following equivalent forms can be derived.

$$K(M + G) + K'(M' + G) = 1$$

$$K(M'G') + K'(MG') = 0$$

$$G'M \leq K \leq (G'M')'$$

$$G'M \leq K \leq G + M$$

Let us examine the formula G . Since G represents the original dependencies of the relation, each term of G will contain at least one complemented attribute symbol. Hence, G may not include a minterm containing only uncomplemented attribute symbols. The minterm M containing all of the attribute symbols in uncomplemented form is therefore not included in G . Thus M is included in G' , i.e.,

$$M \leq G'.$$

The foregoing inclusion is equivalent to the Boolean

equation

$$M = G'M;$$

therefore, the expression

$$G'M \leq K \leq G + M$$

is equivalent to

$$M \leq K \leq G + M,$$

which is equivalent in turn to

$$M \leq K \leq BCF(G + M).$$

The reason that $BCF(G + M)$ is used is that it includes all of the information available in terms that contain the fewest possible attribute symbols.

To determine the keys for a relation, only the terms of $BCF(G+M)$ that contain no complemented attribute-symbols are considered. This can be explained by re-examining the bounds on K . The minterm M is the product of all of the attribute symbols, and it forms the lower bound on K . So M must be included in K , and hence K can only include uncomplemented attribute symbols. But K must be included in $BCF(G + M)$; therefore the terms of $BCF(G + M)$ that are keys must contain only uncomplemented attribute symbols.

From the previous example for Relation $R(X)$ of Fig. 1 where $C = \text{COURSE}$, $N = \text{NAME}$, $R = \text{ROOM NUMBER}$,

and $T = \text{TIME}$, the term M is found to be $M = \text{CNRT}$. Using the set $\{N \rightarrow C, NT \rightarrow RC, NR \rightarrow C, CT \rightarrow NR, CR \rightarrow N, TR \rightarrow CN\}$ of functional dependencies for this relation, together with the equivalence theorem, the set $\{N \Rightarrow C, NT \Rightarrow RC, NR \Rightarrow C, CT \Rightarrow NR, CR \Rightarrow N, TR \Rightarrow CN\}$ of equivalent propositions is generated. The formula

$$G = N'RT + C'RT + C'NT + NR'T + CN'T + CR'T + CN'R$$

is produced by converting each proposition into an equation of equals-zero form, forming the sum $G = 0$ of all of these equations, and writing the formula G . Adding the term M to G and calculating $\text{BCF}(G + M)$ yields the result

$$\text{BCF}(G+M) = CT + RT + NT + C'N + CN'R.$$

Using the expression

$$M \leq K \leq \text{BCF}(G + M)$$

for the bounds on the unknown key K , the relation

$$\text{CNRT} \leq K \leq CT + RT + NT + C'N + CN'R$$

is generated. Now by examining the terms of $\text{BCF}(G+M)$ containing no complemented variables, the keys CT , RT , and NT for the relation $R(X)$ of Fig. 1 are found. Also, the superkeys of a relation can be found by concatenating any number of uncomplemented attribute symbols in the relation to the symbols of a key. Therefore, CNT , CRT , NRT , and CNRT are superkeys of the relation.

If the set of functional dependencies for a relation is known, the above procedure will generate all keys and superkeys that exist in the relation. If an algorithm existed to generate the functional dependencies of a relation, then the generation of keys for a relation could be implemented on a computer or dedicated processor designed to perform propositional analysis. This desired dependency generation algorithm has been developed, and it will be presented in the following chapter. Once both of these algorithms have been presented, they can be combined into a single FD-Key generation algorithm.

CHAPTER IV

GENERATION OF FUNCTIONAL DEPENDENCIES

For the key generation algorithm of Chapter III to be applied, the functional dependencies of a relation must be known. We present in this chapter a procedure for generating the functional dependencies of a relation directly from the rows (tuples) defining that relation. When combined with the key-generation algorithm, this procedure enables the keys of a relational database to be derived quickly and conveniently. We call the combined procedure the **FD-Key Algorithm**.

The FD-Key algorithm may be used to solve a number of problems. Suppose a programmer were assigned the task of setting up a large database; then the generation of the keys could be a very tedious and time consuming task. By using the FD-Key algorithm, the programmer could simply insert the database into the computer system, execute the algorithm, and receive the keys and functional dependencies of the database as outputs.

As another example, suppose a database could be updated by several different users. That is, several

users could be changing data values of tuples in the database. This process might create anomalies in the database. Hence, a functional dependency for the original database might no longer hold in the updated version of the database. This type of error may be detected in the following manner. After each change of data, the FD-Key algorithm could be executed on the new database. If the functional dependencies generated from the new database were different from the functional dependencies of the original database, then the recent data changes had violated the integrity of the database. Therefore, the data-updates should be examined for an error.

This chapter will present the section of the FD-Key algorithm that generates the functional dependencies of a relation. To fully understand the operation of this section of the algorithm, the flowcharts of Appendix A and the examples contained in this chapter should be closely examined.

The algorithm makes extensive use of partitions, whose definition we now recall [16].

Definition. A partition P of a non-empty, finite set S is a collection of non-empty subsets of S . The partition is denoted by $P = \{B_1, B_2, \dots, B_k\}$; the

subsets $B_1, \dots, B_2$ are called the blocks of the partition P . The blocks of a partition must satisfy the following two conditions.

- (i) The intersection of any two blocks, B_i and B_j for i not equal to j , is the empty set.
- (ii) The union of all the B_i 's is the set S .

Generation Algorithm

The problem to be solved can be stated as follows: given a relation R and a specific attribute A contained in the relation, generate the functional dependencies of R that contain A on the right side of the arrow. The desired dependencies will have the form $X \rightarrow A$, where X may be the concatenation of several attribute symbols. By continuing this process for all of the attributes, the set of functional dependencies for the given relation will be generated.

The algorithm to generate the functional dependencies manipulates the data in the relations of the database in three different ways. The first data manipulation involves partitioning. Specifically, the tuples of the original relation are placed into a number of relations containing two sub-relations, each of which is generated by using a two-block partition of the data values for an attribute in the original

relation. After formation of the sub-relations, the second type of data manipulation is performed. Here, the tuples in each pair of sub-relations are compared and a Boolean sum of attribute symbols is generated. This sum actually represents the key for the two tuples in the sub-relations being examined. By repetitive generation of these sums for each pair of tuples, the keys of the pair of sub-relations can be found. After all of these sums are generated for the pair of sub-relations, a product of sums (POS) formula is generated by forming a Boolean product of all of the sums. Each pair of sub-relations will be subjected to this procedure, and a group of POS formulas will be generated. Each of these formulas will either be zero, (indicating that no key exists for the pair of sub-relations) or a product of sums. If a formula is zero, this means that no functional dependency can be found for the chosen attribute of the original relation. If all of the formulas are products of sums, however, a third type of data manipulation is needed to generate the functional dependencies of the relation.

This final data manipulation involves some techniques of Boolean algebra. All of the POS formulas generated from the pairs of sub-relations are

multiplied together to form one large POS formula. This last POS formula is converted to a sum of products (SOP) formula and simplified as much as possible. The SOP formula now contains all of the information needed to produce the set of functional dependencies for the original relation. Each term of the SOP formula contains the attribute symbols that are on the left sides of the arrows in the functional dependencies that have the chosen attribute from the original relation on the right side of the arrow.

In the development of the functional dependencies for a relation, the following three assumptions will be made.

- (1) The data-values of the relation will not be updated during the development period.
- (2) The relation will contain a finite number of tuples.
- (3) The relation has a finite number of attributes.

The algorithm to generate the functional dependencies of a relation will now be presented in seven steps.

Step 1. Choose an attribute to appear on the right side of the functional dependencies.

Step 2. Generate the set, L , consisting of one entry for every unique data value in the column under the chosen attribute.

Step 3. Generate a sequence $(P_0^*, \dots, P_n^*)$ of partitions of the set L in the following manner:

- (i) Let $i=0$. P_i^* contains all the data values of the set L in one block.
- (ii) If the number of elements in the largest block of P_i^* is less than or equal to two, stop the operations. Otherwise do (iii).
- (iii) Let $i=i+1$, and generate a new P_i^* that contains 2^i blocks. The blocks in the new partition are found by splitting each of the blocks in the preceding partition into two disjoint blocks whose cardinality differs at most by one. If a block in the preceding partition contains an odd number of elements, the left block of the new pair of blocks will contain one more element than the new right block. Go to (ii) and repeat.

Step 4. Generate another sequence of partitions $(P_1, \dots, P_k)$, of two blocks each, in the following manner:

- (i) Let $i = 1$, and $j = 1$. Set $P_i = P_j^*$.

- (ii) P_{i+1} is made up of two blocks such that the left block contains the left half of each block of P_j^* . The right block of P_{i+1} contains all the elements in P_j^* not present in the left block of P_{i+1} . If a block of P_j^* contains an odd number of elements, the extra element is placed in the left block of P_{i+1} .
- (iii) If P_j^* is the last partition, stop the procedure. Otherwise, let $i = i+1$, and $j = j+1$.

The previous two steps have been designed to provide maximum skewing of the partitions. That is, the number of elements in the left block of each P_i is as large as possible. This procedure will minimize the number of data comparisons necessary in the sixth step of the total algorithm.

Step 5. Generate n copies of the relation being tested, where n is the number of generated P_i partitions. Split each copy of the relation into two sub-relations according to the data values found in the blocks of the P_i 's. Delete the columns corresponding to the attribute being tested from each of these copies. Let R_{i1} and R_{i2} denote the i th pair

of sub-relations, where the subscripts i_1 and i_2 represent the tuples associated with the data values contained in blocks one and two, respectively, of partition P_i . The generation of the sub-relations is outlined below.

- (i) Let $i=1$, j = the numerical position of the chosen attribute in the list of attribute symbols, P_i = the i th two-block partition of the set of data values for the chosen attribute, and T_1 = the first tuple of the relation.
- (ii) If the j th data item of T_1 is in the left block of P_i , then place T_1 in the sub-relation R_{i1} . Otherwise, place T_1 in the sub-relation R_{i2} .
- (iii) If T_1 is the last tuple of the original relation, then go to (iv). Otherwise, let T_1 = the next tuple of the relation, and go to (ii).
- (iv) If $i=n$, stop this procedure. Otherwise, let $i=i+1$, let T_1 = the first tuple of the relation and go to (ii).

Step 6. Generate a Boolean formula E_i for each sub-relation R_i . The formula generated will be in a **product of sums**, POS, form. That is, a sum of literals logically multiplied by other sums of literals. These formulas are generated by the

following procedure.

- (i) Let $i=1$, obtain both the first tuple t_1 of the sub-relation R_{i1} and the first tuple t_2 of R_{i2} . If R_i doesn't exist, go to Step 7.
- (ii) If $t_1=t_2$, abort the dependency algorithm since no functional dependencies exist with the chosen attribute on the right side of the arrow. Otherwise go to (iii).
- (iii) Compare the data values under corresponding attributes of each tuple. If any pair of data values are distinct, insert their attribute name into a sum S . Continue this procedure until all pairs of data-values in t_1 and t_2 have been exhausted, then go to step (iv).
- (iv) Insert the sum S as a product in the POS formula EI . Go to step (v).
- (v) If t_2 was the last tuple of R_{i2} and t_1 was the last tuple of R_{i1} , let $i=i+1$ and go to step (i). If t_2 was the last tuple of R_{i2} and t_1 was not the last tuple of R_{i1} , replace t_1 with the next tuple of

R_{i1} and t_2 with the first tuple of R_{i2} ; then go to step (ii). If t_2 was not the last tuple of R_{i2} , replace t_2 with the next tuple of R_{i2} and go to step (ii).

It was stated previously that maximum skewing of the partitions will minimize the number of tuple comparisons. For example, assume the relation R_i contains $n+k$ tuples such that the sub-relations R_{i1} and R_{i2} contain n and k tuples, respectively. If k is much smaller than n , so that $k=n-p$, where $p>0$, then the number of tuple comparisons required to generate the formula EI is $nxk=nx(n-p)=n^2-np$. But if k and n are equal, then the number of comparisons required is $nxn=n^2$. And if $k=n+1$, then the number of comparisons would be even larger, i.e., $nxk=n(n+1)=n^2+n$. So it is clearly evident that maximum skewing of the partitions P_i 's is necessary to minimize the number of tuple comparisons.

Step 7. Generate the functional dependencies for the relation. These dependencies will contain the chosen attribute on the right side of the arrow. The procedure is outlined below.

- (1) Let the function EA be composed of the product of all the EI functions previously found in the sixth step of the

algorithm.

- (ii) Convert the POS form of EA to a SOP form by multiplying the products and deleting any terms that contain all the literals of another term in EA.
- (iii) Create a dependency with each term T_i of EA and the attribute A, and place each of these dependencies into a set DEP. These dependencies will be of the form $T_i \rightarrow A$, and DEP will be equal to $\{T_1 \rightarrow A, \dots, T_m \rightarrow A\}$. The set DEP now contains all of the dependencies from the original relation that have the chosen attribute on the right side of the arrow.

To clarify the operation of the algorithm, the relation $R(X)$ in Fig. 3 will be used to generate an example for each step of the algorithm. This relation can be found in [21]. Also, some supplementary examples are given to clarify steps of the algorithm that are overly simple when applied to this relation.

A	B	C	D
a ₁	b ₁	c ₁	d ₁
a ₁	b ₂	c ₂	d ₂
a ₂	b ₃	c ₁	d ₁
a ₁	b ₁	c ₁	d ₂
a ₂	b ₃	c ₁	d ₂
a ₁	b ₂	c ₂	d ₁

Fig. 3. Relation R(X).

The first step of the algorithm states that an attribute to appear on the right side of the functional dependencies must be selected. So, in the example relation R(X), the attribute B will be chosen. The second step of the algorithm generates the set L of data values associated with this attribute. For our example, this set is $L = \{b_1, b_2, b_3\}$.

Performing the next step of the algorithm on our relation the sequence of partitions (P_0^*, P_1^*) will be generated. These partitions are sets that contain other sets, hence

$$P_0^* = \{\{b_1 b_2 b_3\}\}$$

$$P_1^* = \{\{b_1 b_2\}, \{b_3\}\}$$

is the correct manner of representing these partitions. This notation contains many braces, and it needs to be simplified. Henceforth, all partitions will be denoted by deleting the braces of the blocks

of the partitions, e.g.,

$$P_0^* = \{b_1 b_2 b_3\}$$

$$P_1^* = \{b_1 b_2, b_3\}.$$

To further clarify this step of the algorithm, let us examine the flowchart of Fig. 9 and another set of data values, namely, $L_1 = \{a_1, a_2, a_3, a_4, a_5, a_6, a_7, a_8, a_9, a_{10}, a_{11}, a_{12}\}$. The following partitions will be generated by this step of the algorithm.

$$P_0^* = \{a_1 a_2 a_3 a_4 a_5 a_6 a_7 a_8 a_9 a_{10} a_{11} a_{12}\}$$

$$P_1^* = \{a_1 a_2 a_3 a_4 a_5 a_6, a_7 a_8 a_9 a_{10} a_{11} a_{12}\}$$

$$P_2^* = \{a_1 a_2 a_3, a_4 a_5 a_6, a_7 a_8 a_9, a_{10} a_{11} a_{12}\}$$

$$P_3^* = \{a_1 a_2, a_3, a_4 a_5, a_6, a_7 a_8, a_9, a_{10} a_{11}, a_{12}\}$$

Now, performing the fourth step of the algorithm on the sequence of partitions generated from the set L , the partitions

$$P_1 = P_1^* = \{b_1 b_2, b_3\}$$

$$P_2 = \{b_1 b_3, b_2\}$$

will be generated. Again, a flowchart and another example is given to clarify this step of the algorithm. Examining the flowchart of Fig. 10 and the sequence of partitions for the set L_1 , the sequence

$$P_1 = P_1^*$$

$$P_2 = \{a_1 a_2 a_3 a_7 a_8 a_9, a_4 a_5 a_6 a_{10} a_{11} a_{12}\}$$

$$P_3 = \{a_1 a_2 a_4 a_5 a_7 a_8 a_{10} a_{11}, a_3 a_6 a_9 a_{12}\}$$

$$P_4 = \{a_1a_3a_4a_6a_7a_9a_{10}a_{12}, a_2a_5a_8a_{11}\}$$

of partitions is produced.

The fifth step of the algorithm will generate several copies of the original relation $R(X)$. Using the partitions P_1 and P_2 of the set L , the copies R_1' and R_2' of Fig. 4 for relation $R(X)$ of Fig. 3 will be generated. This figure shows how the two copies R_1' and R_2' appear before the columns corresponding to attribute B are deleted.

The first copy R_1' of $R(X)$ is partitioned in the following manner. Block one of partition P_1 contains the data values b_1 and b_2 . Therefore, any tuple of $R(X)$ containing these data values under the column B will be placed in the sub-relation R_{11} . Since block two of P_1 contains only b_3 , the sub-relation R_{12} will only contain tuples that have the data value b_3 under the column B . Similarly for the second copy R_2' of $R(X)$, R_{21} will contain tuples that have the data values b_1 and b_3 under the attribute B . Likewise, R_{22} will only contain tuples that have the value b_2 in the column B .

	a ₁	c ₂	d ₁

(b) Copy R₂ of relation R(X).

Fig. 5. Copies of R(X) with attribute B removed.

The sixth step of the algorithm will be illustrated by examining the two relations of Fig. 5 and the flowchart of Fig. 12. In the generation of E₁ for relation R₁, the tuples $t_1 = \langle a_1, c_1, d_1 \rangle$ and $t_2 = \langle a_2, c_1, d_1 \rangle$ are the first two tuples examined. Now by comparison of data values, it is found that only attribute A will be in the first sum S. At this point, therefore, E₁ consists of only one sum, (A).

After performing the tests in step (v), the tuple t_2 will be changed to $t_2 = \langle a_2, c_1, d_2 \rangle$, and t_1 will remain the same. These two tuples are compared, and the new sum $S = A + D$ is generated. The new sum S is placed in the formula E_1 , and this changes E_1 to $E_1 = (A)(A + D)$. Again the tests in step (v) are performed, and this time both t_1 and t_2 will be changed to $t_1 = \langle a_1, c_2, d_2 \rangle$ and $t_2 = \langle a_2, c_1, d_1 \rangle$. After all the tuples of R_1 have been examined, the formula E_1 is found to be

$$E_1 = (A)(A + D)(A + C + D)(A + C)(A + D)(A)(A + C)(A + C + D),$$

which is equivalent to the formula $E_1 = A$. Performing the same operations on the relation R_2 will yield the result

$$E_2 = (C + D)(C)(C)(C + D)(A + C + D)(A + C)(A + C)(A + C + D),$$

which is equivalent to $E_2 = C$. For the final step of the algorithm, the formula EB and its derivation is shown below.

$$EB = (E_1)(E_2)$$

$$EB = (A)(C) = AC$$

Therefore the set DEP contains only the functional dependency $AC \rightarrow B$. By repeated application of this algorithm for the other attributes, the complete set

$$\{B \rightarrow A, AC \rightarrow B, B \rightarrow C\}$$

of functional dependencies for relation $R(X)$ of Fig. 3

can be produced.

Recalling the key generation algorithm presented in the preceding chapter, the following results can be found from the set of functional dependencies. Since the relation $R(X)$ contains the attributes A, B, C, and D, the term M will be equal to ABCD, and from the preceding set of dependencies the equivalent equation $G = 0$ can be derived, where $G = A'B + AB'C + BC$. Using the technique of iterated consensus on M and G, the following results can be obtained.

$$BCF(G+M) = A'B + AB'C + BC' + BD + ACD$$

$$ABCD \leq K \leq A'B + AB'C + BC' + BD + ACD$$

Therefore the set of keys for the relation $R(X)$ of Fig. 3 is {BD,ACD}, and the corresponding set of superkeys is {ABD,BCD,ABCD}. The results generated above may also be generated by visual observation for this relation. A much larger relation may be very hard to analyze visually, but the preceding algorithm will always generate the desired results. The implementation of this algorithm would be very easy in a language designed for logic programming and character string manipulations. Fortunately, the programming language PROLOG has these capabilities and it is very easy to operate from a user's view. This language is presented in the next chapter and the

actual implementation of the FD-Key generation algorithm, using PROLOG, will be presented in Chapter VI.

CHAPTER V

INTRODUCTION TO PROLOG

Basic Structure

In the past few years, several logic programming languages have been developed. One of the most powerful of these is PROLOG, a programming language based on predicate calculus; this language was developed at the University of Marseille starting around 1970. A later, interactive version of PROLOG was implemented on the DECsystem-10 in 1977 [22]. This newer version, containing both an interpreter and a compiler, allows the user to easily write clear, readable, and concise programs. The interpreter aids in the quick development and testing of programs, and also allows access to compiled programs. The compiler produces code that executes ten to twenty times faster than the interpreter, but it is advisable to compile only well-tested programs. Any compiled program can easily be provided with an interpretative interface to the programmer. We present a brief summary in this chapter of the features of PROLOG; for a more detailed description, see [20] and [11].

Components of Prolog

Generally, any object in PROLOG can be called a term. A term can either be a constant, a variable, or a compound term. A constant can be any integer between -131072 to 131071 or an atom. The integers can be written in any base from two to ten. An atom can be any sequence of characters, and any possible confusion with other terms should be eliminated by enclosing the sequence in quotes. For example, 'Rabbit', rabbit, [], and = are all atoms.

A variable is distinguished by an initial capital letter or the leading character "_". Whenever a variable is only referenced once, it can be denoted by the single character "_". For example, Rabbit, X, _32, _result, and _ are all variables.

A compound term is formed with a functor of some arity greater than one. The arity of a functor is the number of terms used as arguments. In the term member(X,[H|T]) for example, the functor "member" has an arity of two since X and [H|T] are the two terms used as arguments. The term [H|T] represents a list, where H is the first element and T is the tail or all remaining elements in the list. An atom may be considered as a functor of arity zero.

The names and arities of functors are totally

arbitrary. That is, the programmer can introduce as many different arguments for a desired functor as needed. PROLOG contains several built-in functors used to perform basic system operations.

A PROLOG program consists of a set of procedures which contain clauses. These clauses are made up of terms, organized into two basic forms. The propositional logic form of the first type of clause, called a conditional Horn clause, is of the form

$$A \leftarrow B_1 \& B_2 \& B_3$$

where A is called the head of the clause and B is called the body of the clause. This clause is read "A is true if B₁ and B₂ and B₃ are true." A conditional horn clause may also have the form

$$A \leftarrow C_1 + C_2$$

where this clause is read "A is true if C₁ or C₂ is true." The second type of Horn clause, known as a unit clause, is a true statement such as

$$A$$

which is read "A is true."

The PROLOG language requires the head of a clause to be separated from the body by the symbol $\leftarrow$, which represents the word "if" in a logic statement. Also, any clause must end with a period. For example, the

three preceding clauses translated into PROLOG would be written as

A:-B₁,B₂,B₃.

A:-C₁;C₂.

A.

These clauses taken together can be viewed as procedure A, where B₁, B₂, B₃, C₁, and C₂ are goals or other procedures to be called by the PROLOG program. The goals in the body of a procedure are separated by the symbols "," or ";" which represent logical conjunction and disjunction, respectively. These goals are procedures that impose conditions upon the head of the clause.

PROLOG also contains provisions for expressing grammar rules. These rules provide an easy method of parsing strings into specific components, and using these components in any manner specified by the program. The typical grammar rule has the form, LHS-->RHS, and it is read as "a possible form for the left hand side is the right hand side." Any PROLOG procedure can be used as a condition on the right side by simply enclosing the procedure in braces, "{}". Grammar rules may seem very confusing when first encountered, but they can be written as ordinary PROLOG clauses. For example, the grammar rule

$p(X) \rightarrow q(X)$ can be translated into the clause
 $p(X, S1, S) :- q(X, S1, S)$. As an example, the procedure

$delim \rightarrow "+"$.

$delim \rightarrow []$.

is a rule to remove the character "+" from a list of characters. If "+" were not the first character in the list, the original list would be the result.

Prolog Semantics

PROLOG semantics can be presented in two different ways. The procedural semantics describes the sequence of states through which the program passes during an execution, and the declarative semantics allows the program to be broken down into many independent programs or procedures. These smaller procedures are usually clear and easily executed.

The declarative semantics makes no reference to the ordering of clauses or procedures in a goal or program. This type of semantics is used to recursively define the conditions necessary for the head of a clause to be true. That is, the head of a clause is true if all of the terms in the body of the clause are also true, and each term is true if it, in turn, is the head of a clause instance which is true. Also a term in the body of a clause may be a compound

term which is the disjunction of two other terms. For example, the clause

$A:-B;C.$

is true if the compound term $B;C$ is true, and the compound term is true if either B or C is true.

The procedural semantics depends upon the ordering of clauses in a program, and the goals in a clause, for crucial program control information. The execution of the program depends upon this information, and the reordering of a set of goals or clauses may completely change the function of a clause or program. The execution of a goal is performed by searching for the first clause whose head matches the goal. This is done in a top-down fashion. That is, the matching starts at the top of the program and continues until a match is found. If a match is found, the goals in the body of the clause are executed from left to right in the same manner. If no match is found, the system backtracks to the most recent clause, discards any substitutions caused by that clause, and the search for another match of the original clause is continued from this clause down through the rest of the program.

There is one other type of control information

available in PROLOG, called the cut symbol. This symbol, "!", is used as a goal in a clause and always succeeds when it is first called. If PROLOG ever backtracks to the cut symbol, the goal that caused the clause containing the cut symbol to be called will always fail. This symbol allows the programmer to force a goal to succeed or fail after it has been partially executed.

Examples of Prolog Programs

Two simple examples of PROLOG programs will be presented. The first example will consist of a program to solve the following logic problem.

Bob likes logic.
 Mary likes logic.
 Bob likes anyone who likes logic.
 What does Bob like?

The PROLOG program will consist of two unit clauses and one conditional clause involving the predicate "likes":

```
likes(bob,logic).
likes(mary,logic).
likes(X,Y):-likes(Y,logic).
```

After the program has been interpreted by the computer, the input query

likes(bob,X).

will yield the results:

X=logic;

X=bob;

X=mary

Here, the symbol ";" is used to request an alternate answer for the query after one answer has been found.

As another example, consider the problem of concatenating two lists together to form a third list. The procedure could be formulated as follows:

concatenate([],L,L).

concatenate([X|L],T,[X|K]):-

concatenate(L,T,K).

The predicate "concatenate" is defined by the program; that is, PROLOG does not know what this procedure means until it receives these statements. However, the symbols [] and [[]] are known to the language. The first clause states that the empty list concatenated with a second list is simply the second list. The second clause states that the list [X|L] concatenated with the list T is the list [X|K] if the list L

concatenated with the list T is the list K. When the query

```
concatenate([a,b,c],[d,e,f],K)
```

is presented to this program, the variable K will be returned as the list [a,b,c,d,e,f]. The above procedures are but two of many possible examples, and it should be noted that an excellent source [11] of programming examples exists.

The next chapter contains a description of the operation of the FD-Key algorithm presented in the preceding chapters. This description contains the syntax rules that must be obeyed for proper operation of the program. and some possible modifications that the user may wish to use.

CHAPTER VI

SYSTEM REQUIREMENTS AND SYNTAX

The purpose of this chapter is to present the syntax rules and system requirements for the correct implementation of the FD-KEY algorithm as it is currently programmed using the language PROLOG.

System requirements. For the FD-Key program in Appendix C to run correctly, the user's computing system should meet the following requirements. First, Version 3 of Dec-10 PROLOG or its equivalent must be used. Otherwise, several clauses in the program will not function correctly. For example, any clause that uses the built-in predicate 'read' to input information from a data file will usually have a test for the end of file marker, 'end_of_file'. If an earlier version of PROLOG is used, this marker may be ':-end', and the program will never cease to input information from the data file. Therefore, a loop will be created, and the program will either fail or yield an erroneous result.

The other requirement is that the user's system must have an adequate amount of memory storage available. This is because the FD-Key program

generates several files for data input and output during execution. Also, the program and its compiled version require several blocks of storage. It should be noted that the program deletes all of the data files created during execution. The only exception to this is the file 'propa', which contains the functional dependencies of the input relation.

FD-Key algorithm. The FD-Key algorithm consists of two main routines. The first routine is the functional dependency algorithm, presented in Chapter IV. The second routine is the key generation algorithm presented in Chapter III. The operation of these algorithms is explained in the following section of this chapter.

The FD-Key algorithm is designed to perform the following tasks:

- (i) Input a list of attribute symbols for a given relation.
- (ii) Output the functional dependencies for the relation.
- (iii) Output the keys for the relation.
- (iv) Output run-times for various routines in the algorithm.

Since the language used is PROLOG, all constants must be in lower case letters. For example, the list

of attribute symbols for relation $R(X)$ of Fig. 3, would be $[a,b,c,d]$. If the attribute symbols in the list were capital letters, PROLOG would interpret the contents of the list as unknown variables. This interpretation could lead to meaningless answers or to the failure of the entire program. It should be noted that the ordering of the attribute symbols is very important. The symbols must be in the same order as the columns of the relation. For example, if the list for $R(X)$ of Fig. 3 were changed to $[b,a,d,c]$, the algorithm would not generate the correct functional dependencies. The generated keys would be invalid for the relation.

As the FD-Key algorithm is currently programmed, the relation to be examined must be stored in a particular form. Each tuple of the relation must be stored as a list. For example, the tuple

$$\langle a_1, b_1, c_1, d_1 \rangle$$

would be stored as the list

$$[a_1, b_1, c_1, d_1].$$

Each list must be followed by a period or the program will not be able to input the data correctly. The file 'base' contains the lists that correspond to the tuples of the given relation. To run the main

algorithm, the system must be in PROLOG, and the compiled version of the FD-Key program must be restored. For example, consider the output of Appendix C for the relation $R(X)$ of Fig. 3. The program is called by the predicate

`mainthing([a,b,c,d]).`

The argument, `[a,b,c,d]`, of the predicate is simply the list of attribute symbols for the relation $R(X)$. When this predicate is executed, the relation in the file 'dbase' is examined; the functional dependencies for this relation are stored in the file 'propa', and the keys of the database, along with the run-times for various routines in the algorithm, are output to the user.

If the user wishes to generate the keys for a relation whose functional dependencies are known, the set of dependencies must be stored in the file 'propa'. Each dependency must be written as a logical proposition followed by a period. Thus, the functional dependency $A \rightarrow B$ would be stored in the file 'propa' as

`a=>b.`

To call the key generation section of the program, the following predicate is used:

`solve_for_keys([a,b,c,d]).`

In this example, the argument [a,b,c,d] is the list of attributes for the relation containing the functional dependencies found in the file 'propa'.

To make any other predicate of the program available to the user, a public statement must be used to declare the predicate, and the new program must be compiled. For example, to declare the predicate

concatenate(X,Y,Z).

of Chapter V, the statement

:-public concatenate/3.

must be inserted in the program. The format of this statement is

:-public name/arity.

In this statement, the name of the predicate is separated from the number of its arguments by the slash.

The flowcharts of the FD-Key algorithm can be found in Appendix A. These flowcharts are written at a level which will enable the user to translate the algorithm to another language if PROLOG is not available. The PROLOG program of the FD-Key algorithm is found in Appendix B. This program contains numerous comments designed to explain each set of clauses. Generally, the purpose of the set of clauses

and a brief example is contained in each comment. Appendix C is made up of some sample runs of the FD-Key algorithm for various relations. Each run contains the input commands to the computer, a listing of the input relation, a listing of the keys for the relation, and a listing of the functional dependencies generated by the algorithm.

CHAPTER VII

PROPOSALS FOR FUTURE WORK

There are a number of ways in which the present FD-Key routine might be improved, i.e., made more efficient or extended in application. Three such improvements are detailed below.

Employment of an inferential processor. Since the key generation routines depend upon two separate calculations of the Blake Canonical Form, a processor capable of performing this calculation in hardware would be very advantageous. Fortunately, an inferential processor has been proposed [8] that can generate the Blake Canonical Form very quickly. This device receives a sum of terms formula from a host computer and outputs the Blake Canonical Form of this sum to the host. By using this type of device, a large portion of the key generation program could be replaced. A revised algorithm to generate the keys is presented below.

- (i) Input the set S of functional dependencies for the relation.
- (ii) Express the set S as a Sum of Products formula F .

- (iii) Add the term which corresponds to the list of attributes to F.
- (iv) Output F to the hardware processor.
- (v) Input $BCF(F)$ from the processor.
- (vi) The set of keys K corresponds to the terms of $BCF(F)$ that contain only uncomplemented literals.

This key generation algorithm clearly reduces the amount of software used, and consequently the cost of processing and the computer time required would be reduced. By using this technique, the algorithm may be speeded up to be used in a real-time data processing situation. Another method of speeding up the key generation routine is presented in the next section.

Multi-valued dependency generation. As the FD-Key algorithm is presently formulated, only functional dependencies of a relation are manipulated. The inclusion of the information contained in the multi-valued dependencies of the relation would speed up the

key generation routine. However, two problems remain to be solved before this improvement can be made. First, an algorithm to generate the multi-valued dependencies from the relation would have to be developed. Secondly, an algorithm to translate these dependencies into a sum of products form would have to be created. After these problems are overcome, the new SOP formula could be added to the SOP formula for the functional dependencies, and the resulting Blake Canonical Form of this formula may provide some additional information not contained in the original Blake Canonical Form for the functional dependencies.

Program modifications. Another area of improvement would be to change the PROLOG implementation of the FD-Key algorithm. The new PROLOG program would be different in two ways. First, the routines that manipulate the Boolean formulas would be changed. These new routines would work directly on the sum of products or product of sums formulas instead of a list of lists. This modification would not only speed up the data manipulations, but it would also remove the routine used to parse a formula into a list of lists. Although this modification would involve major

revisions in the program routines, a large saving of run-time should be realized.

A second way to improve the efficiency of the program would be to keep as much data as possible in fast memory, that is, not to store data in files for later use in the program. By keeping the data in fast memory, the data retrieval time will be very short and the algorithm would execute more efficiently. This modification would also require major revisions in many of the procedures, but the run-times should be quicker.

Normal form generation. A final area of future work might be the development of an algorithm to produce normal forms of a relation. If an algorithm to generate both functional and multi-valued dependencies existed, a method to generate the normal forms of a relation based upon this algorithm could be produced. The development of this normalization routine should be a very straight-forward, since the normal forms of a relation are generated by examining the keys and dependencies that are associated with that relation.

CHAPTER VIII

CONCLUSIONS

The purpose of this thesis was to present an algorithm capable of generating the keys and functional dependencies of a relational database. The feasibility of this algorithm was demonstrated by implementing it with the computer language PROLOG.

The key generation algorithm is based on a theorem, due to Sagiv, concerning the equivalence of logical propositions and functional dependencies. This theorem allows the formidable problem of key generation to be solved by techniques of Boolean analysis.

An algorithm based on partitioning was then developed to generate the functional dependencies of a database. These two algorithms were combined to form the FD-Key algorithm, which was implemented using the logic-programming language PROLOG.

This implementation involved many different uses of propositional logic, Boolean analysis, and the Blake canonical form for the actual generation of functional dependencies and keys for a relational database. The execution of the FD-Key algorithm imposes a distinct set of computer system

requirements. These requirements were presented and some actual executions of the FD-Key algorithm were given as examples.

The FD-Key algorithm provides a convenient method for generating the keys and functional dependencies of a database. This algorithm has produced a solution to a difficult and complex problem of relational databases, namely the identification of the keys necessary to access the information stored in the database, by using the techniques of propositional logic and Boolean analysis.
