During the austral summer of 1979-1980 a four microphone infrasonic array was reinstalled at Windless Bight (77°45'S, 167°45'E) on the Ross Ice Shelf near McMurdo Station Antarctica. The analogue infrasonic wave recording system was placed at McMurdo Station for the continuous recording of data on paper chart and slow speed magnetic tape throughout the following year. The infrasonic system installation is described in our report titled:

GIR80-1, Antarctic Atmospheric Infrasound System Installation and Development, 13 Dec 79 to 22 March 1980.

The development of the digital data acquisition and analysis system was completed by October of 1980 as is described in the above listed report GIR80-1. One year of infrasonic data from Windless Bight was analyzed for a background noise study to show that 90% of the time the peak-to-peak noise level is less than 2.5 microbars. These results were presented in our report:

GIR80-2, Noise Analysis for Windless Bight Infrasonic Array, 23 March 1980

The newly developed digital infrasonic system was connected to the existing microphone array at Fairbanks to test its capabilities. Studies were also made of the digital analysis system using data tapes digitized

from analogue magnetic tapes from the Fairbanks microphone array on which signals had been recorded from volcanic eruptions and mountain associated infrasound. During October 1980 microbaroms, auroral infrasonic waves and the atmospheric test of a nuclear weapon in China were all recorded and analyzed in real-time by the new system as described in our report:

GIR80-3, Digital Acquisition and Analysis System for Antarctica:
Hardware, Software and Testing, 31 October 1980

The new digital system was taken to Antarctica and installed in the Cosmic Ray building at McMurdo station in November of 1980. A new three microphone array with one kilometer spacing was added to the existing 4 microphone array in Windless Bight (see Figure 1). On December 2, 1980 the digital system was operational and began detecting signals immediately as described in our report:

GIR81-2, Digital Infrasonic system Installation in Antarctica, 26
February 1981

The digital system continued to acquire and analyze infrasonic microphone data in real-time throughout the year with the exception of a six week period from 1845 U.T. 11 June 81 to 1327 U.T. 1 August 1981 when the RTG power supply cable developed an open circuit dropping the telemetry system off the air. The repair of this fault was delayed by

bad weather conditions causing difficulty in finding the RTG site in the winter night darkness.

The development by Dr. John V. Olson of the Geophysical Institute staff of a data-adaptive polarization filter technique for analyzing time-series data resulted in our testing his methods on infrasonic tapes to see if we could enhance our signal detection capabilities. We were able to show that by use of the polarization filter technique we could detect a synthetic sine wave signal in a random noise background with the digital system when the signal level was -12db with respect to the noise. This work is described in our report:

GIR81-1, Infrasonic Signal Detection Enhancement by a Pure State Filter, 16 February 1981

The great success of the polarization filter technique with infrasonic data led to our proposal to up-grade the Antarctic digital system to include pre-filtering of the microphone outputs with Olson's pure state filter. Upon receipt in April 1981 of a \$50,000 increase in the project funding work was begun on developing the hardware and software for the polarization filter digital system.

The training of the winter-over technician for Antarctica, Mr. Bruce McKibben, an electrical engineer from Oregon State University, was begun in September following the NSF Antarctic Orientation Conference. Mr. McKibben has worked with Dr. Olson writing the software for the off-line frequency-wavenumber analysis in the frequency domain to be used

in Antarctic on signals detected by the time domain real-time digital system. He has also worked with the digital design engineer, David Spell, on the new computer hardware.

Bruce McKibben will deploy to Antarctica on December 12 while David Spell and Charles Wilson will leave in late December. The new building that is being built at McMurdo Station for the infrasonics project should be ready by December 15, 1980.

Summary of Infrasonic Data Collected

Analogue Data

Slow speed analogue magnetic tape recording (0.25 inch per minute) and Esterline-Angus paper chart recordings (at 0.75 inches per minute, 1 cm chart displacement equals one microbar of pressure) have been made of the three microphone array (RTG, Erebus and Terror sites) at Windless Bight since 29 January 1980 through December 1, 1980 when an additional microphone (ROSS site) was added to the long period or F array.

Analogue recording of these four microphone sites has been continuous since 1 December 1980 until the present time with the exception of the period 11 June 81 to 1 August 81 when the telemetry system lost power as discussed in section 1 of this report.

The analogue data for the period 29 January 1980 to 3 February 1981 is archived at the Geophysical Institute, University of Alaska at Fairbanks. The rest of the analogue data is still at McMurdo Station but will be sent to the University of Alaska in January 1982.

Digital Data

The collection of digital data from a four microphone long-period F array (Erebus, Terror, RTG and Ross sites) and three microphone short-period T array (RTG, Aurora and Vee sites) began on 1 December 1980. The microphone pressure time series data are recorded digitally on 1/2 inch x 2400 feet R165C55 3M computer tape with a format described in our reports GIR81-2 and GIR 80-3. The real-time analysis of the F and T array data are printed out every two minutes with a format described in our report GIR81-2 giving information on signal azimuth, horizontal trace velocity, amplitude, period and cross-correlation between microphone pairs.

The digital magnetic tapes and analysis printout sheets are archived at the Geophysical Institute for the period 1 December 1980 to 3 February 1981 (tapes 80-1 to 80-7 and 81-1 to 81-6). The digital data for the period 4 February '81 to the present are at McMurdo Station and will be returned to the University of Alaska in January 1982.

Antarctic Infrasonic Signals

No funding was provided for a general analysis of the first year's analogue infrasonic data with the exception of that for certain selected time periods. Analyses were made for the infrasonic waves for the eruption of St. Helens volcano on May 18 of 1980 and for the Chinese atmospheric nuclear test of October 16, 1980.

The analogue chart record data was scaled for February and November of 1980 in a search for auroral infrasonic waves (AIW). The high trace velocity signals that were found and tentatively identified as AIW are listed below in Table I.

Table I

High trace velocity signals from analogue chart data

Date	Time	Azimuth	Trace velocity (m/sec)
1 Feb. 80	0535	138°	505
	1729	115	400

9 Nov. 80	2354	109	345
21 Nov. 80	1005	197	355
	1040	197	355
	0938	150	570
8 Dec. 80	1255	143	647

An infrasonic wave train was observed at 0542 U.T. 19 May at Windless Bight from the 0832 PDT 18 May 1980 explosive eruption of Saint Helens volcano. At 1615 U.T. on the same day the antipodal path infrasonic signal from the St. Helens eruption arrived at the microphone array from an azimuth 180° out of phase with the direct great circle path signal. The great circle path from St. Helens to Windless Bight is 14,562 km long and lies 60° east of north in direction. From the arrival times of the two signals the transit velocity was calculated to be 285 m/sec. for the direct great circle path signal and 286 m/sec. for the antipodal great circle path signal. The observed

azimuth of the direct signal varied from 67° to 74° throughout the two hour long wave train while the azimuth of the antipodal signal varied from 234° to 246° . The direct signal azimuth was from 7° to 14° east of the true azimuth (60°) while the antipodal signal azimuth varied from 6° west to 6° east of the true azimuth (240°). This deflection was caused by transverse winds along the ray path. The data for the St. Helens signals are given in Table II and the signals are shown in Figures 2 and 3.

Table II

Infrasonic Waves from St. Helens Eruptions

Great circle direct path

arrival time 0542 U.T. 19 May 1980
 trace velocity 280 to 300 m/sec
 azimuth of arrival 67° to 74°
 average period 56 sec
 duration of wave train 0542 to 0750
 dispersion long waves first
 transit velocity 285 m/sec

antipodal path

1615 U.T. 19 May 1980
 320 to 356 m/sec
 234° to 246°
 70 sec
 1615 to 2030
 not clear
 286 m/sec

A large infrasonic signal was received at Windless Bight on 16 October 1980 at 1650 U.T. from the Chinese test of a nuclear weapon in Lop Nor. The detonation time for this event is not known so the transit velocity could not be calculated. The wave train is shown in Figure 4 from the analogue chart records at Windless Bight. The dominant period of the wave train was 30 seconds. At 1700 U.T. the azimuth and trace velocity of the wave were 294° and 350 m/sec. At 1720 U.T. the values

of θ and V_h were 289° and 337 m/sec respectively. A search was made for the antipodal great circle path signal from Lop Nor but none was found. The azimuth of Lop Nor from Windless Bight is 291° . This compares well with the observed signal azimuth.

Analysis of the digital data has been confined to signals within the period 1 Dec 1980 to 3 February 1981 for which the digital tapes are at the Geophysical Institute. At the end of the austral summer season in Antarctica when we return with the digital data tapes for the period 4 Feb 81 to 1 Feb 82, this data will be analyzed at the Geophysical Institute.

The digital infrasonic data tapes that were recorded at McMurdo Station prior to the closing of the mail in March 1981 have been analyzed. Infrasonic waves have been identified from auroral electrojet motions in the lower ionosphere, volcanic eruptions, marine storm sea wave activity and mountain lee wave sources.

Microbaroms

Standing wave patterns on the sea surface in marine storms produce infrasonic waves in the atmosphere called microbaroms of six-second period that will propagate great distances in the stratospheric sound channel. The storm centers that produce the microbaroms are within the quasi-stationary lows in barometric pressure at sea level that lie off the coast of Antarctica, as shown in Figure 5 for the austral summer period in January. The expanded sensitivity range for the new infrasonic system in Windless Bight down to waves of one second period allows us

for the first time to observe microbaroms from the Antarctic marine storms. In Figure 6 the azimuth of arrival (the direction from which the waves have come) and the horizontal trace velocity V_h (defined as $V_h = C \sec \alpha$ where C = local sound speed and α = angle between the wave vector and horizontal) are plotted for all the microbarom wave packets for which the correlation coefficient (that is a measure of the coherence between the waveform at pairs of microphones) was greater than 0.6 for the data period 8 December 1980 to 9 May 1981. Because of the very large number of microbarom wave packets observed from the direction of the Ross Sea low (around 1660 in all) and the Bellinghausen Sea low (around 150) not all the data are plotted in the figure but there are enough points to give a general idea of the variation of both number of microbarom events and horizontal trace velocity with azimuth of arrival.

From the location of the low pressure areas shown in Figure 5 it can be determined that these four storm-producing regions subtend the following angles as seen from the Windless Bight infrasonic microphone array; Ross Sea low $15^\circ - 50^\circ$; Bellinghausen Sea low $110^\circ - 140^\circ$; South Atlantic Ocean low $190^\circ - 240^\circ$; South Indian Ocean low $250^\circ - 290^\circ$.

The microbarom data, a sampling of which is plotted in Figure 6, show that storms in the Ross and Bellinghausen seas are strong sources of microbaroms infrasound. Microbarom events from the Ross Sea are numerous and at times persist for many days. The Ross sea low is much closer to the infrasonic array than the other barometric lows, thus one would expect more microbarom events from the Ross sea sources.

Propagation conditions play a very important role in determining whether or not microbaroms are observed from a particular source. The horizontal trace velocity measured for a particular microbarom wave packet is equal to the scalar sound speed at the height of reflection of the ray path plus the component of the wind speed at the reflection level in the direction of propagation of the wave.

For this reason the average trace velocity seen for the microbaroms from the Ross sea (about 350 m/sec) is higher than that for microbaroms from the Bellinghausen sea (about 300 m/sec) because the propagation path from the Ross sea storms to the infrasonic microphone array is, on the average, parallel to the stratospheric winds while the propagation path from the microbarom producing storms in the Bellinghausen sea to Windless Bight is anti-parallel to the stratospheric flow. Thus one would expect that the trace velocity of microbaroms from the Bellinghausen sea would be diminished with respect to those from the Ross sea.

Although the above statistical picture of the variation of microbarom trace velocity as a function of propagation path relative to the mean stratospheric flow is crude, it is however suggestive of the future studies that will be made when the upper air wind data become available. It is anticipated that by studying the seasonal variations in the microbarom trace velocity from the different storm centers around Antarctica we can say something about the seasonal morphology of the mean stratospheric flow.

The analysis of auroral infrasonic waves signals, a mini-eruption air wave from Mt. Erebus and an unidentified infrasonic signal from

107° azimuth are all described in our report GIR81-2. Additional high trace velocity auroral signals that have been abstracted from the signal list summaries that were sent by telex from Antarctica during the winter night are listed in Table III below.

All of the data tape summary sheets are reproduced below for the period 8 December 1980 to 1 October 1981. The items listed for each signal where the cross-correlation coefficient was greater than 0.6 are: data block number, date-time, T or F array, maximum and minimum amplitude in microbaroms, period in seconds, correlation coefficient, azimuth, and horizontal trace velocity.

Table III

BLKS 2177, 2191 SIMILAR.

8. BLK 2390, 9 APR, 1008Z, T, MAX 0.7, MIN 0.7, P5.1, R66, AZ 131, V 270.

9. DISCUSSION OF TAPE DRIVE PROBLEMS: AFTER INVESTIGATION OF THE
CAPSTAN CONTROL CIRCUITRY IT WAS FINALLY POSSIBLE TO ZERO THE CAPSTAN
CONTROL VOLTAGE PER PARA 10.2.1. HOWEVER NO DEFINITE COMPONENT
FAILURE WAS FOUND. AS OF 1120Z, APR 9 THE DIGITAL DATA IS APPARENTLY
BEING RECORDED. SINCE NO DEFINITE FAILURE HAS BEEN FOUND THE TAPE
PROBLEM MAY REOCCUR.

10. FOLLOWING IS A SUMMARY OF THE SITUATION WITH THE CAPSTAN CONTROL
TO DATE: A) TP15 GAVE A VOLTAGE OF -1.4V THAT COULD NOT BE AFFECTED
BY THE ZEROING POTENTIOMETER.

B) PIN 2, U4 GAVE A CONSTANT -0.09V THAT DID NOT VARY.
PIN 3 WAS A CONSTANT ZERO VOLTS.

C) THE CAPSTAN TURNED CW AT A RATE VARIABLE BY THE ZERO POT
TO A LIMITED DEGREE.

D) LATER THE CAPSTAN CONTROL RESPONDED TO THE CALIBRATION
OF PARA 10.2.

E) IF THE PROBLEM RETURNS I WILL ATTEMPT TO USE QUICK
FREEZE TO LOCATE THE INTERMITTENT COMPONENT.

REGARDS, DAVID FULLERTON

SUBJ: INFRASONICS REPORT

1. PRINTOUT 81-19A. 26 APR, 1236Z TO 27 APR, 0347Z. 456 BLKS. NO SIG.
2. PRINTOUT 81-19B. 27 APR, 1125Z TO 04 MAY, 0425Z. 4830 BLKS. SIG.
3. BLK 49, 27 APR, 1301Z, T, MAX 1.6, MIN 1.5, P5.3, R63, AZ 123, V 314.
4. BLK 701, 28 APR, 1047Z, T, MAX 1.7, MIN 2.3, P5.6, R68, AZ 169, V 317.
5. BLK 3659, 02 MAY, 1327Z, T, MAX 1.5, MIN 1.4, P5.1, R63, AZ 117, V 293. 5 BLKS SIMILAR TO 3881.
6. BLK 4648, 03 MAY, 2227Z, T, MAX 1.2, MIN 1.1, P5.0, R66, AZ 356, V 346. BLK 4759 SIMILAR
7. BLK 4727, 04 MAY, 0105Z, T, MAX 1.0, MIN 1.0, P4.9, R61, AZ 222, V 303.
8. BLKS 4827 TO 4833, 04 MAY, 0425Z, F, MAX 1.5, MIN 1.6, P30, R GREATER THAN 67, AZ APPROX 211, V APPROX 430. AFTER A 15 MIN PRINTOUT I TOOK THE COMPUTER OFF LINE AND RESTARTED IT AS I FEARED THE PRINTOUT MIGHT BE INFINITE. THE AZS APPEARED CONSISTENT. NOTHING DRAMATIC APPEARED ON THE PAPER TAPE AT THIS TIME SO I DOUBT THIS REAL SIGNAL.
9. PRINTOUT 81-19C, 04 MAY, 0451Z TO 07 MAY, 2342Z. 2725 BLKS. SIGNALS. NOTE: PRINTOUT READS MONTH AS APR AND SHOULD READ MAY.
10. BLK 811, 05 MAY, 0751Z, T, MAX 1.0, MIN 1.0, P58, R63, AZ 210, V 324. BLKS 995, 1025 SIMILAR.
11. BLK 1675, 06 MAY, 1240Z, T, MAX 1.5, MIN 1.6, P5.5, R68, AZ 133, V 307. 83 BLKS SIMILAR TO 2725.
12. BLK 2491, 07 MAY, 1554Z, T, MAX 1.2, MIN 1.2, P5.9, R68, AZ 343, V 269. BLK 2693 SIMILAR.
13. TAPE 81-20, 07 MAY, 2346Z TO 14 MAY, 1525Z. 4783 BLKS. SIGNALS. NOTE: PRINTOUT AND TAPE INCORRECTLY READ MONTH AS APR AND SHOULD READ MAY.
14. BLK 05, 07 MAY, 2354Z, T, MAX 1.3, MIN 1.2, P5.3, R75, AZ 125, V 292. 122 BLKS SIMILAR TO 4135.
15. BLK 978, 09 MAY, 0822Z, F, MAX 1.7, MIN 1.6, P23, R62, AZ 340, V 354. 9 BLKS SIMILAR UP TO BLK 1092 ENDING 09 MAY, 1210Z. SUGGEST THIS SIG MAY REPRESENT ERUPTION OF SAME VOLCANO YOU QUERIED ME ABOUT ON 04 MAY. NO SIGNALS WERE FOUND ON APR 27 TO APR 28.
16. BLK 1062, 09 MAY, 1110Z, F, MAX 1.8, MIN 1.5, P20, R75, AZ 337, V 342. THIS HIGHEST COEFFICIENT SIGNAL OUT OF 10 BLKS RECORDED.
17. BLK 4751, 14 MAY, 1415Z, T, MAX 1.2, MIN 1.1, P5.0, R63, AZ 14, V 396.
18. TAPE UNIT CURRENTLY WORKING BUT NOT FIXED. I WILL TRY REPLACING THE U-4 OP AMP THE NEXT TIME IT FAILS.
19. DAVID HONEA AND I RETURNED TO THE RTG SITE ON MAY 16. THE LONG DELAY WAS DUE TO POOR WEATHER AND LOGISTICS PROBLEMS. WE WERE ABLE TO RAISE THE RTG OUTPUT VOLTAGE TO 2.9V AND THE INVERTER TO 25 VOLTS MAKING THE XMTR INPUT VOLTAGE APPROX 11V. THE PROBLEM WAS APPARENTLY CAUSED BY STRESS ON THE RTG OUTPUT CABLE INDUCED BY THE WEIGHT OF THE HANGING CABLE. WE SUSPENDED THE CABLE AND RELIEVED THE STRESS. SIGNAL TONES IN CHANNELS 1, 2, 3 ARE STILL IMPURE DESPITE INCREASED VOLTAGES.
20. PLEASE MAIL SPARE PAPER TIGER RIBBONS TO ME IMMEDIATELY IN CASE WE GET A MID-WINTER AIR DROP. MY SUPPLY WILL PROBABLY LAST UNTIL WINFLY BUT IT WILL BE CLOSE.
21. SORRY ABOUT THE DELAY IN RESPONDING. I WAS WAITING FOR THE OUTCOME OF THE TRIP TO WINDLESS BIGHT AND THE TRIP KEPT BEING POSTPONED.

REGARDS, DAVID FULLERTON

NOISE SUPPRESSION USING DATA-ADAPTIVE POLARIZATION FILTERS:
APPLICATIONS TO INFRASONIC ARRAY DATA

by

John V. Olson
Geophysical Institute
University of Alaska, Fairbanks
Fairbanks, Alaska 99701

November, 1981

ABSTRACT

We shall describe the construction of a data-adaptive filter which is based upon the multivariate coherence of signals from an array of sensors. The measure of coherence used, called the degree of polarization, is constructed from invariants of the spectral matrix composed from the data and is rotationally invariant. Application of this filter to an infrasonic data suite is shown in which signal to noise level contrasts are enhanced by as much as 20db.

I. Introduction.

Noise suppression or rejection techniques are usually constructed based upon an assumed characteristic of the noise which is different from that of the signal. In processing multi-channel data from detector arrays it is commonly assumed that the noise field is isotropic and stationary as would be the case for noise associated with the individual detector electronics. Alternatively, the noise may be assumed to have a directional aspect as would be the case for waves generated by a distant source. Under such assumptions optimum techniques for signal to noise ratio enhancements may be defined. (See, Monzingo and Miller, 1980 and references therein).

In this paper we shall describe a technique for noise suppression which is dependent upon a measure of the multivariate coherence in a multi-channel signal. This measure is derived from the data themselves and may be used to define a filter which selectively removes the incoherent noise from the data. We shall take the point of view that the noise is simply less polarized, in a unitary space, than is the signal. This is a very general definition of signal versus noise and allows us to construct our filter. However, the filter is not optimally defined through this definition and one is led to the manipulation of several adjustable parameters. We have found that these parameters permit a wide range of choice with little effect on filter performance. In the final section of this paper we shall discuss the extension of the technique to an optimum filter design.

II. The Degree of Polarization, P.

A definition of the degree of polarization of a multivariate data sequence has been developed which is consistent with the concept of polarization as defined in optics and quantum mechanics (Samson, 1973; Olson

and Samson, 1980). In this development the degree of polarization of a data sequence is investigated in the frequency domain where it is derived using the invariants of the spectral matrix. The formulation proceeds as follows. (A more detailed discussion is given in Samson and Olson, 1981).

Multi-channel time series may conveniently be represented by the vector

$$\underline{x}(t) = (x_1(t), x_2(t), \dots, x_N(t))^T \quad (1)$$

where the $x_j(t)$ are the data derived from the j th sensor, $j = 1, N$, and T denotes the transpose. We begin constructing the spectral matrix, $\underline{S}(f)$, as follows:

$$\underline{S}(f, \delta) = \int_{f-\delta/2}^{f+\delta/2} \underline{Z}(g) \underline{Z}^+(g) dg \quad (2)$$

where

$$\underline{Z}(g) = \int_{-\infty}^{\infty} \underline{x}(t) \exp(-2\pi i g t) dt \quad (3)$$

Here $\underline{Z}(g)$ is the Fourier transform of $\underline{x}(t)$ and $\underline{Z}^+(g)$ represents the Hermitean conjugate of $\underline{Z}(g)$. The spectral matrix is obtained from the outer product of $\underline{Z}(g)$ and $\underline{Z}^+(g)$ smoothed over some bandwidth, δ . Henceforth the dependence upon smoothing bandwidth will not be shown explicitly. It is well known that the spectral matrix is Hermitean and may be expanded in terms of its eigenvalues, λ_j , and its eigenvectors, $\underline{U}_j$, $j = 1, N$:

$$\underline{S}(f) = \sum_{j=1}^N \lambda_j \underline{U}_j(f) \underline{U}_j^+(f) \quad (4)$$

The vectors $\underline{U}_j(f)$ are, in general, complex and form a complete, orthonormal basis in a unitary space N dimensions. The eigenvalues λ_j are real. We shall now consider the characteristics of a polarized signal in this unitary space.

If $\underline{S}(f)$ represents a pure-state (Fano, 1957) then it has only one non-zero eigenvalue and hence

$$\underline{S}(f) = \lambda_1 \underline{U}_1(f) \underline{U}_1^+(f) \quad (5)$$

To the extent that $\underline{S}(f)$ represents random, incoherent noise the eigenvectors become equal $\lambda_1 = \lambda_j$, $i, j = 1, N$. Thus, when $\underline{S}(f)$ may be represented as a single outer product, as in (5), we shall call the signal state a pure-state and describe it as completely polarized. More detailed descriptions and discussions of these ideas are found in the papers by Samson (1973, 1977). Samson showed in the works cited that a measure of the degree of polarization, P , can be derived from the scalar invariants of $\underline{S}(f)$. It is given by

$$P(f) = \frac{N(\text{Tr} \underline{S}^2(f)) - (\text{Tr} \underline{S}(f))^2}{(N-1)(\text{Tr} \underline{S}(f))^2} \quad (6)$$

Here $\text{Tr} \underline{S}(f)$ is the trace of $\underline{S}(f)$. $P(f)$ is a scalar which ranges $0 < P(f) < 1$. Since $P(f)$ is constructed from scalar invariants of $\underline{S}(f)$ it is rotationally invariant. That is, it is not dependent upon the direction of arrival of the waves which traverse the array, as is, for example, the coherence.

III. Designing a Polarization Filter.

We may now proceed in a straight-forward manner to design a filter based upon the degree of polarization in the data. Given an N channel data segment, $\underline{x}(t)$, we first calculate its transform and from that the spectral matrix, $\underline{S}(f)$, and ultimately the degree of polarization, $P(f)$, as described above. Then, the transform of the data is weighted by a suitable function of $P(f)$ and the inverse transform is computed. In this way we have constructed a filtered data set whose spectral components are those for which $P(f) \sim 1$. It is composed of the pure-state components of the original data. The incoherent components have been suppressed wherever they occurred in the frequency domain.

If the filter length is equal to the length of the original data series, T_0 , then the filtered data set is given by

$$\underline{Y}(t, \delta) = \frac{1}{2\pi T_0} \int_{-\infty}^{\infty} P^k(f, \delta) \underline{Z}(f) \exp(2\pi i f t) df \quad (7)$$

where

$$\underline{Z}(f) = \int_{-T_0/2}^{T_0/2} \underline{X}(t) \exp(-2\pi i f t) dt \quad (8)$$

Here, $P(f, \delta)$ is computed from the spectral matrix as defined in (2) and (6). The exponent k is a positive number which can be used to enhance the noise rejection of the filter. The details of constructing a sliding filter for discrete, multivariate data as well as examples of the application of the filter to data suites from various geophysical instrument arrays are given by Samson and Olson (1981).

IV. Application to Infrasonic Array Data.

During the period 1966 to 1981 an array of three infrasonic microphones was operated in Fairbanks, Alaska by the Geophysical Institute of the University of Alaska. Figure 1 shows the superposed, pressure versus time, analog records from a spaced array of four infrasonic microphones for a two hour segment of 28 February 1979. The data are divided into two panels and each shows a large amplitude pressure disturbance: the first just after 2130 UT and the second beginning just after 2201 UT. Elsewhere the record shows the presence of noise from boundary layer turbulence and microbarum pressure fluctuations. The pressure record from each station has been shifted slightly in time with respect to the other records to display the strong signal coherence. These signals resulted from the an earthquake of magnitude 7.3 that occurred at 2127 UT on 28 February, 1979 near Yakataga, Alaska. The first pressure disturbance near 2130 UT was produced by infrasound generated by the vertical component of the local ground motion as the surface seismic waves passed through the array. The longer pressure wave burst occurring after 2200 UT is due to the infrasonic waves that were produced by vertical ground motion near the earthquake epicenter. The infrasonic wave at 2200 UT propagated in the stratospheric soundchannel from Yakataga 563 km to the Fairbanks array. The pressure disturbance at 2130 associated with local ground motion has a horizontal trace velocity that is characteristic of surface seismic wave velocity of about 1,700 m/sec. The pressure wave that arrived at 2200 U.T. has a horizontal trace velocity of 322 m/sec and thus can be identified as an air wave that propagated to Fairbanks from Yakataga in the stratospheric sound channel. (See Wilson and Forbes, 1969).

The data from the original data records shown in Figure 1 were hand digitized to provide a sample every 1.8 seconds and low pass filtered to

remove the high frequency contamination introduced by the digitization process. The resulting data for the half hour interval containing the infrasonic wave arrivals are shown in Figure 2. In Figure 3 we show the same data after treatment with the polarization filter. In this case the filtering was done using a sliding window 9 minutes long. That is, data from sequential 9 minute segments of the original 3 channel input stream were purefiltered and concatenated after trimming the filter transients as described in Samson and Olson (1981). The most obvious feature of the filtered data is the clarity of the onset of the arrival of the infrasonic waves at the array. As well, one may discern a frequency dispersion through the event with the low frequencies arriving first.

The spectra of the signal from the microphone at Ballaine Lake before and after filtering are shown in Figures 4 and 5. While the overall power levels have been reduced by the effect of the filter, there is considerable enhancement of the contrast between the central peaks and the noise, particularly at low and high frequencies. For example, the noise level at 10^{-3} Hz has been reduced by approximately 3 orders of magnitude while the low frequency signal peak near 10^{-2} Hz has suffered a reduction of less than a factor of 10. This results in an overall enhancement of the signal to noise power for these two frequencies of approximately two orders of magnitude, or 20 db. The polarization filter technique is particularly useful in treating infrasonic microphone data because the principal source of noise, boundary layer wind turbulence, produces pressure fluctuations that are uncorrelated over the scale size of the microphone array. In Figures 6 and 7 we show sonograms of the signal from the Ballaine Lake sensor. Here power levels are contoured at 3 db levels from the peak power with cross hatching showing values within 6 db of the peak. In both sonograms the signal dispersion noted

in the discussion of the original time series is evident with low frequency power arriving first. However, the separation of the signal power into two principal frequency bands is much clearer in the filtered sonogram.

While the filtered signals shown in Figure 2 were derived from a sliding polarization filter, it is instructive to observe the shape of the polarization filter derived from the entire 30 minute, 3 channel data suite. Figure 8 shows the estimates of the degree of polarization as a function of frequency as computed from the entire data suite. Although one expects $P(f)$ to approach zero for infinite random data sequences, finite values of $P(f)$ occur when one treats finite length data suites. Olson and Samson (1980) have shown that for random noise at 12 degrees of freedom one expects $P(f) < 0.6$ at a 95% confidence level. We can see in Figure 8 that significant values of $P(f)$, and thus pure signal states, occur at a number of locations in the spectrum; principally near 0.05 and 0.12 Hz. Again, the net result is shown in the spectrum of Figure 5. Figure 8 reinforces the idea that the filter is adapted to the data and incoherent signals are suppressed wherever they may occur in the spectrum.

Traditional analyses of infrasonic signals have relied upon least-square estimators to provide velocity and azimuth information. These algorithms rely on ones ability able to estimate the delay times between the arrival of the signal at the various sensors, or equivalently upon the estimates of phase differences between spectral components at dominant signal frequency. In the time domain estimates of signal delays may be obtained by computing the cross correlation between a pair of signals and searching that function for a maximum. The filtering process has a strong effect on the cross correlation function. First, it enhances the magnitude of the peak value and second, it produces some oscillations in the wings of the autocorrelation function since

the noise has been removed from the data and it now appears more harmonic in content. These effects are evident in the cross correlation function derived from the data from the Ballaine Lake and Gold Hill microphones as shown in Figure 9. It has been our experience that the enhancement of the primary maximum in the cross correlation function has added reliability to the determination of signal delays for cases of marginal signal to noise level.

In both frequency and time domain analyses of signals from filtered data one must be careful to avoid biases in the estimated parameters introduced by phase distortions which result when sliding data windows are used. In the case where large data sequences are processed piece-wise and patched together signal distortion can occur at the edges of the data windows. This is true for any filtering process, and particularly for data adaptive filters such as the one we are describing. One must exercise some care in selecting the window sequence so as to minimize or eliminate these distortions. The problem arises when one applies an analysis routine over a data segment which is different in length from the segment used in the filtering procedure. Often the problem may be avoided by proceeding directly to subsequent analysis after filtering a segment of data.

V. Extensions.

The filter design as we have described it is based upon the assumption that signals can be differentiated from noise in a multi-channel data suite by virtue of a measure of the multivariate coherence. In the case where the noise is truly incoherent the filter works remarkably well. However, when the noise has coherence or is polarized in some sense it will not be rejected by this technique. Such noise fields arise in infrasonic studies, for example, when one sensor is subjected to excessive wind noise producing what seems to

be linearly polarized signals within our framework. Another source of contamination is the arrival of signals from "uninteresting" sources in other frequency bands or from other directions. The resolution of these problems can be approached through the modification of the spectral matrix which represents the data in such a way as to reduce the noise components.

Consider the detection of a signal in the frequency domain as the projection of the information contained in the spectral matrix upon a subspace represented by the signal. The projection can be written as a quadratic form

$$D = \underline{a} \underline{S} \underline{a}^+ \quad (10)$$

where $\underline{S}$ is the spectral matrix, $\underline{a}$ is the vector which represents the signal in a unitary space and D represents the scalar power in the $\underline{a}$ direction. In equation (10) $\underline{S}$ can be thought of as a metric which defines the signal space being investigated. If we want to assure minimum response to a noise field represented by the matrix $\underline{Q}$ then we would like to change the metric so as to project our signal power onto a subspace orthogonal to the principal eigenvectors of $\underline{Q}$. This can be done by through the transformation of $\underline{S}$ to $\underline{S}'$ given by

$$\underline{S}' = \sqrt{\underline{Q}}^+ \underline{S} \sqrt{\underline{Q}} \quad (11)$$

Then, having conditioned our signal spectrum by the noise spectrum which is present we may apply the polarization filter to $\underline{S}'$ with the prospect of signal to noise enhancement. Clearly, the efficacy of this procedure depends upon the extent to which $\underline{Q}$ represents the noise in the data. Hopefully, the noise is stationary enough that $\underline{Q}$ can be estimated from a patch of data which occurs

just prior to the arrival of the signal. We are investigating this approach to pure-state filtering at present.

VI. Conclusions.

We have described the construction of a data-adaptive filter which is based upon the multivariate coherence of the signals in a data suite and showed its application to infrasonic data. Under most circumstances it serves as an effective method for enhancement of the signal to noise ratio of the data, often by as much as 20 db. This enhancement increases the observers ability to detect arrivals of various wave packets across his array as well as his ability to discriminate features of multiband signals. We are currently studying its extension to non-random noise fields through the modification of the spectral matrix described above.

Figure Captions

- Figure 1. Superposed analog records from a spaced array of four infrasonic microphones located in Fairbanks, Alaska. The data show microphone responses to signals from the Yakataga, Alaska earthquake of 28 February, 1979. The records have been shifted in time to display the strong signal correlation. See the text for details.
- Figure 2. Digitized data sequences taken from the records shown in Figure 1 and covering the interval 2150 UT to 2220 UT on 28 February, 1979. These data are from the Gold Hill (GH), Airport (AP) and Ballaine Lake (BA) sites in the Fairbanks, Alaska region.
- Figure 3. The data shown are those which result from the of the pure-state polarization filter to the data shown in Figure 2. Note the reduction in noise prior to $t = 8$ minutes. The data after $t = 22$ minutes have been set to zero arbitrarily.
- Figure 4. The power spectrum of the raw, digitized data from the Ballaine Lake microphone as shown in Figure 2. The spectrum has been smoothed to yield estimates with approximately 12 degrees of freedom. The 95% confidence limits are shown by the small bar on the plot.

- Figure 5. The power spectrum of the Ballaine Lake signal after pure-state filtering. Again, the spectrum is characterized by 12 degrees of freedom. Note the suppression of the noise, especially near 10^{-3} Hz compared with that shown in Figure 4.
- Figure 6. A sonogram of the raw Ballaine Lake signal showing the temporal evolution of signal power. The power levels have been contoured in 3db steps. The small cross shows the frequency and time domain window sizes.
- Figure 7. A sonogram of the pure-state filtered Ballaine Lake data showing the temporal evolution of the signals. The separation of low and high frequency signal components is clearer than that shown in Figure 6.
- Figure 8. The pure-state polarization filter amplitude function which results when data from the three microphones shown in Figure 1 are used. See the text for details.
- Figure 9. This figure shows the changes in the cross correlation between the Ballaine Lake and Airport signals which occur when the data are filtered. The peak value of the cross correlation is increased substantially after filtering. The oscillations in the skirts result from the filtering process having removed non-harmonic components.
