20. ABSTRACT (Continue on reverse side if necessary and identify by block number) Atmospheric transmission was measured along a 4.07 km overwater path in May 1979 at San Nicolas Island (SNI), California. A deuterium fluoride (DF) laser and a high-resolution Fourier transform spectrometer (FTS) system were used to generate high-quality transmission spectra of the 4.07 km path accurate to ±3 to 5% in absolute transmission. Details and procedures used and results obtained in the absolute transmission calibration of the spectra are presented. Path-integrated values for water vapor density have been derived from the FTS spectra. (Continued)

and show good agreement with fixed-location dew-point hygrometer measurements. Comparisons of measured DF laser extinction coefficients with calculated molecular absorption values are presented which suggest modifications to existing water vapor continuum absorption models and which also provide a measure of infrared aerosol extinction. The aerosol extinction values thus derived have been found to show little correlation with concurrent measurements of visibility, windspeed, and relative humidity. Comparisons of spectral-band-averaged FTS data with Pacific Missile Test Center broadband transmissometer measurements show good average agreement with significant scatter in the data attributable in part to sizable fluctuations in transmission occurring during the time scales used to acquire the FTS data.

RESULTS OF LASER-CALIBRATED HIGH-RESOLUTION TRANSMISSION MEASUREMENTS AND COMPARISONS WITH BROADBAND TRANSMISSOMETER DATA: SAN NICOLAS ISLAND, CALIFORNIA, MAY 1979

1. INTRODUCTION

This report contains the results of an experiment performed in May 1979 at San Nicolas Island (SNI), California by the Optical Radiation Branch of the Naval Research Laboratory (NRL) and by the Electromagnetic Systems Division of the Pacific Missile Test Center (PMTC). Atmospheric transmission was measured over a 4.07 km overwater path using a low-power deuterium fluoride (DF) laser together with a blackbody infrared source and a high-resolution Fourier transform spectrometer (FTS) system. The portable instrumentation facility used for these measurements is designated the Infrared Mobile Optical Radiation Laboratory (IMORL) and is described in greater detail in Section 2 of this report where additional references are given for further information. Results of laser extinction and FTS measurements are presented in Sections 3.1 and 3.2.

The measurements were performed using a 4.07 km overwater path between two shore locations on the northwest coast of SNI. Figure 1 shows the location of SNI 55 nmi from Point Mugu off the California coastline. The inset shows the relative locations of the three sites A, B, and C used in the PMTC optical transmission measurements. The NRL long-path transmission measurements described herein were performed using the 4.07 km path between sites A and C.

Meteorological measurements were performed by two NRL groups, Codes 4320 and 6530. Data were collected by Code 4320 during the experimental period as part of an extensive ongoing micrometeorological characterization of the island and are contained in a separate report. The data collected by Code 6530 are presented in Section 3.4. Visibility was measured during the experiment by use of a telepyrometer technique described in Section 3.5 which also contains a tabulation of results.

The measurements and analysis described in this report were supported by the Navy Electro-Optical Meteorology Program as part of an extensive program to characterize the maritime environment at SNI. An ongoing transmission measurement program conducted by PMTC under sponsorship of the Navy Optical Signatures Program used the same measurement path between sites A and C described above. Part of the measurements described in this report involved a cross-comparison of data taken with the NRL IMORL system to the PMTC transmissometer measurements so that results obtained with the two independent transmission measurement systems and procedures could be compared. These comparisons are presented and discussed in Section 4.2. Results of path-integrated water vapor density measurements derived from the NRL long-path FTS data and comparisons to point-sampled dew-point hygrometer results are presented and discussed in Section 3.3.

The data and analyses in this report show that the 3- to 5- μ m water vapor continuum absorption models when compared with the infrared transmission data show consistent disagreement. Procedures and results are described showing that high-accuracy (± 3 to 5%) absolute transmission spectra of the overwater path at SNI can be measured with the IMORL system.

Atmospheric aerosol extinction coefficients at DF laser wavelengths obtained from the long-path transmission data show a wide range of variation and do not exhibit significant correlations with visibility, windspeed, or relative humidity.

*Manuscript submitted April 23, 1982.

Fig. 1 - San Nicolas Island, California measurement site

Based on the results obtained in the work described in this report, it is recommended that additional long-path field measurements of laser extinction and high-resolution transmission spectra be used to improve existing atmospheric molecular absorption models, particularly for the 3- to 5- μm water vapor continuum absorption. The need to improve the agreement between infrared aerosol extinction data derived from overwater transmission measurements, and that obtained from aerosol spectrometer measurements, is demonstrated by results presented in this report.

The importance of path-integrated measures of water vapor density and aerosol extinction coefficients for use in atmospheric transmission model evaluation is discussed, and it is recommended that measurements of this type be included in future experiments.

2. EXPERIMENTAL EQUIPMENT AND PROCEDURES

The Infrared Mobile Optical Radiation Laboratory (IMORL) has been developed at NRL as a field laboratory for precision atmospheric propagation measurements. Detailed descriptions of the electro-optical instrumentation contained in the IMORL facility are presented in Refs. 1 and 2. Only the essential features of the IMORL system are reviewed in the present report.

The IMORL system, used to collect laser-calibrated high-resolution atmospheric transmission spectra, comprises several infrared laser and backbody sources, large stable telescope optics, a Fourier transform spectrometer (FTS) system, and various support equipment, all of which are transported in and operated from several large semitrailers. The usual measurement configuration consists of an optical transmitter trailer housing HeNe, Nd-YAG, DF, CO, and CO₂ single-line cw laser sources, relay optics, and a large, stably mounted, precisely pointed, 91-cm aperture, f/35, Cassegrainian collimating telescope. The small cw combustion-driven DF laser used for much of the laser extinction work requires a large 755 l/s (1600 cfm) vacuum system for operation. This pump is housed in a separate trailer. A 20-cm-diameter vacuum line is installed once the two trailers are properly located at the measurement site. Two additional trailers contain office space, meteorological signal-processing and recording electronics, and bottled gas and other consumable supplies used during an experiment.

The FTS system and apparatus used for laser extinction measurements are housed in a receiver trailer that contains a 120-cm aperture, f/5 Newtonian telescope. The large receiver telescope aperture ensures that the entire laser beam used during long-path (typically 5 km) extinction measurements can be entirely collected, thereby providing reliable absolute transmission calibrations for the FTS measurements. High-resolution transmission spectra are taken by substituting a 1300 K blackbody source for the laser source in the transmitter optical system and adjusting the receiver optical system so as to couple the FTS system to the 120-cm collecting telescope. Repeated calibrations and extensive experience with this measurement system in field experiments have demonstrated that absolute transmission can be reliably measured for long atmospheric paths with an uncertainty less than $\pm 3\%$.

Figure 2 shows the transmitter trailer at site A (SNI) during the recent experiment. At the right in the figure can be seen the optical transmitter trailer. The 91-cm aperture telescope mirror and telescope frame may be seen through the open doors. The vacuum pump trailer is shown to the left in the figure; the demountable vacuum line connecting the two trailers can be seen supported about 1 m above ground level. Figure 3 shows the receiver trailer at site C (SNI), shown with the rear door open. The Newtonian telescope secondary mirror support can be seen immediately inside the open door. The inside diameter of this support frame matches the full 1.2-m diameter of the primary mirror.

Figure 4 depicts the experimental arrangement used for laser extinction measurements. The output beam from any of the several laser sources used is first collimated by auxiliary optics to a diameter of approximately 18 mm. The beam is then focused via the off-axis parabolic mirror shown in the upper left in Fig. 4 and then diverged to fill the 91-cm transmitter telescope aperture. A 37 Hz, 50% duty cycle chopper modulates the beam near the focus formed by the off-axis parabola. The beam is alternately transmitted through the telescope and reflected onto the stationary detector as shown. The mobile detector shown in Fig. 4 is placed in the "XMTR" position for calibration measurements in which the relative response of the two detectors is measured. The mobile detector is then placed near the focus of the 120-cm aperture receiver telescope for (a) calibrations of the large telescope optical efficiencies or (b) long path extinction measurements. The calibrations are measured with the transmitter and receiver trailers immediately opposite one another, i.e., for $\sim$ zero atmospheric path. When the trailers are separated for long path measurements, the two types of calibration data are then used to determine absolute atmospheric transmission for the several laser lines studied. As shown in Fig. 4 the signal produced by the mobile detector in the receiver trailer at one end of the measurement path is relayed to the transmitter by means of a pulse-rate-modulated (PRM) GaAs-laser-based data link. This signal, proportional to laser power at the receiver, is connected to the numerator input of a special purpose analog ratiometer [2]. The stationary detector signal, proportional to the transmitted laser power, is connected to the denominator input of the ratiometer. Thus, a real-time measure of transmission for the laser line being studied is available at the transmitter site. The ratiometer reading must be corrected for the relative response of the two detectors for that laser line (monitored daily) and the efficiency of the large optical elements beyond the chopper in order to obtain absolute transmission

readings. As shown in Fig. 4, the voltage-controlled oscillator (VCO) and frequency-to-voltage converter (FVC) used with the GaAs data link are also connected in the numerator circuit of the ratiometer when the mobile detector is used in the "XMTR" position, so that their combined transfer function is normalized out of the final extinction ratio. Additional information concerning the measurement instrumentation and procedures is contained in Refs. 1 and 3.

Local meteorological measurements are usually performed at each end of the measurement path to monitor absolute humidity, air temperature and pressure, and wind conditions in order to document local conditions during a series of measurements. The period required to make both laser extinction and FTS measurements in turn is typically about 1 hour. Extensive measurements using an aerosol spectrometer system have been performed during some experiments. In some cases infrared aerosol extinction estimates based on Mie scattering calculations utilizing the measured particle distributions have shown good agreement with results derived from infrared extinction measurements at DF laser wavelengths [3], especially for those situations where aerosol sampling occurs at locations representative of conditions along the entire optical path.

During this measurement on SNI we relied primarily on the NRL Aerosol Van (Code 6532) for meteorological and aerosol measurements although some meteorological values tabulated below came from the NRL Micrometeorological Tower (Code 4320). The equipment associated with the tower is described elsewhere [4]. Both facilities were located near Site A of Fig. 1. We briefly describe the Aerosol Van here.

An EG&G Model 110 system provided air temperature and dewpoint readings. An R.M. Young Gill propeller vane gave values for wind speed and wind direction. All the aerosol-particle size distributions referenced here come from two Particle Measuring Systems (PMS) particle spectrometers. The Active Scattering Aerosol Spectrometer Probe (ASAP) measured the small particles (0.13 to 0.75 μm),

and the High-Volume version of the Classical Scattering Aerosol Spectrometer Probe (CSASP-HV) measured the larger particles (0.75 to 15 μm). (All particle sizes referenced here are in terms of radius.) A data acquisition system accessed both probes and the air temperature/dew point/wind vector set simultaneously with 1-s time resolution. More details of the Aerosol Van description are in Ref. 5.

3. EXPERIMENTAL RESULTS

3.1 Laser Extinction Measurements

Laser extinction was measured using the 4.07 km path between sites A and C on the northwest coast of SNI. The measurements were performed in conjunction with high-resolution spectroscopic measurements to provide a means for absolute transmission normalization of the FTS data. A multi-band Barnes transmissometer system was operated simultaneously by the Pacific Missile Test Center (PMTTC); cross-comparisons of the two independent transmission measurements are described in Section 4.2.

Long-path laser extinction was measured on 8 days between 1 and 10 May 1979. The majority of measurements were performed using several deuterium-fluoride (DF) laser lines. A few measurements using the P_{20} (001 $\rightarrow$ 010) line of the CO_2 laser at 10.591 μm were possible on 8 to 10 March, since the laser was inoperable during the first several days of the experimental period.

Table 1 summarizes the transmission values measured for the series of lines in the 2 $\rightarrow$ 1 DF vibrational band available from the cw DF laser source used in the experiment. The P2-8 (2 $\rightarrow$ 1, P-8) line at 2631.067 cm^{-1} was measured three times during a "run" or measurement sequence in order to ascertain constancy and repeatability of the transmission measurements. Columns 7 and 8 of Table 1 respectively list the measured transmissions T and corresponding extinction coefficients α in units of km^{-1} . Column 9 lists the calculated molecular absorption (CMA) in km^{-1} corresponding to the meteorological conditions documented in Section 3.4. Column 10 contains the difference values, $\text{DIFF} = \alpha - \text{CMA}$.

The transmission values listed in Table 1 require that the zero path optical system efficiency for the extinction measurement system be known since it is part of the calibration procedure (see Refs. 1 and 3 for detailed descriptions and examples of this procedure). Due to space constraints at site A (the IMORL transmitter location) and experimental schedule requirements while the equipment was on the island, the zero-path calibrations for the data contained in this report were performed once the IMORL system was returned to the Chesapeake Bay Detachment (CBD) of NRL near Washington, D.C. Table 2 and Fig. 5 summarize the results of the optical system efficiency measurements obtained from this calibration carried out during 1 to 2 July 1979. The slight dependence of T_0 on wavenumber apparent in Fig. 5 was not included in the reduction of data for this experiment since the peak-to-peak excursions represent less than $\pm 1\%$ of the average value of T_0 and are comparable in magnitude to the experimental uncertainty on each measurement of T_0 . Accordingly the values shown in Table 2 were simply averaged without regard to wavelength. Using the single average value of $T_0 = 0.722 \pm 0.0044$ greatly simplified the reduction of the long path data without introducing any significant additional error.

The values tabulated in Table 1 show that for most of the DF laser lines measured transmissions between 0.5 and 0.7 were observed. The P2-10 line, which is located on the shoulder of an atmospheric N_2O absorption line, showed consistently lower transmission. The locations of the DF laser lines listed in Table 1 relative to atmospheric absorption lines are shown in detail in Section 3.2. The measurements performed on DAY 124 centered around 0133 Greenwich Mean Time (GMT) (5-3-79, 1833

Fig. 5 — Zero-path optical system efficiency measurements

Pacific Daylight Time (PDT)) showed the highest transmission values: 84 to 87% for the P2-8 DF laser line; while data taken on DAY 130, at 1526 GMT showed the lowest transmission values: 30 to 37% at the P2-8 line. The difference values $\text{DIFF} = \alpha - \text{CMA}$ listed in column 10 of Table 1 for each of the "runs" tabulated in Table 1 are plotted against wavenumber and are shown in Figs. 6 through 10. One expects the difference values to be independent of wavenumber over the interval from 2580 cm^{-1} to 2720 cm^{-1} shown in the figures, however a systematic decrease of ($\alpha - \text{CMA}$) with increasing wavenumber can be seen.

Fig. 6 — Measured extinction coefficients minus calculated molecular absorption coefficients vs wavenumber for NRL measurements at SNI of several DF laser lines

Fig. 7 — Measured extinction coefficients minus calculated molecular absorption coefficients vs wavenumber for NRL measurements at SNI of several DF laser lines

Fig. 8 — Measured extinction coefficients minus calculated molecular absorption coefficients vs wavenumber for NRL measurements at SNI of several DF laser lines

Fig. 9 — Measured extinction coefficients minus calculated molecular absorption coefficients vs wavenumber for NRL measurements at SNI of several DF laser lines

Fig. 10 — Measured extinction coefficients minus calculated molecular absorption coefficients vs wavenumber for NRL measurements at SNI of several DF laser lines

The wavenumber dependence shown is most likely due to the use of a water vapor continuum absorption model in deriving the CMA values which predicts too large an increase of absorption with increasing wavenumber. This observation is consistent with earlier comparisons [6] of long-path field transmission data to the H₂O continuum model of Watkins and White [7] which represents an improvement over the H₂O continuum model proposed earlier by Burch et al. [8].

Both GMT and PDT have been listed for each of the runs in Figs. 6 through 10, also the salient meteorological conditions present at the time of the measurements. No correlation can be determined between the size of the (α -CMA) decrease with increasing wavenumber and meteorological parameters such as absolute humidity, wind speed, or visibility.

3.2 High-Resolution Fourier Transform Spectroscopy Measurements and Absolute Transmission Calibration

Twenty-six high-resolution spectra were measured during the period 1 to 10 May 1979. Table 3 summarizes the FTS measurement times, FTS beamsplitter/detector configurations used (determining wavelength range covered), and the corresponding laser extinction measurement times used for absolute transmission normalization of the FTS spectra. Column 8 of Table 3 lists the designations assigned to the ratioed and normalized spectra obtained in the experiment. The spectra acquired over the 4.07 km path are first ratioed to a spectrum obtained using a local source (i.e., one inserted into the receiver

telescope optical train approximately 3 m from the FTS instrument) to remove detector, blackbody, and beamsplitter response functions. The color temperature of the local source was adjusted to match that of the distant source located in the transmitter trailer by monitoring each with an optical pyrometer. Spectrum SNI 15 was taken using the local source and was used as a denominator in ratioing the long-path spectra. Sixteen of the long-path spectra acquired were suitable for absolute transmission normalization using laser extinction measurements, and these are indicated by the suffix DRN in column 8 of Table 3. The suffix D indicates that only a portion of the 0 to 7900 cm^{-1} spectrum between 1800 cm^{-1} and 3200 cm^{-1} was archived; the R indicates that the spectrum was ratioed (in this case to spectrum SNI 15:B); and the N indicates that the spectrum was normalized for absolute transmission using the independent laser extinction measurements.

The ratioed spectra were converted from relative to absolute transmission by determining the scale factor needed to scale the relative transmission value of a spectrum at a particular laser frequency to the absolute transmission value obtained by means of the independent long path laser extinction measurement. Column 7 of Table 3 lists the time of the laser extinction measurements used for absolute transmission normalization of the several spectra obtained in the experiment. Long-path spectra were obtained usually within 1 hour of the laser extinction measurements used for normalization.

Detailed comparisons of the amplitude of each normalized spectrum to the individual DF laser line transmission measurements used to generate the normalization are contained in Table 4 for each of

the spectra labeled with an "N" suffix in column 7 of Table 3. An average multiplicative factor was determined by averaging the individual factors obtained for the several laser transmission measurements in any particular measurement series. The laser line identification and position in cm^{-1} are listed in columns 1 and 2, respectively in Table 4. The next four columns list: (a) the wavenumber of a spectrum sample, ν' ; (b) the measured laser transmission, τ ; (c) the individual amplitude, τ' , of a spectrum sample adjacent to or coincident with (to two decimal places) the appropriate laser line wavenumber; and (d) the difference between the amplitude of the spectrum sample and the actual transmission value measured at the laser frequency, δ . The average of the δ values and standard deviation are listed at the bottom of each column of δ values. Values for τ' and δ for more than one spectrum normalized by a given set of laser transmission values τ are repeated in successive columns in Table 4. As can be seen by examining the comparisons listed in the table, the average δ value or residual offset is typically a few tenths of a percent transmission and only slightly larger ($<2\%$) in a few cases. The random error in the normalization procedure approximated by the standard deviation in δ is generally less than $\pm 3\%$ transmission except in the cases where the spectral signal to noise ratio is poorer, e.g., spectra SNI12DRN, SNI16DRN, and SNI17DRN. The measurement accuracy in an individual laser extinction measurement is estimated to be $\pm 3\%$ under good measurement conditions. Nine or ten individual laser extinction measurements are averaged in arriving at the normalization factor used in scaling a given spectrum in units of absolute transmission, thus redundant laser transmission measurements should combine to produce an average scale factor accurate to about $\pm 1\%$. When applied to a given spectrum the resultant absolute transmission calibration should be valid to $\pm 2\%$ in the best case of a high signal-to-noise ratio spectrum with the accuracy correspondingly degraded to about ± 4 or 5% in cases where the spectrum signal-to-noise ratio is poorer.

Figures 11 to 18 represent portions of two of the ratioed and normalized spectra listed in Table 3, namely SNI24DRN and SNI26DRN. These figures were reproduced from CRT displays of the spectra obtained with FTS system software. Reading from top to bottom of each column in each of the figures, the location of each of the laser line positions listed in Table 4 is shown. The top photograph shows the atmospheric transmission structure in the vicinity of the individual laser line which is specified at the bottom of each column. The lower photograph in each column shows the same portion of the spectrum at increased dispersion so that individual samples in the spectrum (0.06 cm^{-1}) are evident. The cursor shown in each photograph marks the spectrum location in cm^{-1} (top number) to two decimal places and the spectrum amplitude at that location to four decimal places. These values are the ν' and τ' values listed for spectra SNI24DRN and SNI26DRN in Table 4.

Some general observations can be made upon an examination of Figs. 11 through 18. The majority of the $2 \rightarrow 1$ band DF laser lines are located fortuitously at positions which are relatively free of coincidence with atmospheric absorption lines. The P2-10 line located at 2580.096 cm^{-1} , the P2-9 line at 2605.806 cm^{-1} , and the P2-6 line at 2680.179 cm^{-1} being the three notable exceptions (see Figs. 11-18). The P2-10 DF laser line is located on the shoulder of an N_2O absorption line as can be seen in the figure and consequently is a poor choice for use in obtaining an absolute transmission normalization for the FTS spectra. The P2-9 and P2-6 lines are located near HDO absorption lines where adjacent FTS sampled amplitudes are changing rapidly with wavenumber.

The substantial change in FTS spectrum amplitude values between the two adjacent spectrum samples bracketing the indicated DF laser lines introduces a significant uncertainty into the laser transmission normalization procedure and can introduce additional errors into the procedure due to any misregistration of the laser line position with the FTS spectrum. Both types of problems are minimized when laser line positions free from coincidence with absorption lines are used to derive the absolute

transmission normalization. Examples of the laser lines which are preferable for use in deriving the normalizations are the P2-8, P2-5, and P2-4 lines. The remaining DF laser lines, namely P2-7, P2-6, P2-9, and P2-11 can be seen to be useful in addition for derivation of absolute transmission normalization factors depending upon the particular spectra being studied. Data presented in an earlier report [9] represent a more favorable case than the present one where long-path transmission spectra were measured under higher water vapor partial pressure and higher total atmospheric pressure conditions than in the measurements at White Sands Missile Range discussed in Ref. 9. The P2-7, P2-6, P2-9, and P2-11 laser lines are sufficiently close to atmospheric HDO and H₂O absorption lines (P2-7, P2-6, and P2-9) and to an atmospheric N₂O absorption line (P2-11) so that appreciable overlap of the absorption line wing and the laser line position occurs under the higher pressure conditions. For the comparisons listed in Table 4 and shown in Figs. 11 through 18 the amplitude of a spectrum sample value (τ' values listed in Table 4) varies usually no more than 1% in absolute transmission between two adjacent samples which bracket the position of the laser line used to normalize the spectrum for absolute transmission. The notable exception is the P2-10 line as previously observed. The average multiplicative normalization factor derived by comparing measured laser transmission to spectrum sample amplitudes at each of the ν' values shown in Table 4 did not include the measurements for the P2-10 line and the other lines indicated by an asterisk in the table.

3.3 Path Integrated Molecular Absorber Concentrations

Figures 19 and 20 are plots of limited portions of three of the ratioed, normalized spectra listed in Table 3, for the spectral interval 2680 to 2800 cm^{-1} . Several reasonably well-isolated HDO absorption lines appear in this region, and absorption profiles of these lines can be used to derive path-integrated average concentrations of this isotope occurring during the measurement times. Using the standard sea-level model atmospheric abundance ratio of 0.03% HDO/H₂O [10] the path integral HDO measurements can be used to infer values for water vapor concentrations along the path. In the 2680 to 2800 cm^{-1} region shown in Figs. 19 and 20 only a few relatively weak H₂O absorption lines can be identified in contrast to the typical condition of very strong H₂O absorption lines in almost all other spectral regions of the near infrared. Provided that the accepted value for the sea-level HDO/H₂O ratio is correct, the spectral region shown in Figs. 19 and 20 is then quite useful for determining average absolute humidities over long atmospheric paths.

In addition to the few weak H₂O absorption lines that can be identified in the spectral regions shown in Figs. 19 and 20, a few weak, relatively isolated absorption lines of methane and nitrous oxide can also be identified.

Figures 21 and 22 show portions of three spectra recorded in an earlier experiment carried out at White Sands Missile Range (WSMR), New Mexico, shortly before the SNI measurements [9]. The top spectrum shown in these figures (ASL04RN) is annotated with identifications of most of the prominent spectral features in the 2680 to 2800 cm^{-1} region which is the same region shown in Figs. 19 and 20.

Table 5 lists the spectral features identified for the three spectra shown in Figs. 21 and 22. Column 1 of the table lists the line position contained in the 1978 edition of the AFGL line atlas [11]. Column 2 contains the observed line position measured from the WSMR spectral records shown in Figs. 21 and 22, generally to a precision of 0.05 cm^{-1} . Columns 3, 4, and 5 contain the species identification, line strength, and line half-width respectively as contained in Ref. 11. The same notation for molecular species used in Ref. 10 is used, namely 162 = HDO, 161 = H₂O, 211 = CH₄, and 446 = N₂O. Column 6 of Table 5 lists the transmission at line center (maximum absorption) for each of the prominent absorption lines identified in spectrum ASL04RN. The AFGL line atlas [10,11] lists over 2600 lines in the 2680 to 2800 cm^{-1} region whereas Table 5 contains an identification of 165 these for which the product of line strength and concentrations is highest. The observed line positions (column 2 of Table 5) are seen to be consistently about 0.05 to 0.07 cm^{-1} less than the AFGL values

NRL REPORT 8618

listed in column 1, which is the limiting accuracy of the FTS hardware and plotting software. Improvements in the FTS frequency scale calibration to $<0.05 \text{ cm}^{-1}$ are possible by using independent measurements of multiline laser spectra and interpolation procedures, but this was not done for the spectra shown in Figs. 19 to 22 which are sufficiently well calibrated in frequency to provide unambiguous comparisons to the spectral lines listed in column 1 of Table 5.

Derivation of path-integral HDO concentrations was performed by simply measuring the peak absorption (minimum transmission) values of each absorption line at line center and relating this measurement (appropriately corrected for the spectral line base absorption value, i.e., local transmission maximum) to the average numerical density of the HDO molecule along the absorption path. This procedure is less exact than integrating the area under a spectral absorption line and equating that value to the line strength, particularly when the line profile suffers significant modification due to the effects of finite resolution of the measuring instrument. In the present case the full unapodized-base width of the FTS instrument function is 0.0625 cm^{-1} which is equivalent to about 0.05 cm^{-1} for an apodized spectrum using a conventional spectroscopic definition for resolution (Rayleigh criterion).

This value is 25 to 50% of the full-width at half maximum (FWHM) value for most of the lines listed in Table 5 and accordingly does not contribute significantly to a reduction in peak line intensity. HITRAN calculations have been performed for conditions similar to those corresponding to the measurements shown in Figs. 19 to 22 including convolution with $(\sin x)/x$ instrument functions. Very minor differences are apparent between infinite resolution calculations and those done with instrument functions up to 0.08 cm^{-1} wide, therefore it was determined that the errors introduced by measuring minimum transmission at line center as opposed to integrated line area would be less than 10%. A more important factor contributing to errors in determining path-integral molecular concentrations from the spectra shown in Figs. 19 to 22 for many cases is the blending of many weak unresolved lines with a marginally stronger line being measured. This situation exists for most of the H_2O , CH_4 , and N_2O lines present in the 2680 to 2800 cm^{-1} region. Only a rigorous correction for the contribution of the several weaker lines blending with the line being measured would improve the measurement accuracy for the weaker lines. Such an analysis procedure can only be realistically accomplished using several iterations with a HITRAN calculation in the interpretation of the weaker features appearing in these spectra.

Path-integral molecular concentration values were obtained for several of the spectra listed in Table 3 by using the following procedures. The transmission values shown in Figs. 21 and 22 can be related to absorber concentrations and the path length as follows:

$$T = \exp(-u_L K_L - u_C K_C) \quad (1)$$

where T is the measured transmission, u_L and u_C are the absorber amounts corresponding to line and continuum absorptions respectively, and K_L and K_C are the corresponding absorption coefficients. Equation (1) can be written as:

$$\ln T = -u_L K_L - u_C K_C \quad (2)$$

Away from an absorption line $K_L = 0$ and the "continuum transmission," T' is related to the product $u_C K_C$ by:

$$-\ln T = u_C K_C \quad (3)$$

Equation (1) can then be written as:

$$\ln(T'/T) = u_L K_L \quad (4)$$

Now

$$u_L = 7.34 \times 10^{21} \frac{P L}{\theta} \quad (5)$$

J. A. DOWLING ET AL.

where P is the pressure in atmospheres, L is the path length in centimeters, and θ is the temperature in degrees kelvin.

The spectral absorption coefficient for a single Lorentz absorption line (true for atmospheric pressures above 0.1 atm) is given by

$$K_L(\nu) = \frac{S}{\pi} \left[\frac{\alpha}{(\nu - \nu_0)^2 + \alpha^2} \right] \quad (6)$$

where S is the line strength in $\text{cm}^2 \text{mol}^{-1} \text{cm}^{-1}$, α is the line half-width in cm^{-1} , and ν is the wavenumber in cm^{-1} . At line center when $\nu = \nu_0$ then Eq. (6) simplifies to

$$K_L = \frac{S}{\pi\alpha} \quad (7)$$

For the measurements under consideration here L in Eq. (5) is $4.07 \text{ km} = 4.07 \times 10^5 \text{ cm}$, and an average representative temperature is $55^\circ\text{F} = 286 \text{ K}$.

Therefore Eq. (4) can be written as:

$$\ln(T'/T) = 4.272 \times 10^{21} \frac{S}{\alpha} P \quad (8)$$

with the absorber partial pressure P in units of torr.

The line strength values for HDO listed in Ref. 11 incorporate the HDO/H₂O abundance ratio of 0.03%; therefore the partial pressure of H₂O corresponding to measurements of the HDO absorption line-center transmission values for the spectra shown in Figs. 21 and 22 is given by

$$P(\text{torr}) = \ln(T'/T) \times 2.341 \times 10^{-22} \frac{\alpha}{S} \quad (9)$$

Equation (9) has been used to derive path-integral values for H₂O based primarily on measurements of several strong, well-isolated HDO lines in the 2680 to 2800 cm^{-1} region shown in Figs. 21 and 22.

The results of this analysis are contained in Table 6. For the several HDO lines measured average absolute humidity values are summarized in Table 7 and compared to fixed dew-point sampled measurements obtained using the NRL aerosol van system (NRL Code 6532) and by the NRL-operated meteorological tower mounted system (NRL Code 4320) permanently located at site A. Figure 23 is a plot of these comparisons.

3.4 Meteorological Measurements

For the purposes of this report the dew point and the aerosol-particle size distribution are probably the most important meteorological parameters. From the dew point derives the water vapor pressure which determines the major portion of the molecular absorption for the wavelengths involved in this measurement. The aerosol-particle size distribution is required to calculate the aerosol extinction at those wavelengths. For certain types of studies in the marine environment the air temperature, the wind speed, and the wind direction can also be important. This is not so much the case for this measurement on SNI, however, because the air temperature and wind direction showed little variation for the period of the experiment. That is, little can be said about changes in results as a function of these parameters.

Fig. 23 — Comparison of FTS and point measurements of water vapor concentration

In the aerosol van the PMS Data Acquisition System stores the aerosol-particle size counts and the analog meteorological data on 9-track magnetic tape. Simultaneously, the data are directed to a PDP 11/34 computer for real-time processing. For displaying and analyzing our aerosol and meteorological data we have developed a rather elaborate set of software [12]. This software allows postprocessing of the magnetic tape as well as real-time processing. As an example of the postprocessing, and in support of the statement about the small variation in air temperature, Fig. 24 shows the frequency-of-occurrence of the air temperature for the 290 30-minute averages obtained during the experiment.

One reason for measuring meteorological parameters during optical propagation experiments is for aid in validating or developing models. The Wells-Munn/Katz-Ruhnke (WMKR) aerosol model [13,14] has wind speed as one of its input parameters. There was some variation in wind speed as Fig. 25 shows. At beach sites, however, it is important to keep track of wind direction because the surf-generated aerosol can be dominant in the aerosol particle size distribution. Figure 26 gives the distribution of the wind direction. Since the direction is nearly the same for the entire period, that can simply be noted. Unfortunately that direction is directly from the sea, and the surf spray was quite strong at the aerosol sampling site. The problem is exacerbated by the fact that a group of rocks lie just off shore and upwind where more surf action occurs. Thus, to attempt to use the measured wind speeds in an open-sea aerosol model such as the WMKR would be foolish because of the surf influence.

The last one-dimensional meteorological parameter we measured is dew-point temperature. Figure 27 shows the distribution of those measurements. As stated earlier, we use this parameter to determine the water vapor pressure for molecular absorption calculations. Figure 28 shows how the resultant partial pressure varied during the period. For many aerosol studies, the relative humidity is an important value. We derive that from the air temperature and dew point reading. Figure 29 gives the distribution of the relative humidity, showing that the values were usually high. Thus, we can assume that the aerosol particles are made primarily of water and hence spherical.

To calculate extinction due to aerosols we use measured aerosol-particle size distributions. Figure 30 provides a sample aerosol-particle size distribution for each day of the measurement. Note that there is a hump in the curves near $0.8 \mu\text{m}$. This is due to a double-valued sensitivity function and is thus an artifact of the measurement process. Therefore, in doing the extinction coefficient calculations we discard the data from the eight largest bins of the active probe and replace them with a straight line.

Because the transmittance measurement equipment takes longer to set up than the meteorological and aerosol equipment, Figs. 24 through 30 include several days of data during which there were no transmittance results. For the sake of completeness, and for other participants who may have use for the data from those other days, Table 8 includes all the 30-minute averages obtained during our stay on SNI.

Table 8 needs little explanation with respect to the meteorological parameters discussed above. One point to note for comparison purposes is that the listed times are the ends of the 30-minute averaging periods. The last four columns are calculated aerosol extinction coefficients in units of inverse kilometers. We obtain those values by doing a Mie-scattering calculation on the measured aerosol-particle size distribution, assuming spherical particles of water (supported by Fig. 29), using the equation

$$\sigma_{\text{ext}}(\lambda, n) = \int_R \frac{dN}{dR} Q(\lambda, n) \pi R^2 dR,$$

where dN/dR is the particle size distribution in particles $\text{cm}^{-3} \mu\text{m}^{-1}$ and Q is the Mie extinction efficiency function. As noted Q is a function of wavelength and the complex index of refraction of the particle material. In this table, molecular absorption is not included.

For readers who wish to do their own calculations from the aerosol data, we are including in the appendix all the aerosol spectrometer results. At the beginning of that appendix are the bin locations of the two probes. For the ASAP we include only the counts from the first seven bins since we exclude the last eight bins because of the double-valued sensitivity function that occurs in that size region.

3.5 Visibility Measurements

Visibility was determined by the contrast method developed by Koschmieder [15]. Here visibility is defined as the distance from an object which produces a threshold contrast between the object and the background.

The contrast formula is

$$\frac{B_X - B_H}{B_H} = e^{-\alpha X} = T_X \text{ (contrast transmittance)}$$

where B_X and B_H are the radiances of the cone of air in front of the target at distance X and the horizon, respectively. The attenuation coefficient α in the visible region can generally be attributed to aerosol scattering. However, in high-visibility conditions the molecular component is a significant factor and must be considered in determinations of aerosol effects.

For visibility determination we define γ as the threshold contrast where the target is minimally visible and R as the range at that contrast. For our work we let $\gamma = 0.02$ at a wavelength of $0.55 \mu\text{m}$ so that

$$\frac{B_R - B_H}{B_H} = e^{-\alpha R} = 0.02$$

or visibility $= 3.91/\alpha$. An optical pyrometer is a convenient instrument to use for the determination of B_R and B_H . Using a programmable hand calculator, a visibility observation can be made in about 1 minute. Table 9 summarizes the visibility measurements made during the experiment.

Visibility measurements derived from long-path optical transmission measurements performed by PMTC using a Barnes transmissometer system operating in the spectral band between 0.50 and $0.61 \mu\text{m}$ were recorded also during the experimental period. These measurements are tabulated as well in Table 9. In cases where differing values were obtained from the NRL-optical pyrometer and PMTC-transmissometer measurements an average value for $\sigma_{0.55}$ for the two measurements was used for the data listed in Table 1 and Figs. 6 through 10.

4. COMPARISON OF MEASURED AND CALCULATED TRANSMISSION VALUES

4.1 Laser Extinction Measurements

Table 1 and Figs. 6 through 10 show comparisons of measured extinction coefficients to calculated molecular absorption values for the DF laser lines studied in this experiment. It was observed in Section 3.1 that the consistently negative slope of the plots of α -CMA shown in Figs. 6 through 10 is probably due to an overestimation of the molecular absorption coefficient by the H_2O continuum model of Watkins and White [7] at the high-wavenumber end of the interval shown in the figures.

If it is assumed that the Watkins and White H_2O continuum absorption model predicts approximately the correct absorption coefficient magnitude near the center of the interval shown in Figs. 6 through 10, i.e., $\sim 2650 \text{ cm}^{-1}$ but that the wavenumber dependence of the model is too strong, then the values of α -CMA from the curves shown in Figs. 6 through 10 at 2650 cm^{-1} can be used as measures of the aerosol extinction occurring during the measurement time. These values for σ are seen to vary from a maximum of 0.250 km^{-1} occurring on 10 May 1979 at 0826 PDT to a minimum value of

about 0.005 km^{-1} on 1 May 1979 at 1004 PDT and again on 3 May 1979 at 1833 PDT. In the latter two cases the measured visibilities were among the higher range of values recorded during the experiment and were 48 km and 35 km respectively.

Attempts to establish correlations of the σ values obtained from the long-path DF laser extinction measurements with windspeed (WS) and/or relative humidity (RH) have not been successful as no trends can be determined from the data for the ranges of σ , WS, and RH observed in the experiment.

Recently the long-path DF laser extinction data collected at SNI have been reviewed as part of a maritime environment characterization [16]. During this review the values of σ_{DF} obtained from the curves, shown in Figs. 6 through 10 and values for aerosol extinction at visible wavelengths derived from visibility measurements were used to form ratios of $\sigma_{\text{DF}}/\sigma_{\text{VIS}}$. These ratios were then compared with $\sigma_{\text{IR}}/\sigma_{\text{VIS}}$ predictions obtained using the Katz/Ruhnke (K/R) [14] and LOWTRAN 5 [17] aerosol models for the measurements where visibility and DF laser extinction data were both available.

Table 10 contains a summary of values for σ_{DF} and $\sigma_{\text{DF}}/\sigma_{\text{VIS}}$ thus obtained for several measurements at SNI. Comparison values obtained from aerosol spectrometer data presented in Section 3.4 are shown also. Predicted values of $\sigma_{\text{DF}}/\sigma_{\text{VIS}}$ based on the K/R and LOWTRAN 5 models are shown as well.

Table 10 — Comparison of Values for σ_{DF} and $\sigma_{\text{DF}}/\sigma_{\text{VIS}}$ Obtained from Long-Path Optical Transmission and Aerosol Spectrometer Measurements with Predictions Based on the K/R and LOWTRAN 5 Aerosol Models

Before making comparisons concerning the aerosol spectrometer results a few words are in order about the value of those measurements at the SNI location. Earlier we noted that a rock pile in the surf upwind from the aerosol spectrometers made comparisons with models less than desirable, especially if those models are based on open-sea parameters. The K/R model has such a base, as does LOWTRAN 5. Thus we do not expect to find much agreement with those models, and we do not. As for the transmittance data, because the transmittance measurement path is neither all downwind from the rocks nor from the surf in general, it is unlikely that the comparisons with those data will be very enlightening, either. Again, we are not disappointed in our prediction.

NRL REPORT 8618

With respect to the transmittance measurements we would expect, since the aerosol spectrometers are sitting in the surf spray, that the aerosol-predicted extinction coefficients would be higher than the values from the long-path IMORL measurement. This is usually the case. Also, since the aerosol particles near the surf are likely to have a larger mean diameter than over the open water, the extinction should be relatively higher at longer wavelengths, i.e., the values for σ_{DF}/σ_{VIS} should be larger in the surf. Again, this is usually, but not always, the case.

We should point out that the aerosol sensors are not literally sitting on the beach in the surf spray. We did place them at the same level as the transmittance path, about 15 m above the water surface. Nevertheless the increased number of larger particles typical of surf conditions was quite evident. A detailed description of the aerosol probe location and comparisons of the results from several aerosol probes at that location is found in Ref. 18.

The conclusion is, then, that the conditions of wind direction combined with aerosol spectrometer and transmittance path location do not lend themselves to reasonable comparisons.

4.2 Fourier Transform Spectrometer and Broadband Transmissometer Values

FTS spectra such as shown in Figs. 11-22 can be averaged or convolved with a broadband filter response function for comparison to a transmissometer measurement performed at the same time as the FTS spectra are recorded. Simultaneous measurements using the NRL laser-calibrated FTS system and the PMTC Barnes transmissometer system were performed at SNI. The FTS spectra were then convolved with measured responses for each of the transmissometer filters for several sets of measurements. The results of the two simultaneous and independent transmission measurements were compared (Table 11).

Figures 31 through 42 show comparisons for a series of eight filter bands each identified by a different symbol and code number. The half-power bandwidths of the filters are given in the inset in Fig. 30. As shown in the figures, there is generally good agreement between the two measurement systems within the combined measurement accuracy of the two techniques, the possible exception being with respect to the filter identified by the code 2154.* Figure 43 shows an overall comparison for all the data collected during the simultaneous experiments. The overall agreement between the two measurement techniques is good on the average; however, appreciable scatter about the unity slope line is evident in the figure. The scatter shown in Fig. 43 is due in part to changing atmospheric conditions occurring during some of the measurement periods. Measurements with both laser and broadband transmissometer systems during this experiment showed variations as large as $\pm 30\%$ in transmission for several repetitions of the same measurement within a 30-minute time span. Such an example is shown in Fig. 36. The scatter evident in Fig. 43 is probably the minimum that one can expect to obtain in comparing two long-path transmission measurements in a dynamic, coastal environment where surf-generated aerosols and open-sea conditions can give rise to rapidly fluctuating transmission conditions.

*It was established after the reduction of the data shown in Figs. 31-42 that numerical errors in the convolved and band averaged spectra corresponding to PMTC filter number 2154 had occurred which render the comparisons of FTS and PMTC data for this filter band unreliable.

5. CONCLUSIONS AND RECOMMENDATIONS

Several conclusions can be reached as a result of analysis and evaluation of the measurements described in this report. The most important findings can be summarized as follows:

- The DF laser extinction measurement data presented in Figs. 6 through 10 consistently show that the differences between measured extinction coefficients and calculated molecular absorption coefficients systematically decrease with increasing wavenumber, leading to a conclusion that the water vapor continuum absorption model (Watkins and White) used in the data reduction predicts too strong an increase of absorption at wavenumbers $\gtrsim 2650 \text{ cm}^{-1}$.
- The average aerosol extinction coefficient values, σ_{DF} , derived from the long-path DF laser extinction measurements, show a wide range of values between 0.005 km^{-1} and 0.250 km^{-1} (see Figs. 6 through 10). The magnitude of σ_{DF} thus determined does not show a significant correlation with measured visibility, windspeed, or relative humidity.
- Several accurately calibrated high-resolution transmission spectra of the 4.07 km overwater path between sites A and C at SNI were obtained. The data contained in Table 4 show that absolute transmission normalizations of these spectra are consistently within a range of $\pm 2\%$, occasionally showing a larger variation but still within a range of $\pm 5\%$.
- Path integrated water vapor density measurements compare favorably to within $\pm 15\%$ with point measurements obtained with dew point measurement systems located on shore near site A. Figure 23 shows an example of these comparisons. Some difference in the overwater path-integrated readings compared to the fixed-site shore measurements can be expected due to inhomogeneities along the 4.07 km path. The data shown in Fig. 23 indicate that these differences are within $\pm 20\%$ for the several comparisons considered. These differences are about twice the magnitude of the differences seen between the two sets of dew point readings shown in Fig. 23.
- Meteorological conditions observed during the comparison portion of the experimental period remained fairly constant. Air temperature varied between 11.9° and 13.8°C , absolute humidity ranged between 7.8 and 9.9 torr partial pressure of H_2O , and windspeed values varied between 8 and 14 m/s.
- Visibilities measured during the experiment varied between a high value of 64.5 km on 8 May 1979 at 0945 PDT and a low value of 8.8 km on 4 May 1979 at 1039 PDT. A comparison of visibility measurements performed by PMTC and NRL shows that for most of the data where the visibility or meteorological range, R_V , was less than 35 km, the NRL data were consistently lower than PMTC values by typically 10 to 15% and occasionally by as much as 25%. For data acquired on 8 May 1979 when $R_V > 45 \text{ km}$, NRL data were higher than the PMTC data by about 25%. On 7 May 1979 when $R_V \approx 17$ to 20 km, the NRL readings were 5 to 25% higher than the PMTC values.
- Excursions of as much as $\pm 30\%$ in transmission were observed during 30-minute intervals in the PMTC measurements. Comparisons of average transmission values in spectral bands corresponding to the PMTC transmissometer bandpasses showed comparable scatter when compared to the transmissometer readings. The large scatter is indicative of the fact that instantaneous values can show that much variation with respect to 30- to 60-minute average values in the dynamic, surf-influenced SNI environment.

Certain recommendations are appropriate upon evaluation of the observations discussed above; principal among these are the following:

- (1) The data described in this report and shown in Figs. 6 through 10 should be used together with other field-measured long-path laser extinction and laser-extinction-calibrated FTS data in a systematic validation of the 3 to 5 μm water vapor continuum absorption model.
- (2) Further attempts should be made using overwater infrared transmission data to quantify infrared aerosol extinction, to relate the observed values to meteorological observables such as windspeed and relative humidity, and to improve the modeling prediction of infrared aerosol extinction in the marine environment. The use of aerosol spectrometer measurement locations for comparison purposes which are not affected by artificial surf-generated aerosols should be emphasized. Airborne or shipborne aerosol counter measurement platforms, and possibly off-shore tower sites should be considered in planning future experiments.
- (3) Although shore-based and path-integrated water vapor density measurements have shown good agreement in this experiment, some differences have been noted, most probably due to moderate inhomogeneities along the several-kilometer optical path. Consideration should be given to the use of path-integrated water vapor measurements obtained from high-resolution transmission spectra such as described in this report in future transmission model validation exercises. Development of a single-ended LIDAR type system for both aerosol and water-vapor profile measurements should be considered. An advantage offered by a system of this type compared to the measurements described herein is that slant-path measurements could be performed.
- (4) Comparable measurement averaging times should be used in any future comparisons of transmissometer-band-averaged FTS measurements since it has been observed in this experiment that fluctuations in transmission values as large as $\pm 30\%$ were observed within a 30-minute period. Hence it seems reasonable that if a 30- to 45-minute measurement interval is required to obtain the laser-calibrated FTS transmission band values, that a comparable averaging time should be used in obtaining comparison values with a banded transmissometer system such as the one used by PMTC in this experiment.

6. ACKNOWLEDGMENTS

The authors express their thanks to Dr. Juergen Richter, manager of the Navy Electro-Optical Meteorology Program, for support of the measurements described herein. The help in logistics and equipment transportation provided by Chuck Elliott, PMTC is greatly appreciated. The assistance of Gary Matthews, PMTC in making the PMTC transmissometer filter wheel assemblies available to NRL personnel for filter response measurements and the use of a MIDAC Corp. owned FTS system identical to the NRL system provided by Gerald Auth of the MIDAC Corporation were both essential to the comparison measurements described in this report, and as such are greatly appreciated. The assistance of Stephen J. Dowling in completing data reduction was most helpful. The authors also thank Claude Acton for his assistance in preparing many of the figures. The painstaking typing, especially of the numerous and lengthy tables in this report, by Mrs. Nell Grimely is especially appreciated.
