### Abstract

Executive Order 12003 requires that all federal activities reduce their energy consumption by 20% from fiscal year 1975 use by fiscal year 1985. The Defense Energy Information System for shore activities (DEIS II) provides a system of measuring, reporting, and comparing energy use levels in pursuit of that goal.

The use of regression and time series models of energy use were examined for application within the present DEIS II system. A data base of monthly electricity use, gross floor areas, four weather variables, and building area category identification codes were used in a framework study of 12 Naval Regional Medical Centers. Specific methodologies for model development, interpretation, and application to a control system are demonstrated and discussed.

## I. INTRODUCTION

### A. BACKGROUND

Prior to 1973, energy was considered an inexhaustible and expendable supply. It was an inexpensive commodity. During the period between 1950 and 1973 the price of most energy products increased less rapidly than the price of other commodities. In fact, in terms of 1976 dollars, the real price of energy was actually declining. The real price of residential electricity fell by 55% (\$20.30/MBTU to \$8.94/MBTU), that of gasoline by 21% (63.0/gal to 49.7/gal), and that of natural gas by 20% (\$2.01/MBTU to \$1.60/MBTU) [Ref. 1]. A large population of observers reasoned that energy demands are determined by technological progress and economic growth. The implicit assumption was that the price of energy had a negligible impact on the use of energy.

As predicted by the first law of economic demand, decreasing energy prices encouraged consumption. By 1973, bargain priced electricity had increased in per capita use by 350%. Less dramatic declines in natural gas resulted in per capita consumption increases of 60% [Ref. 2]. The American automobile became heavier and more powerful as fuel economy became less of a consideration.

Building construction was also affected by the price of energy. Buildings were designed and constructed primarily with initial costs in mind. Construction materials were not selected on the basis of insulation qualities. Aesthetics favored large window areas. Siting was based on factors other than the benefits of solar position. The result was the creation of a vast inventory of commercial buildings which, by today's standards, utilize excessive amounts of

energy. Commercial buildings today account for approximately 8% of our national energy use [Ref. 3]. This present inventory is being replaced at the rate of only 2-3% per year. The majority of existing buildings for many years to come will be those which were originally not designed with energy conservation in mind.

The 1973 Arab oil embargo abruptly ended declining real energy prices. The effect on supply and the soaring energy prices shocked the world, dispelling the belief in an inexhaustible and expendable supply. Moreover, the belief in vertical supply and demand curves was recognized as erroneous. With the sharp rise in energy prices, energy use declined. In accord with the second law of economic demand, the response was greater in the long run than in the short run. The initial response was relatively weak as lights were turned off, thermostats reset, and fewer miles were driven. In the two year period from 1973-1975, per capita use decreased by 7%; national energy use dropped by 5% [Ref. 4]. Long range response, however, required more capital investment and time for implementation. Additional building insulation, installation of more fuel efficient machinery, and purchase of smaller cars were a few of such longer range responses.

More than an applied lesson in economic laws, the fuel crisis demonstrated how reliant American society had become on foreign oil. Such reliance was recognized as a threat to the national security. The federal government initiated programs to become less dependent upon, if not totally independent from, foreign oil. Such programs called for sharp reductions in use and the development of alternate energy sources. But such a national appeal could not overlook the fact that the federal government itself was the largest single energy user in the nation, consuming more than the

combined total of the five largest private users of energy--U.S. Steel, Union Carbide, Gulf Oil, International Paper, and General Motors Corporation. FY 1978 federal use accounted for 2.2% of the national use [Ref. 5]. The federal appeal to conserve energy precipitated a "physician, heal thyself" role.

## B. ISSUES

To achieve an objective, one must first define the objective. Setting goals is very important in meeting the objective. The objective must first be realistic. If set too low, the system will not realize its full potential. If set too high, the system may even waste resources and effort trying to achieve the unattainable. It may tend to circumvent the objective, realizing its inability, failing to attain even an optimal response. Instrumental in achieving the ultimate objective is setting targets, or goals, to direct progress and efforts. Such goals must also be realistic to properly drive the intended system response.

Once goals have been established, monitoring provides a means of assessing the realities of the goals and objective. The effectiveness and efficiency of accomplishment also become major items of concern.

These general principles are applicable to the federal energy conservation effort. The federal government, being a large energy consumer, must play a major role in achieving national energy reductions. DOD is in a similar role within the federal government. In FY 1975, total federal energy use was over 1800 million MBTU. Buildings and facilities accounted for almost half of such use at almost 900 million MBTU. DOD use represented over 81% of the total federal energy use. Its buildings accounted for over 67% of the total federal building energy use. Consequently, strong

attention has been given to reducing energy use in federal buildings and facilities.

Initially, federal goals and objectives were established relative to total energy use in FY 1973. As reporting and monitoring systems were refined, short range targets gave way to formalized planning. A formal plan was officially instituted by President Carter with the issuance of Executive Order 12003 of July 20, 1977. Defining FY 1975 as the baseline year, and defining objectives and targets in terms of energy use per square foot of floor space (MBTU/SF), target percentage reductions through FY 1985 were specified within the federal sector. Defense Energy Program Policy Memorandum (DEPPH) No. 78-2 of 1 March 1978 formally implemented these goals within DOD. The following goals for building use were directed:

1. A 20% reduction in average annual energy use per square foot of existing buildings (constructed or design completed) by FY 1985.
2. A 45% reduction in average annual energy use requirements per square foot of new buildings (design completed after the date of promulgation).

Defense Energy Policy Program Memorandum (DEPPH) No. 80-6 of 3 June 1980 extended energy goals through FY 2000. These goals, which implemented not only total energy use reductions, but targets for percentage of use by energy source, in 5-year phased targets. The following goals, relating to building energy use, were specified relative to the FY 1975 baseline:

By FY 1985:

1. 20% reduction in total energy use.
2. 30% reduction in natural petroleum fuels use.
3. 10% of total use for solid fuel conversion sources, i.e., coal, solid waste, wood, etc.
4. 1% of total use from renewable sources, i.e., geothermal, wind, solar, lowhead hydropower, etc.

By FY 1990:

1. 25% reduction in total energy use.
2. 35% reduction in natural petroleum fuels use.
3. 15% of total use from solid fuels conversion.
4. 5% of total energy from renewable sources.

By 1995:

1. 30% reduction in total energy use.
2. 40% reduction in natural petroleum fuels use.
3. 20% of total use from solid fuels conversion.
4. 10% of total use from renewable sources.

By FY 2000:

1. 35% reduction in total energy use.
2. 45% reduction in natural petroleum fuels use.
3. 20% of total use from solid fuels conversion.
4. 20% of total use from renewable sources.

To gain a perspective of the extent of this application, twenty two federal agencies owned about 3.2 billion square feet of floor space in more than 490,000 buildings worldwide when the Executive Order was issued. DOD was the largest single owner with over 394,000 (80.6%) of the total federal buildings, totalling more than 2.1 billion square feet (68%) of the federal building floor space in FY 80. The total DOD building energy use was 69% of the total use in all federal buildings [Ref. 6].

The results to date of federal, DOD, and DON efforts have been less than expected. Table 1 shows the results of their efforts to date.

The reasons for this lack of satisfactory progress need to be examined and corrected if the overall 20% objective is to be reached. One explanation might be that the goals are unrealistic, either in the short range, or in the final objective, or both. Another explanation might be that the implementation methods are not effective or efficient enough to produce the intended results. One obvious, although

impractical solution for meeting the energy goals is to channel greater capital investments to the bases to eliminate the most inefficient plant inventory and replace it with more modern, energy efficient construction, or make major conservation effective alterations. Obviously, the capital resources required will be a significant factor in such decisions. Less desirable actions to reduce base operations, or even close down bases could provide other alternatives. Such actions assume that the goals are inflexible and realistic in nature. With the assumption that the energy goals are realistic and feasible, attention is directed to the effectiveness of the implementation process. Can the current means of accomplishment be expected to achieve the objective, or are modifications necessary to improve the response?

**C. PURPOSE AND SCOPE**

The purpose of this thesis is to develop more effective methods of evaluating progress toward achieving energy

conservation goals. Although the present system is quite functional, its simplicity, permitting some level of control for the vast shore activity complex, has inherent problems that can distort reported results. The potential impact has financial consequences in that capital investment decisions can be adversely affected by such distortions. The limited capital resources available to undertake corrective projects can thus be less than effectively channeled.

The methods presented in this thesis are a framework that is intended to be general enough to be applied at the activity level, or functional command level, such as major claimants. The intent of this thesis to develop and discuss the realistic applications of energy use models. A brief presentation of concepts of theory will only introduce the reader to the necessary basic concepts useful in understanding and interpreting the basic methodology. A comprehensive treatment of theory will be left to textbooks. In order to be applied by the corporate body of energy managers, the methodology can not be too technical or dependent on theoretically oriented decisions. The intent here is to show the major elements of useful models to suggest working tools for general application.

The use of computers with software to handle the extensive regression and time series calculations is implicit in this methodology. The system used in this development was the IBM 370 hardware with the MINITAB software package. MINITAB is a terminal oriented, statistical package developed at the Penn State University, and was found to be flexible and easy to use without extensive previous knowledge of computers. The method developed herein is not dependent on MINITAB, however, and is readily adaptable to various statistical software packages.

The objective of the proposed methods is to identify a means of forecasting energy use to improve the effectiveness of the energy management program. The models developed will have advantages and disadvantages in particular situations that will determine actual uses. Discussion of model characteristics will demonstrate such applications.

The methods will be demonstrated within the framework of electricity use at Naval Regional Medical Centers (NRMC). This narrowing of scope will allow a more concentrated focus on the methods, without undue confusion created by introduction of indigenous issues. Selection of electricity as the energy type was based on its major, and still increasing, percentage of total energy use. Selection of the NRMCs as the sample was made on the basis of the particular characteristics of an NRMC, such as hours of operation, uniformity in mission and capabilities, separate siting at a location, concentration of spaces within one building or complex of buildings, and their geographical distribution affording sampling from different weather zones.

#### D. SPECIFIC RESEARCH QUESTIONS

There are three major questions that will be addressed in this thesis. The first question is: what is the impact of seasonal weather variations on energy use in Naval Regional Medical Centers? Relative to this question is the impact of such effects on established baselines and subsequent energy use evaluations for NRMCs as well as application to other types of activities.

The second question is: what are the effects of categories of use on total energy use? It is intended to determine whether particular functional uses of a building can be identified with a standard coefficient of use for each type of functional use.

The final question is: can the results be used to determine a method for establishing a control system to identify realistic goals and actual energy conserved?

## **B. METHODOLOGY**

Development of proposed methods of forecasting energy use will be accomplished in two phases. The first phase will develop forecasting models for energy consumption using regression models and time series models. Models will be developed for each of the individual activities as well as for the total study group.

The regression model will assume four predictor variables: average monthly temperature, monthly heating/cooling degree days (sum of the departures of daily mean temperatures from the base 65 degrees F.), and monthly precipitation totals. Humidity was felt to be an additional factor of consideration. This data was not as readily available from the Naval Weather Service Detachment, Asheville, N.C., of the Naval Oceanic and Atmospheric Administration in their normal Station Climatic Summary publication. Since the emphasis herein is on methodology vice numerology, it was felt that such data was beyond a reasonable request at this time for the courtesy service provided.

Both types of models will be used to develop trends of energy use per square foot from the established FY 75 baseline. The models will be used to compare projected FY 81 use with actual use. Forecasts of FY 82 use will be shown.

The second phase of analysis will attempt to determine standard coefficients of use for electrical consumption by category code of functional use. Data analysis will be performed by regression of average monthly electrical consumption and area of functional spaces. The main

emphasis of this phase will be on the baseline data. The development of standards of use for specific category codes will be shown as a means of adjusting baseline data for changed building uses.

Finally, the results will be evaluated to demonstrate useful applications. In particular, use of the developed forecasting techniques in a control system will be demonstrated.

#### F. THESIS OVERVIEW

Chapter I introduces the reader to the background of the federal energy challenge and the issues involved in setting and meeting energy conservation goals. Chapter II discusses the energy conservation program for buildings and facilities within the Naval Shore Establishment with regard to the energy conservation approach, the inherent implementation problems, and the resources available to achieve the desired results. Chapter III presents the methodology proposed in the development and analysis of models of energy use for the sample NRECs and total study group to illustrate the application of the developed models. Standards of energy consumption for categories of functional use and their application for a modular baseline are examined in Chapter IV. Chapter V, Summary and Conclusions, reviews the problems of the present system of evaluating energy reduction progress, and discusses the advantages of the particular energy use models within a control system framework.

Appendices A-E summarize the model development for each of the sample sites and total study group. The parallel structure of these appendices will facilitate a comparison of results. A summary of forecasts by time series models is presented in Appendix N. A summary of data is provided in Appendix O. Statistical tables are given in Appendix P as a means of ready reference.

## II. THE ENERGY CONSERVATION PROGRAM

Thus far, it has been shown what the building energy conservation goals are. Assuming that the goals are realistic and mandatory, this section will describe the implementation of these goals within DON. It will show the approach taken by DON to impose the goals, the actions by the implementing commands, and some inherent problems in the implementation.

### A. THE APPROACH

The basic approach taken by Executive Order 12003 was to establish a total use standard and to specify a percentage reduction target. Such a percentage reduction was in turn allocated to the various departments. DON in turn allocated such target percentages to its fleet commands, which continued the suballocation by percentage goals to their component commands, or activities. This is a simple and basic approach, and assumes that every command is capable of identifying its energy uses and can take the necessary steps to reduce its energy use. By virtue of the size and complexity of the Naval Shore Establishment, and to an even larger extent BOD, the approach to energy conservation has to be one that is relatively simple. To get too specific and exacting would require an even greater bureaucratic network than is already required to administer the program and would become very difficult to manage effectively.

The type of energy approach in use can generally be termed an end-use restriction. Its primary focus is in achieving a particular quantity limitation. It allows a relatively simple means of establishing goals, monitoring

progress, and identifying variance. In short, it provides a means of immediate impact.

There are numerous drawbacks to such an approach, however. The National Electrical Manufacturer's Association (NEMA) makes the following critical analysis of the end-use restriction approach: [Ref. 7]

The extent to which a system is used has no bearing on its efficiency. If, for whatever reason, a system is inefficient, it will waste energy every time it is used. End-use restrictions fail to take into consideration the systems which produce the end-use product, be it heating, cooling, lighting, etc. In other words, end-use restrictions tend to ignore the significant energy savings which can be realized by making systems operate as efficiently as possible. In a similar manner, end-use restrictions fail to consider the fact that every building is a unique system whose many systems interrelate. As a result, lowering a thermostat in winter can sometimes cause consumption of more energy, not less. Likewise, removing lamps and luminaires can sometimes cause consumption of energy sources which are in the shortest supply.

By way of contrast, NEMA advocates an alternative approach called Total Energy Management (TEM) which focuses less on the end-use and more on the efficiency of use. In describing TEM in general terms, they state: [Ref. 8]

In essence, TEM considers every building as a unique, complex system. To conserve energy one first must understand how the building consumes energy; how user needs are met; how the systems interrelate; how the external environment affects it, and so on. By understanding how a specific building consumes energy, one can make energy conservation improvements which can be integrated into the system itself. Then, when the system is used, it runs efficiently and therefore uses the least amount of energy to get the job done. Application of a wide variety of end-use energy modifications--which are an integral element of the TEM concept when applied with flexibility----would result in even more savings."

From a macro sense, end-use goals are necessitated by the scope of the buildings involved. From a micro view, i.e., the particular bases, a more flexible approach, such as presented by TEM, is very feasible. Such an approach may, or may not be in use at the individual bases, or its component commands, already. Requirements are dictated

externally only in the setting of heating and cooling temperature standards, directing the execution of functions necessary to fulfill mission requirements, and guidelines for the protection of life, property, and security.

## **B. MONITORING**

The Defense Energy Information System (DEIS) was established to monitor total energy use within DOD. Specifically, DEIS II identifies energy use in the buildings and facilities of the shore activities. A monthly report is sent by each shore activity which identifies its energy use by energy source, i.e., fuel oil, electricity, natural gas, etc., unit cost of such energy source, and explanations for differences from target. Weather variations are often identified as the source of otherwise unexplained difference.

The reports are transmitted by message to NEESA, where they are compiled and summarized by activity, type command, etc. Feedback summary reports are provided via the Energy Audit Report (EAR), showing quarterly results for each command, and for each level of command. For example, Commander, U. S. Naval Air Forces, Atlantic (COMNAVAIRLANT) would receive a summary of the stations under its command. The next echelon of command, Commander-in-Chief, U. S. Atlantic Fleet (CINCLANTFLT) would receive reports for COMNAVAIRLANT as well as the other type commanders (TYCOM) and individual stations reporting to it.

## **C. MEASUREMENT**

The scientific nature of the reporting and monitoring efforts may lead to the erroneous conclusion that measurement is precise and fairly routine. To understand

the limits of such data, the nature of the reporting commands and the means of measuring use needs closer examination.

A base defines an area, or group of activities under one general command. Such a command may be further broken down into operational commands. An extreme case would be the Naval Operating Base (NOB), Norfolk, Virginia. Within the fenced perimeter of the base are two major divisions--the Naval Air Station and the Naval Station--identifying air support and ship support functions. However, there is no clear line of demarcation separating the two functions within the fenced perimeter. Supporting activities may be located in either or both general areas. Functions such as the industrial Public Works Center supports all of the on base facilities, as well as facilities off base, such as family housing and NRNC Portsmouth. Each operational command has its own major claimant to which it reports. Thus, several major claimants are accountable for different portions of NOB's total energy use. There are a large number of such on-base individual commands ranging from staff headquarters to a Communications Station. Further contributing to the complexity is the fact that different commands might occupy one building or parts of several buildings. Since each command reports its energy use over its assigned floor space, measurement of the uses within buildings can be difficult.

By way of contrast to the complexity of NOB, some commands occupy a complete building in an off base location, such as some NRNCs. Energy use is more easily identified and measured in such cases, especially if the building is considered as a single metering customer by the power company.

Ideally, each building, if not each component use, would be metered so that exact use determinations would be simplified. Unfortunately, energy suppliers, such as a power company, considers a base as a single user. Its metering responsibility is only for energy delivered "at the gate". Submetering becomes the responsibility of the base itself. Off base locations may be metered by the power company as a single customer. Family housing, either on- or off-base is usually metered per house if billing is done on the residential rate schedule.

The vast number of meters required to submeter specific uses represents a large potential cost to the government; submetering is thus considered cost prohibitive as yet. A pilot program to introduce portable electricity meters to measure specific, short term loads is to begin in FY 82. The purpose of this program is to gain perspectives on actual uses for energy conservation purposes rather than for allocation of use, though.

The alternative to metering is engineering estimates. Each subcommand of a base is generally assigned a percentage of total base use, based on connected load and estimates of actual use. Baselines and monthly uses are assigned accordingly. Adjustments can be made if projects or management actions can provide justification. This method leaves a lot to be desired in terms of accuracy and accountability. Since actual use can not be identified, there is no strong incentive to conserve at the individual command on a daily basis. There is a dependence on large scale correction projects as a result.

Without specific metering, there is a major problem of identifying actual savings. While engineering estimates may indicate a level of savings, the effects of systems' inter-relationships of building systems may, in fact, be energy

additive or deductive and overlooked in calculating energy use. Thus, the possibility exists of underfunding a project which would actually have high energy savings, or overfunding a project with low energy savings, on the basis of faulty assumptions in the calculations. Portable metering as mentioned above may aid in increasing the effectiveness of estimation.

#### D. EVALUATION

The energy baselines are a month by month standard based on use in FY 75. Some adjustments have been made to reflect exceptional conditions that would adversely affect future comparisons. Current use is compared to the comparable baseline period and a percentage of change calculated. The calculated percentage, compared to the target percentage, provides a basis for evaluating progress. This comparison effort is done at the command level, base level, TYCOM level, major claimant level, etc. Statistics, such as shown in Table 1, provide a basis for quantitative analysis. From Table 1, it can be concluded that federal, DOD, and DOW progress is below target.

To make a valid comparison, however, one must understand what is being compared. There are particular inherent factors in the present measurement system that could possibly distort the data and lead to erroneous conclusions.

One strong influence on energy use is weather. Hot, humid weather will cause greater use of air conditioning, which is a large electricity user. Cold weather usually results in higher fuel oil use, recognizing that steam heating is produced by oil fired boiler plants. Electricity and fuel oil accounted for almost 72% of total building energy use in FY 1975, and 74.5% in FY 1978. The impact of weather on these dominant energy sources is then likely to

be significant. If, however, the baseline year experienced severe weather variation, say a long, hot summer, a mild summer in the comparison year could overstate the actual conservation progress. Conversely, normal weather during the baseline month or year and an extreme variation in the comparison period could understate actual conservation results. While weather effects are significant in the magnitude of energy used, a valid comparison requires similar weather conditions in order to study controllable consumption for evaluation purposes.

A second consideration in the validity of comparisons is that the composition and specific natures of military bases are constantly changing. Energy use on a per square foot basis is an important consideration in allowing for construction and demolition changes. However, there is no consideration for the uses of buildings. Technology has continued to progress along energy intensive lines. Greater emphasis on electronics has increased the needs for environmental controls, i.e., humidity, temperature, air filtration, etc., increasing consumption beyond that needed for just equipment use. If new technological installations include construction of new facilities to house them, design and construction incorporating energy efficiencies could offset, at least partially, any increased total use or total use per square foot. Construction funding often lags technical installations, though, and bases are forced to adapt existing facilities to meet the increased requirements. For example, aviation trainers have been installed in converted warehouse spaces, increasing the electrical load with no change in square footage. Such conversion of low energy intensive use to a higher intensity use will offset other energy savings achieved.

Building uses are also often changed to correct particular facility deficiencies, such as lack of storage space. Since construction funds are limited, often with long lead times between project submission and project completion, demolitions of unnecessary but still useable buildings are reluctantly requested. Bases prefer to convert buildings no longer necessary for their original purposes to contingency uses. The low priority given to warehouse construction, often identified as a facility deficiency, invites conversion of unused, or marginally used, buildings to storage spaces which have a low energy intensity. Such buildings are usually older and beyond their expected useful life, and highly energy inefficient. Thus, while a base might show a statistical improvement, there would be no real increase in the efficiency of use.

The above examples may well be practical and wise managerial applications of using existing resources, commendably saving construction funds. However, all can distort energy use comparisons. Setting standards of use by functional category of use would permit a modular technique of evaluating energy use or adjusting baselines.

A final distortion potential consideration exists in the equity of energy baselines. It was previously mentioned that the baseline year was initially established as FY 73 and later changed to FY 1975. A command which took actions to comply with the energy reduction goals prior to FY 75 would tend to show less favorable results in later comparisons with FY 75 than the base which took no immediate reduction actions. This effect, however, would be minimal inasmuch as the measures taken at the time were directed at obvious wastes and of relatively small magnitude.

Overall, the present evaluation system is limited to providing a snapshot of use in a particular period subject

to a particular set of conditions. Such a snapshot, being subject to distortions, does not afford a good basis for comparison purposes. Nor does it permit a sound basis for control since it does not isolate non controllable factors such as weather. Modifications are needed to provide a more effective means of evaluating energy consumption relative to established targets.

#### **E. CAPITAL INVESTMENT CONSIDERATIONS**

The energy reductions required to meet the specified energy goals will require far more than individual effort to turn off lights, limit heating and cooling, or economize uses. Buildings and installed systems will require major modifications to overcome the effects of construction during the era of cheap energy as well as to offset the deterioration of buildings and their installed equipment systems. In many cases, complete replacement, incorporating energy efficiency considerations will be the cheaper alternative. It must also be realized that the interrelationships of technology, missions, and support facility requirements have not remained constant since baseline FY 75. In particular, the rapid growth and dependence on electronics has increased electricity use significantly. As a consequence, actual reductions will have to be greater than the planned target percentages to compensate for any growth. The need for capital resources to effect the required changes becomes obvious.

The investment capital required to make such modifications is not linearly related to the quantity of energy conserved. One author has described energy conservation as a "depleting resources industry" [Ref. 9]. The economic theory of depletable resources is generally associated with the law of diminishing marginal returns, which states that

when production from any activity is to be increased it can be done by adding capital or labor. As additional quantities of any one of these inputs are added to a fixed factor of production, the incremental or marginal returns associated with the inputs tend to decline. The converse of this law is the law of increasing costs which states that, since the input must be purchased, the incremental (marginal) costs of production increase. In application to energy conservation, output can be considered as the energy saved, that is energy not required to be produced. Inputs would be the material for conservation capital stocks as well as the labor costs of installation. A graph of cost versus energy conserved may be shown for the general case in Figure 1.

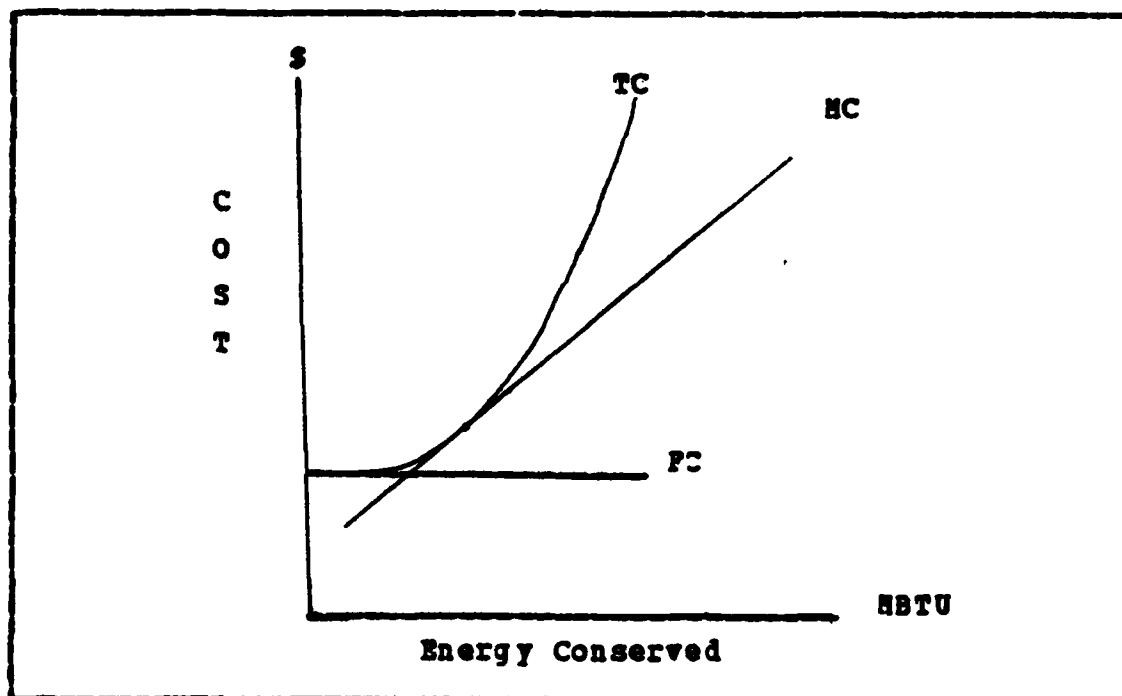

Figure 2.1 Diminishing Marginal Returns of Energy Conservation

It can be seen that there will be a fixed cost (FC) of energy. As output, conserved energy, is increased total costs (TC) will begin to rise at a low marginal cost (MC). The marginal cost, the rate of change in total costs, will increase as output increases. Succintly stated, greater energy savings incur greater costs at an increasing rate. Thus, initial conservation takes little capital investment. To achieve greater conservation levels, increasing rates of capital investment are needed.

The implication of this characteristic is that greater rates of capital investment are necessary in order to achieve the increasing percentages of total reductions required. In perspective, with the growth of electricity requirements, there is an increasing level of capital investment required just to maintain the percentage reductions thus far achieved.

The dramatic rise in energy costs since 1975 provides offsetting benefits for the capital investment requirements. Rising energy costs serve to decrease payback periods. An energy savings project can often pay for itself within a few months or years in this perspective. Under appropriated funding, however, the savings are a statistical savings, if payback periods extend beyond fiscal years. In fact, savings are more realistically cost avoidance in such cases.

There are various sources of investment dollars within the federal budget. The response to a specific project approval and the funds available vary with the cost of the project. Commanding Officers have the authority to fund projects costing less than \$15,000 from their operating budgets. With no specific approvals required, funding can be done as needed. This may require sacrifices of other funding plans. Unless the payback period is short enough to realize savings within that fiscal year so that savings can

be applied elsewhere, given the expiring nature of appropriated funding, there is little motivation to make strong sacrifices of short term needs for the longer range goals. Even if the cost of purchased energy exceeds budget allowances, major claimants have no recourse but to fund the deficiency with little danger of repercussion to the Commanding Officer.

Energy programs to provide supplemental funds for energy conservation projects have been established in recognition of funding limitations and the conflicting priorities within operational budget funding. The Energy Technology Application Program (ETAP) provides funds of up to \$100,000 for retrofit of existing buildings. Program funding is requested from annual Congressional appropriations. Prior to FY 82, funding and specific project approvals were administered by the Naval Facilities Engineering Command (NAVFAC). Its geographical Engineering Field Divisions (EFD) served to provide technical expertise to evaluate and, if requested, initiate projects as well as provide funding administration within their large geographical areas. Although NAVFAC provided final approval, the EFD recommendations were generally heeded. The major commands have now been tasked with this administration and control of ETAP funds. Technical guidance will continue as a NAVFAC function. This shift of control will allow more control of energy conservation progress by the particular claimants. It will also bring greater accountability.

Major claimant control of their own energy destiny may also prove a disadvantage to the overall energy plan of DON, though. Funds are more likely to be invested in less efficient single uses, benefitting individual commands, but with less impact on the total DON requirements due to a decreased range of alternatives available to major

claimants. Each major claimant, if given a proportional share of the funds available to distribute among its total commands, will have less flexibility in magnitude of funding. Funding of a wider range of smaller projects can be expected, thereby missing opportunities for optimal funding in a wider range of greater savings projects.

Energy conservation projects to retrofit existing buildings costing over \$100,000 fall under the Energy Conservation Investment Program (ECIP). As these funds are within the Military Construction Program (MILCON), they are administered by NAVFAC. Projects are submitted via the EFDs for technical approval and forwarded to NAVFAC as a line item budget submission for Congressional funding approval. Project approvals are based on economic justifications and subject to the budgetary politics of the federal budget process. With the requirement for Congressional approval, the response time between project submission and completed construction is slowed to a minimum of three fiscal years.

While ETAP and ECIP funding provide capital investment funds to effect energy conservation corrections, it must also be recognized that the political realities of appropriation funding tend to limit the amount of funds available. Cost avoidance is not an attractive proposition to the political entrepreneur. Voters receive no tangible benefits in energy conservation projects and see only an increase in government spending. Actual cost reductions are hidden in the amount of continuing rate increases. As a result, conservation funds are subject to the 'budget axe' when budget reductions are necessitated. The energy investment programs are in fact more saleable under the patriotic banner of energy independence from foreign sources.

The combined effect of these factors have put a large strain on investment dollars. The net result of the diminishing marginal returns nature of energy conservation serves to increase the greater need for investment dollars. Coincidental to this need, the amount of dollars made available tend to be limited and restrictive. The more decentralized control of investment funds at the ETAP level may limit the effectiveness of investment funding further. The message then is very clear: investment decisions will have to be made wisely to achieve the maximum effectiveness from the dollars available. Accordingly, rational decisionmaking will depend on the accuracy and reliability of the information on which it is based.

### III. MODELS OF ELECTRICITY USE

#### A. MODEL TYPES AND USES

The decisionmaker, for purposes of this thesis, will be defined as the person evaluating the energy reduction progress of an activity or group of activities with access to capital investment funds. The issues for the activity decisionmaker are how to effect the necessary energy reductions, what investment funds are needed to implement further reductions, how effective the implemented measures have been, and what level of reduction can be realistically expected relative to the prescribed targets. A higher echelon command, such as the major claimant, would be confronted with allocating its limited investment dollars. Both decisions would necessitate evaluation of the current and expected progress.

The basic document to provide current progress is the Energy Audit Report (EAR). Figure 2 is a sample of such a report. The evaluator can read electricity use in kWh and MBTU for the baseline and current 12 month periods, the percent change from FY 75 and percentage of total use. It further shows FY 75 and current fiscal year floor areas and percent change from FY 75, MBTU/thousand square feet comparisons, and a comparison of total reduction and target reduction. EARs are provided on individual activities on their use as well as to higher echelon summarizing the progress of their reporting commands.

In a simplistic, cursory examination of the EAR, one could assess whether an activity was above or below target. One could also identify the progress by energy type. In this example, the activity relied on electricity for almost

one third of its energy use but had only achieved a 2.7% reduction in such use, offsetting the large percentage decreases in its other energy sources.

Taking an EAR at its face value might well lead to the erroneous conclusions discussed in Chapter II. But the energy manager has little else to base his conclusions on except to review past EARs and develop an intuitive or perhaps a graphical picture of the general energy reduction progress. Would a 12% increase this fiscal year have really indicated non compliance? Or were temporary phenomena responsible? Does the 10% decrease indicate compliance? An example of this issue is provided by a review of electricity use at NREC Jacksonville as shown in Figure 3. A sharp peak for May 1978 is evident. A comparison of FY 78 with FY 75 shows only a 5% decrease, corresponding to a target of 6%. The EAR, by itself, would not show the use spike. The 1% variance might not be considered too serious. However, visual inspection of the data would raise questions concerning the real decrease percentage.

In verification of the data with the activity, it was learned that new water chiller units were being tested during that month, "probably" causing the spike. The activity might have reasoned that without this created extra load, it would have achieved an 8% reduction instead of the reported 5% decrease. Without knowing the real effect of the additional use for the water chillers, such reasoning might be erroneous. A large expected use, perhaps due to weather conditions, would have shown less than a 3% difference due to water chillers. A low expected use might have shown more than a 3% increase. In either case, the energy manager could have evaluated the situation and taken appropriate action as a result.

The implication of this type of framework is the existence of a control system. But, such a control system is dependent upon the ability to determine expected use, rather than setting a target, directing effort toward that goal, and suffering the blurring effects of noncontrollable factors.

Predicting future events, or forecasting, with relative certainty has become a scientific discipline in the last several decades, particularly with the widespread introduction and use of computers. Programs have been made readily available for almost all quantitative forecasting techniques. "The need for forecasting is increasing as management attempts to decrease its dependence on chance and become more scientific in dealing with its environment" [Ref. 10]. Techniques vary considerably with the situation, time horizons, factors involved, assumptions made, and types of data patterns. A basic underlying premise in almost all forecasting methods is the assumption of constancy, i.e., the pattern of the past will continue into the future.

There are two major types of forecasting models: regression and times series models. Regression models assume the factor to be forecasted has a continuing relationship with one or more independent variables. The purpose of the model is to exploit those relationships and use them to forecast future values of the dependent variable. System responses are observed and input relationships of that response are developed. To use Ohm's Law as an illustration, voltage (E) can be predicted by inputs of current (I) and impedance (Z), and the known relationship  $E = I \times Z$ . The key to this method is identifying the significant input variables (stimuli) and their relationship to the the output (response).

Figure 3.2 Energy Use for NRHC Jacksonville

The time series model, on the other hand, makes no effort to explain the factors that affect system response, treating the system as a black box. Its main concern is observing particular events and predicting future states. Weather can be forecast by use of a time series model. The pattern of historical events is described by mathematical relationships and used to forecast expected temperatures, sunlight, and even rainfall, without necessarily understanding the climatic conditions responsible for the results. Both models have particular advantages in particular applications and will be examined in this thesis for application to energy forecasting at Naval Shore Activities.

## B. REGRESSION MODELS

### 1. Concepts of Electricity Use

In this section, an energy forecast model based on four weather variables will be developed using regression techniques. The main purpose of this section will be to demonstrate the techniques and discuss the interpretations of the regression model. A more specific application of regression techniques will be developed in Chapter IV to identify the relationship of energy use and functional uses of activity buildings.

In order to build a model to 'explain' electricity use, it will be useful to define some of the basic terms and concepts of electricity consumption that will be important considerations. A relatively simple model of residential home use provides a useful framework for discussing basic concepts. Each electrical device is rated as to the power it uses to perform its function. The rating is given in terms of watts. The electricity used during that performance is the product of the power rating and the hours of

use, expressed in terms of watt hours. A 60 watt light bulb left on for 8 hours consumes 480 watt hours, or .48 kilowatt hours. The British Thermal Unit (BTU) is often used to express energy use in terms of a common denominator relative to other energy sources, such as steam, coal, or fuel oil. One BTU is equivalent to .0116 kilowatt hours, after adjustment for particular distribution losses. The previously cited example of the light bulb consumption could be expressed equivalently as 5,568 BTUs. The amount of power (watts) required to energize all devices connected to a system is its connected load. A residential home use could be calculated by summing the watt hours of each use of its connected load. In reality, the calculated amount would be less than the actual amount used since every unit has some associated energy loss, or inefficiency. The losses in a typical residential unit are relatively minor, however. The energy efficiency of a device or a system is defined as the percentage of useful energy (rated watts x hours - losses) to delivered energy (rated power x hours).

A simple residential home model would be expected to contain explanatory variables relating the effects of weather, number of occupants, and the hours that the unit is occupied. The model would express the amount of change expected in the electricity consumption per unit change in any one of the variables, or stimuli. To control the response within particular limits, it would be necessary to control the variables, if possible, or adjust the system response to a variable. Since weather is not controllable, adjustment of the system response could be effected by increasing the insulation, resetting thermostat controls, or even replacing inefficient heating or cooling units. The model would indicate the change in electricity use caused by a unit change in any one of the variables when the other

variables remain constant. A user could select the variable(s) to control that would influence the desired response.

Models for industrial electricity, such as for a military installation, are considerably more complex and involve subsystem interrelationships. Power to the installed loads is often three phase power. Simplistically, the total power to the load is provided by several wires which provide the total required power. It is important to the efficiency of the power use that each phase have the same loading. A system is said to be balanced if each phase delivers the same amount of power to a system. As the system becomes unbalanced, the efficiency of use decreases. This concept applies to an entire building supplied with three phase power, a particular internal circuit, or a particular type of load. The efficiency of a building's use can be improved by shifting loads to other circuits to gain a better balance.

The power factor is another important item in energy efficiency. The power factor is the cosine of the phase angle between the current and voltage, ranging in absolute value between 1 and 0. A pure capacitive, or pure inductive load will have a phase difference of 90 degrees, and therefore a power factor ( $\cos 90$  degrees) of 0. The product of power factor and rated power is used to determine the useful or real power used relative to the power delivered. Thus, a load with a power factor of 1 would have no losses as a result of the phase difference, while a load with a power factor of 0 would be a total loss of delivered power. A pure capacitor, for example, would store energy delivered to it and would have a power factor of 0. By adding an inductive load of equal magnitude, the resultant system power factor would increase to 1. Thus, another industrial energy

conservation measure is to attempt to balance inductive and capacitive loads. In fact, power companies often give rate incentives to industrial customers who maintain a power factor of at least 0.8 as a means of increasing the power system's overall efficiency.

The major concept to be understood by the reader is that system interrelationships are significant in explaining the system total response. A change in one component of a system may in fact produce an effect opposite to the intended response. Relative to weather effects, warm weather resulting in the use of large air conditioners may increase or decrease the efficiency of a particular system or subsystem. Thus, a simple calculation of the rated power use of a particular load may not necessarily provide the true overall response. Consequently, the definition of an industrial system response needs to consider the interrelationships of its subsystems. Determining the system response is not a simple matter of inventorying connected loads.

## 2. Concepts of Statistical Theory

This thesis does not presuppose a strong background in statistics, nor is it the intent to provide one. Textbooks suitable for the reader's particular background would provide a more thorough and appropriate source of information. The text of this thesis is written for the corporate body of energy managers who may have had only minor exposure to a study of statistics. Consequently, a brief presentation of important statistical theory concepts will be given only to provide a better basis of understanding the interpretation and application of regression modeling.

Regression models were seen to be based on determining a system response in terms of the relationships of particular input variables, or stimuli. Theoretically, there exists a true function that completely explains output. Such a deterministic model would also be capable of forecasting future values providing the definitive equations did not change, i.e., system interrelationships and input variables remained valid. A true deterministic model of electricity use would detail every use down to the efficiency of the connected loads and the effect of energized loads on load balance, power factors, etc. Obviously, such a model would be difficult to develop and very complex. Despite the ability of computers to rapidly compute the response once the appropriate data is input, collection of that data can be costly in terms of time and money. A lesser model might be sufficiently accurate and far less costly. A useful model would be one which could reliably estimate the 'true' function and be practical enough to be effective.

Since the applied model is not deterministic, there will always be error, or differences between the expected values of the model and the observed data. The technique of least squares is used to minimize the error of a fitted curve to the input data. The sum of the squares of the errors becomes a measure of determining how well the estimator curve fits the data. The coefficient of determination, or  $R^2$ , is the ratio of 'explained' error to the total error. Its values then would range from 0, indicating no relationship between the stimuli and response, to 1, indicating a perfect fit. Maximizing  $R^2$  is one means of determining the usefulness of a model.

The addition of variables to a regression model can not decrease the  $R^2$  value, appearing to improve the

prediction capability of the model. However, an increase may be spurious, caused by measurement errors, or chance results of unrelated data. A plot of  $R^2$  against the numbers and combinations of variables will result in a logarithmic type curve which flattens as it approaches a maximum. Adding variables in this region will provide little increase in  $R^2$ .

Another means of evaluating the fit of the model may be made by examination of the mean squared error (MSE). As its name implies, MSE is computed by squaring the individual error for each data point and then finding the average or mean value of the sum of those squares. The MSE gives greater weight to large errors than to small errors since the errors are squared before being summed. Plotting the MSE against the number of variables results in a parabolic curve. The graph will show a minimum point for a particular combination and number of variables. A decrease in the MSE with added variables, may not be great enough to justify the cost of additional data collection.

The variance of a function, known as  $S^2$ , indicates the dispersion of the data around the mean. This value is used to assess the extent of possible error. The F statistic uses the ratio of the 'explained' variance to the 'unexplained', or totally random, variance about the mean. If there was no correlation of the output variable with the input variables, the mean of observed output would be the best predictor. Since all variance would be 'unexplained', the ratio should be 1. As more variance was explained, the numerator would increase. The F statistic, with a known probability distribution, can be used to compare the explanatory power of different models or assess the various characteristics of a particular model.

Estimating the 'true' function, recognizing that error is involved, leaves room for doubt that a model has predicted a realistic value. Confidence levels are used to express the probability that a predicted value is accurate relative to the 'true' value. A confidence level would indicate the percentage of times, on the average, that a particular outcome would be observed in repeated trials. For confidence intervals, the desired outcome is that the computed interval include the 'true' value. Increasing the confidence level causes the interval to be longer, but less informative. All calculations used in this thesis use a 95% confidence level.

The confidence level is calculated based on known distribution characteristics. The cumulative area under such a curve is the cumulative probability. The central limit theorem states that as the sample size  $n$  increases, the distribution of the mean of a random sample taken from practically any population approaches a normal distribution. A standardized normal distribution, with its mean of 0, and standard deviation of 1, can then be used as a prototype from which to make certain statistical and probability inferences. A useful property of the standardized normal distribution is that about 95% of the area, or probability, lies within 2 standard deviations of the mean. The standardized normal curve and table of values is shown in Appendix P.

The Student's  $t$ , or simply  $t$ , distribution is used for small samples. The  $t$  distribution is actually a family of curves identified by degrees of freedom. Degrees of freedom relates to the number of variables in an equation. The residuals for the variables, i.e., the errors or differences between observed and calculated values, are said to be 'free' in that they can be any value, with the condition

that their sum is zero. Thus, not every residual is free once other residuals have value. Computer printouts usually print degrees of freedom as a normal output of interest. T distribution tables, such as provided in Appendix P, will yield a standardized deviation from the mean. Multiplication of this value by the model's standard deviation will yield the probability that a particular value will be greater than an expected value. It can be seen that the t distribution and standard normal distribution values converge for large numbers of observations.

The aptness of a model may also be determined by examining its prediction capability. A condition of aptness is that error is randomly distributed with constant variance around the mean over a range of values. A plot of residuals against the individual variables will demonstrate error distribution. Figure 4 demonstrates possible patterns of residual error when plotted against a variable. Figure 4 (a) illustrates constant variance (homoscedasticity) over the range of X, satisfying the basic assumption. Figures 4 (b), (c), and (d) exhibit non-constant variance (heteroscedasticity). Use of the variable exhibiting the characteristics of any of the latter three examples, will introduce non random, focused error into particular data ranges and have undesired influence within the model. Correction of heteroscedasticity may be accomplished by transformation of the variables. Residual analysis, other than noting that particular variables may have undesirable influence without adjustment, is beyond the scope of this writing, however.

Multicollinearity, or correlation between independent variables, can also produce undesirable effects in a model. At best, these effects are unpredictable. Multicollinearity should be avoided, if possible.

Figure 3.3 Prototype Residual Plots

## C. REGRESSION MODELING TECHNIQUES

### 1. Parameter Selection

A regression model will have the general form,

$$Y = b_0 + b_1 X_1 + b_2 X_2 + \dots + b_k X_k + \text{error } (e)$$

The initial selection of variables as predictors of system response depend on the purpose of the study, logical

assumptions of relationships, the practical cost/benefit considerations of data availability, and the desired complexity of the model. Selection of the weather variables for this analysis provides amplification of these points. The purpose of a weather parameter study would be to test and compare weather effects on energy use. The general form of the weather model that will be developed is given by,

$$\text{MBTU/SF} = b_0 + b_1 \text{AVGTENP} + b_2 \text{HDD} + b_3 \text{CDD} + b_4 \text{PRECIP}$$

The results of this model will assist in answering pertinent questions, such as, Does electricity use show a strong correlation with weather factors? Which weather factors have the strongest influence? Is there a general relationship between activities in the same climate zone, or even among particular types of activities? More important, though, is what affect does the model have on management decisionmaking?

An important consideration to realize before final selection of the variables is that the final results can be applied only within the context in which they were determined. The final model will show only a relationship between the input variables. For example, cooling degree days may show a strong influence in a particular model. That influence may only be relevant in the presence of the other selected variables. The addition of another variable, such as hours of sunlight, may decrease the relative significance of cooling degree days and increase the significance of precipitation. Selection of parameters for study should be given a broad consideration first with a narrowing focus.

Availability of data and cost of the data are important for obvious reasons. The cost of acquiring data, in terms of time and money, must be cost effective. It makes little sense to acquire data that requires many manhours to

assemble and refine without a strong improvement in a model and a high value placed on such improvement. For example, total year weather summaries, published for each weather station, were used to collect the necessary weather data used in this study for each activity. Selection of a wider variety of variables would have required additional processing costs by the National Climatic Center, and a greater compilation prior to computer processing. The benefits of additional data were considered less than the cost and therefore not collected.

The accuracy of data must also be considered within a cost context. Regression is often used in cost estimating large government contracts, such as the acquisition of weapons systems, ships, and aircraft. Historical data to the nearest penny requires a great deal of research; 'ball park' estimates defeat the purpose of forecasting cost. A reasonable amount of accuracy is determined by the cost of acquiring data and the purpose such accuracy will serve. Similarly, the floor areas of reporting activities must be recognized as having limited accuracy. EARs show only a single area for a fiscal year. Allowing the possibility of a net effect of zero during the year for construction and demolition combinations, the sometimes lengthy transition period between full occupancy and inactive status for new buildings or building demolitions, the attempt to refine square footage to a completely accurate number would have been cost ineffective since the final results may show only a small change for accuracy adjustments. It is highly unlikely that records would be kept to such a level of refinement. Records pertaining to actual energizing/deenergizing dates and occupancy status would be an exception rather than the rule. However, the user should realize the limits of the data and the effect on the final model before

expecting too much from the model. Alternatively, model uses can be specified to insure the data will be of appropriate accuracy.

## 2. Building The Model

Although graphical comparison of system response and various system stimuli is not necessarily an integral part of regression modeling, it does provide a visual indication of particular patterns and trends that may suggest certain relationships. Parts A and B of Appendices A-H exhibit graphs of energy use and weather conditions from FY 75 through FY 81. The various energy use graphs show a variety of patterns. NBNC Corpus Christi, for example, shows distinctly different patterns before and after the start of FY 79. Prior to FY 79, there was relatively small variations between successive peaks. The largest peaks seem to occur about July of each year. The mean MBTU/KSF was decreasing through FY 76, stabilized in FY 77, and rising in FY 78-79. The July peaks after the start of FY 79 show a sharp increase although winter minimums also show a significant decrease. It can also be seen that there was a milder winter in the baseline year. In fact, there was a mild winter, relative to successive years, at almost all of the sample sites. The composite study group also reflects this occurrence.

An EAR provides only yearly energy use summary statistics. The averaging of the wide variations shows only a relative degree of change of the mean. The visual picture of the monthly energy use might prompt a different type of response for the decisionmaker. One might speculate that the activity added large air conditioning units causing the large summer peaks. Without such air conditioning use, it would be possible that the remaining use level had

decreased, as indicated by the winter lows. The decisionmaker, even with confirmation of these hypothetical explanations, would be unable to assess at this point whether the increase was justifiable, assuming the necessity of the air conditioning. Did weather conditions, i.e., unusually hot, humid conditions cause greater use? Or is air conditioning use excessive?

The results of the four weather variable model for NRMC Corpus Christi is shown in part C of Appendix C. The resultant equation is seen to be,

$$Y = 29.7 - 0.0075 \text{ AVGTEMP} - 0.0086 \text{ HDD} + 0.0169 \text{ CDD} + 0.246 \text{ PRECIP}$$

(1.47)      (-.02)      (-.67)      (1.46)      (1.23)

Interpretation of this equation is that for a unit change in any one of the input variables, system response will change by the signed magnitude of the variable coefficient while the remaining variables remain constant. The magnitudes of the coefficients alone, however, do not indicate their importance, since the units of each variable are different. Relative significance is determined by the t-ratio (coefficient/standard deviation). T-ratios are shown in parentheses below the coefficients. CDD is seen to be the strongest variable by this criteria. Recalling that the equation is an estimator of the 'true' function, the user might want to test the hypothesis that the individual coefficients are 0. That is, is the estimated coefficient non-zero because of the error in the estimate? To determine whether the value is significantly different than 0 with 95% confidence, an evaluator would compare the observed t ratio to the tabulated t distribution. Since each ratio is less than 2, the value of 0 as the true value for each coefficient would be accepted.

The t test can be applied only to a single coefficient. Even though none of the coefficients have a t statistic greater than the critical value of 2.0, it can not be said that all coefficients are 0, since deletion of one variable could change the relative significance of the remaining variables. To test the hypothesis that all coefficients are 0 simultaneously, a similar test can be performed with the F statistic. In the case of NRHC Corpus Christi, F is computed as 16.9 (498.94/29.53). The F table, as provided in part C of Appendix P would be used. Entry of the degrees of freedom of the 'explained' error (4), and degrees of freedom for the 'unexplained' error (79), yields a value of between 5.66-5.69. Interpretation of this test is that the risk of assuming that all coefficients are zero, with an F=16.9, is 95%. It would thus be concluded that all coefficients are 0.

The next step of analysis would be to delete the weakest relative variable, in this case average temperature, to narrow the focus of consideration. However, the fit of the model by  $R^2$  and MSE criteria need to be examined to compare the relative changes in other models. The  $R^2$  value is seen to be 46.1%, which will be the maximum for up to these four variables. It is also, as expected, an indication of a weak fit. (A value in the order of 90% would be hoped for in this type of prediction model.) The MSE (mean square of the residuals in the analysis of variance) is seen to be 29.5. Also shown in the analysis of variance is a listing of fourteen points which were identified from the total of 84 as having adverse effects either by a large standardized residual(R) or a large influence by an X value (X).

The correlation summary indicates a further problem of multicollinearity. A correlation of .956 between average

temperature and CDD indicates that the variations in the two variables are almost identical and move in the same direction. The  $-.884$  correlation between average temperature and HDD indicates these two variables are also strongly correlated but moved in opposite directions. That is, as average temperatures rose, CDD increased and HDD decreased. These results, as previously discussed, were expected. Elimination of average temperature to reduce the unpredictable effects of multicollinearity would further be suggested.

### 3. Evaluation of 'Best' Model

Each of the models which have been developed for four weather variables is considered to be the full model. That is, it contains all of the variables intended. As seen earlier, it will have the best fit since adding variables will always improve the  $R^2$  value. But the full model may not always be the 'best' model. The criteria for 'best' is established by the decisionmaker based on the intended model use.

Prior to considering a model for selection, a determination of aptness should be made. It will be assumed herein that all models are apt since residual analysis is more appropriate to discussion of developing realistic models rather than the methodological approach taken by this thesis. The weather variables selected for this study are known to be interrelated and of little practical value by themselves.

Values of  $R^2$  and MSE are the most commonly used indicators of fit. Criteria to be used will depend on the decisionmaker's needs and preferences. As previously discussed, a curve of  $R^2$  against combinations of variables will generally show a sharp rise initially before flattening

as it approaches a maximum value. The 'elbow rule' criteria sets the selection of 'best' at the point where the flat zone begins.  $R^2$  will change very little for adding variables.

The parabolic curve of MSE against variable combinations will decrease to a minimum point and begin to rise again past the 'best' point. The degree of change as MSE approaches the minimum may also be very slight, though, indicating that the addition of a variable will decrease MSE by only a small amount. The minimum point may not be the same point indicated by the  $R^2$  'elbow rule' criteria.

The F statistic also shows the explanatory power of a model. The F statistic has no maximum or threshold value criteria. A minimum criteria can be set based on the confidence level test that all variables are not 0, as discussed earlier. The minimum point determined for a 95% confidence level was found to be 5.68. Below this F level, the model would be rejected.

An important concept, basic to either criteria, however, is cost effectiveness. The cost of a model must be less than its value. The cost effectiveness should decide the complexity of the model. All else being equal, model selection should be decided by optimizing cost effectiveness.

Table 2 summarizes the results of regressions for each of the 15 combinations of models for one to four variables of each sample. The  $R^2$  and MSE values are shown for the best model in each category of 1, 2, 3, or 4 variables. Continuing the use of NBMC Corpus Christi for illustrative purposes, a 'best' single variable model would use CDD as a predictor, with an  $R^2=44.3\%$  and  $MSE=29.42$ . A 'best' two variable model would add precipitation as a predictor with a corresponding gain in  $R^2$  of 0.9%, with a decrease of 0.16 in

MSE. A three variable model, adding HDD, was found to increase  $R^2$  by 0.9%, with a decrease in MSE of 0.10. The addition of average temperature as a fourth predictor had no noticeable effect on  $R^2$ , but increased the MSE by 0.37. The F statistic shows a continuing decline as variables are added, although staying above the minimum significance level. Assuming little cost difference between a 2 variable and a 3 variable model, the 'best' overall model would appear to be the three variable model 13.

Table 2 provides a basis of making some general observations. Selection of the 'best' models based on changes versus absolute values of  $R^2$  and MSE, and minimum F value criteria, would have made the three variable model the most popular. It is interesting to note that CDD figured as the best predictor in all but 4 of the 13 single variable models, in all but 1 of the two variable models, and in 10 of the three variable models. Non selection of a CDD model was then due to marginal differences in almost every case. The idea that more may not be best was clearly demonstrated. Full models for Oakland and Jacksonville, as well as the three variable model for Oakland were rejected on the basis of F test significance.

The approach to model selection would generally be the same for the activity level and upper echelon decision-makers. However, the issue of cost effectiveness would be greater at the upper echelon command. The activity level decisionmaker could be relatively indifferent to the difference in complexity between a three and four variable model, or between a two variable and a three variable model. However, an upper echelon decisionmaker evaluating a group of reporting commands would find the complexity difference multiplied by the number of reporting activities. In this study, the decisionmaker would have to consider the cost of

acquiring and processing twelve sets of data against the value of increasing the  $R^2$  value by 0.1, with almost no change in MSE, and a moderate decrease in the value of F. The purposes of the information would be a large influence in the selection. It would be expected that the three variable model would be selected.

Regression modeling can be seen to be an involved process. Its value is in the determination of relationships between system response and specific inputs. The relationships would be useful for developing a plan of corrective action. For example, the strong effects of cooling degree days would suggest investigation to determine ways of reducing such effects. An activity may decide to alter circuits to gain a better balance in phase loading, and/or power factor corrections. The effect of air conditioning could make a difference during the cooling season and be opposite in effect during the remainder of the year. Biannual load adjustments might then be appropriate to compensate for such effects. Increased insulation against heat losses or gains might have cumulative effects during heating and cooling seasons. Initiation and prioritization of projects to implement necessary changes might be effected. Similarly, an upper echelon command might review its priorities of funding based on the indications of particular regression models.

Evaluation of projects, however, is perhaps most significant at the EFD technical review. The estimation of energy savings and payback periods provided by the engineering staff is critical to the funding of projects in many cases. Erroneous assumptions of system interrelationships could well provide the difference between funding or not funding a project that could either save energy or waste investment capital. Regression analysis provides a further tool that can be useful in assisting such decisionmaking.

#### D. TIME SERIES MODELS

Regression analysis provides a capability of examining relationships to define system output. Time series models, on the other hand, are concerned only with system output. The model defines historical patterns and trends of a variable by mathematical equations which it uses to forecast future states. The assumption in both cases is that the patterns and trends will continue into the future.

A particular value of this method is in the ability to minimize the effects of unusual events and base forecasts on expected states. One of the concerns expressed for the present system of evaluating energy reduction progress is the susceptibility of energy use to noncontrollable weather conditions. The strong relative influence of cooling degree days on electricity use has been shown. Although a definite factor of use, its influence would be seen in a comparison between months of differing temperatures. Comparison would be enhanced by accounting for a difference in such noncontrollable factors. A review of the monthly electricity use and weather summaries in parts A and B of Appendices A-M illustrate definite patterns.

NRMC Great Lakes shows a specific example of the occurrences of unusual weather variations. The average temperature in January 1977 was 15.5 degrees lower than the same month in the FY 75 baseline. A corresponding increase of 519 heating degree days (44.7%) in FY 77 is then seen. Comparing just the peak cooling degree days, disregarding the month of occurrence, also shows an increase of 38 cooling degree days, almost 10% greater, in FY 77. A comparison of energy uses would certainly be influenced by these noncontrollable factors and somewhat distort an appraisal of energy conservation progress. FY 75 seems to have had a milder winter at almost every one of the sample

sites. The total group summary also reflects this fact. The evaluator needs a means of comparing uses that allows consideration of such effects. By basing its forecasts on historical trends and patterns, the time series model provides a standardized, and perhaps more meaningful, basis of comparison.

### 1. Testing For Time Series

Autocorrelation is used to describe the association or mutual dependence between values of the time series at different time periods. It relates a series for different time lags. A pattern in a plot of residuals may imply autocorrelation. One statistical test for the existence of autocorrelation is the Durbin-Watson, or D-W test. The Durbin-Watson distribution and tabled values are shown in Part D of Appendix P. Upper and lower D-W values of  $D-W(u)$  and  $D-W(l)$  are read for the appropriate number of independent variables ( $k$ ) and sample size ( $n$ ). The distribution curve, symmetrical around 2.0, is divided into five intervals: (1) less than  $D-W(l)$ , (2) between  $D-W(l)$  and  $D-W(u)$ , (3) between  $D-W(u)$  and  $4 - D-W(u)$ , (4) between  $4 - D-W(u)$  and  $4 - D-W(l)$ , and (5) more than  $4 - D-W(l)$ . If the D-W value is in interval (1) or (5), it is likely that autocorrelation is present. The test is inconclusive if the test value is in intervals (2) or (4).

The D-W test value for each sample is shown in part C of Appendices A-H. For 4 independent variables and 84 observations,  $D-W(l)=1.49$  and  $D-W(u)=1.68$ . Thus, for this study, if the D-W statistic is between 1.49 and 1.68, it would be concluded that there is no autocorrelation and time series modeling would not be indicated. Camp Lejeune was the only activity in the no autocorrelation interval; San Diego data proved inconclusive. All others activities indicated definite autocorrelation.

## 2. Concepts of Time Series Analysis

In this section, the basic concepts needed to understand the basic premises of time series analysis before application to modeling techniques will be presented.

The general form of the regression model was established as,

$$Y = b_0 + b_1 X_1 + b_2 X_2 + \dots + b_k X_k + \text{error}(e)$$

A similar concept in time series analysis is autoregression which relates past values of a dependent variable to itself, i.e., auto(self) regression. The general form of the equation would then be,

$$Y = b_0 + b_1 Y(t-1) + b_2 Y(t-2) + \dots + b_k Y(t-k) + e$$

A time lag is the time interval offsetting the variable being forecast. The term  $Y(t-2)$  indicates a time lag of 2 from  $Y(t)$ . Weather data would have a time lag of 12 months, indicating a 12 month repeating pattern.

Autoregression differs from regression in that the residuals of the independent time series variables, i.e.,  $Y(t-1)$ ,  $Y(t-2)$ , etc., usually depend on each other. The number of independent variables to include in a time series is more difficult to determine in autoregression.

Autocorrelation coefficients (ACF) can be computed as an indication of how successive values of the same variable relate to each other. They are also useful in determining whether data are random, stationary (oscillate around a constant mean), the level at which data becomes stationary, data seasonality, and the length of seasonality. Tests similar to those shown for regression analysis can be applied to ACFs to determine characteristics. The ACF in random data have a sampling distribution that can be approximated by a normal curve with mean zero and standard

approximated by a normal curve with mean zero and standard deviation of  $\sqrt{n}$ . Thus, residuals are not considered random if less than 95% of the ACFs are within 2 standard deviations of the mean.

The characteristic of stationarity can also be seen by analysis of ACF. Stationarity means there is no growth or decline in the data, i.e., data fluctuates around a constant, horizontal mean. Electricity use data will be expected to be nonstationary, hopefully decreasing. Weather, however, should be relatively stationary. ACF of stationary data drops to zero after two or three time lags, whereas ACF of nonstationary data will be significantly different from zero for several time periods, exhibiting a trend with increasing time lags. Removal of nonstationarity is necessary to eliminate the effects of a trend in the ACFs before proceeding in time series analysis. This is achieved by a method of differencing. A new series is created by subtracting successive values and using those differences as a new series. The order of differencing is determined by the number of applications before data drops to zero after two or three time lags. Generally, real data will not require more than first or second order differencing.

Normally, a moving average refers to a continuing, or moving, process of computing an average for a set of observations, adding a new observation while excluding the oldest to yield a new average. As applied in this context, moving average indicates a process to isolate data not possible by autoregression models. Instead of basing its forecasts on past values of a variable, the moving average bases its forecast on a linear combination of past estimated errors. A combination of the the two methods to make a single ARMA model is a powerful tool. But, it took third generation computers to make ARMA models applicable on an operational level.

Partial autocorrelations (PACF) are useful in identification of an appropriate ARMA model. PACF is defined as the last autoregressive term of an AR model. For an  $m$  order, or AR( $m$ ), model, only up to  $m$  terms will be statistically different from zero; further terms will not.

Seasonality, defined as a pattern that repeats itself over a fixed interval must be accounted for in time series analysis. Weather factors such as average temperature, heating degree days, and cooling degree days would be seasonal. Seasonality would be detected in an analysis of ACF by a pattern of high values emerging from one period to the next. Weather would be expected to show a 12 month seasonal pattern. A combination of seasonality and trend growths make autocorrelation patterns difficult to determine. Data must be made stationary before seasonality can be easily determined.

Similar to regression models, time series models use the sum of the squared errors (SS) and MSE in determining how well a curve fits the data. Since data points are 'lost' during differencing and time lag calculations, the effective sample size decreases.

## **E. TIME SERIES MODELING TECHNIQUES**

Autoregressive (AR) models were first introduced in 1926. Moving average (MA) models were later developed in 1937. ARMA models did not begin their evolution until 1938. Since then, extensive work has been done to develop efficient procedures and extend results to include seasonal time series. In 1970, George Box and Gwilym Jenkins introduced a comprehensive method of modeling univariate time series. The Box-Jenkins method has become synonymous with general ARMA processes applied to time series analysis, forecasting, and control. [Ref. 11] A schematic representation of their

approach is shown in Figure 5 The Box-Jenkins method will be the general basis of the methodology to be presented in this section. However, it will be modified somewhat to accommodate effective implementation within operational command levels of DON. Models of electricity use per square foot will be developed for the thirteen samples with a discussion of results highlighting important concepts and results.

Figure 3.4 Schematic Representation of the Box-Jenkins Approach

## 1. Phase I: Identification

A specific ARMA model from a general class of ARMA processes is initially selected for computation and evaluation. Selection of a model should normally be based on stationary data, necessitating application of differencing methods prior to model identification. However, some software packages, such as MINITAB, are capable of simultaneous differencing and ARMA processing. The methodology used herein will assume prior or simultaneous differencing.

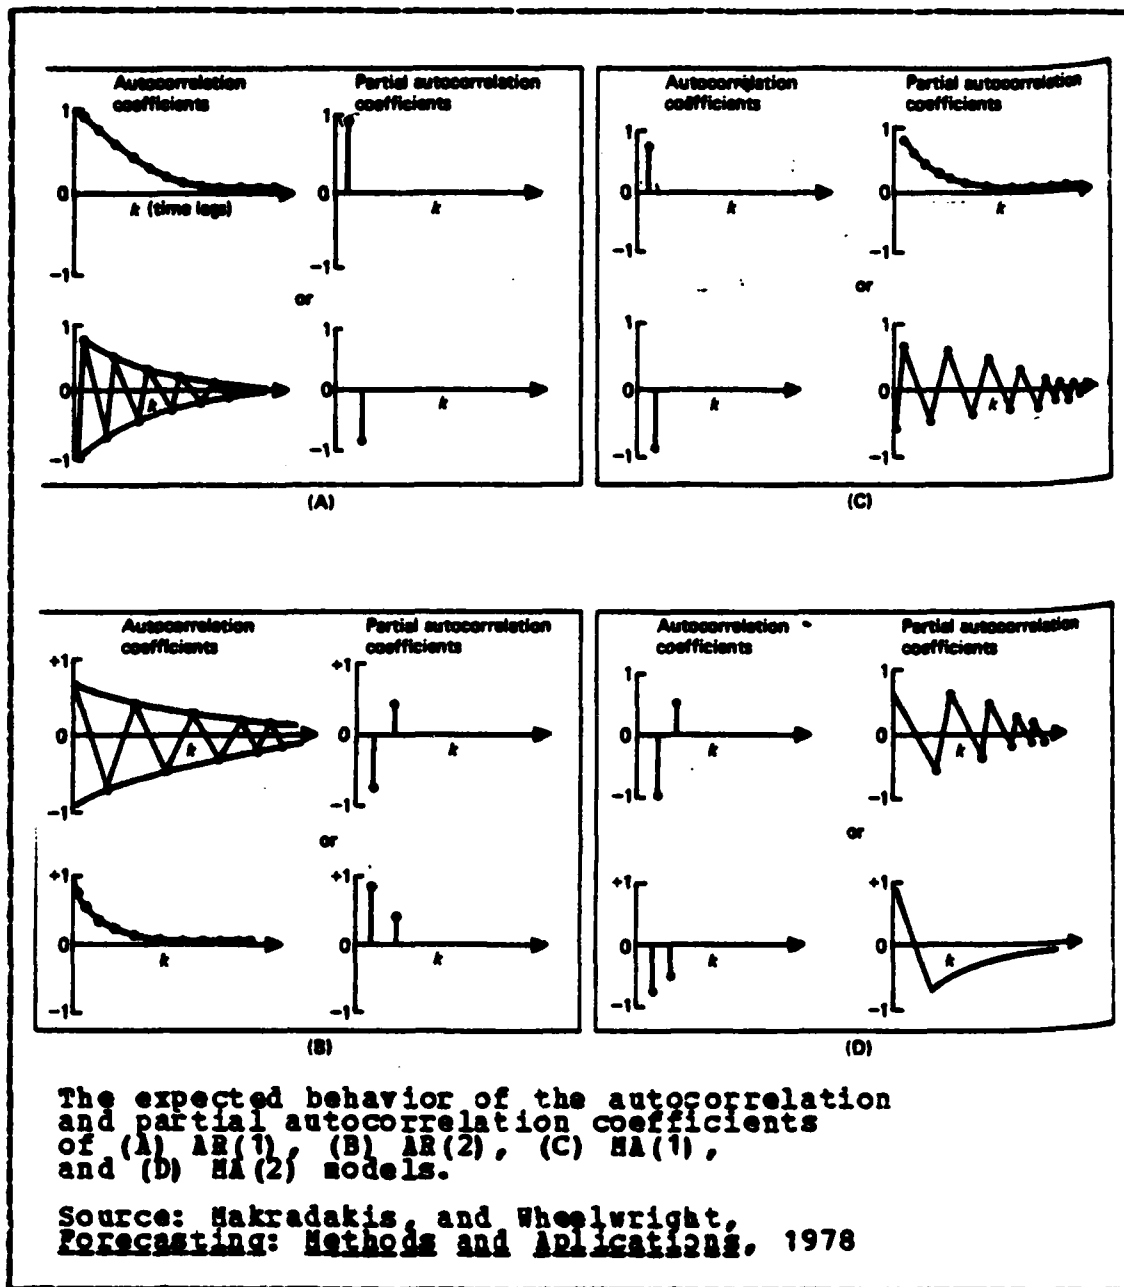

The general notation of a model is  $AR(p)I(d)MA(q)$ , or simply  $ARIMA(p\ d\ q)$ , where  $p$ ,  $d$ ,  $q$  represent the orders of autoregressive, differencing, and moving average processes. A similar notation for a model with seasonality considerations will be  $ARIMA(p\ d\ q)(P\ D\ Q)S=12$ , where the upper case letters have identical meaning as the lower case letters except for their application to seasonal orders.  $S$  is the length of the seasonal period of time, which will be defined as 12 months in this thesis.

There are various ways to estimate the initial values of orders. Such methods can be time consuming, technical, and laborious. Visual analysis, however, can also be effective and will be applied here. Identifying the order of AR process can be done by examination of the PACF plots. It will be recalled that the PACF is defined as the last significant term of an AR model. A sharp drop from a significant value to a nonsignificant value after  $p$  time lags would indicate the order of the AR process. An exponential decay from a high initial magnitude for increasing time lags would indicate an MA process instead. Before making a final first estimate of  $p$ , it must be considered that prior

differencing would normally have been done. If not, the nonstationarity effects of the data may also be included. A combination of trend and seasonality may be difficult to separate from the observed PACF patterns. Seasonality can be seen in the 12 month recurring pattern in PACF. In the observation of monthly energy use of the total study group, a trend of use can be seen after FY 79. Differencing, usually a first order process, would be necessary. The PACF plot shows 4 significant values before dropping to an insignificant value. A value of  $p=4$  is suggested. A basic premise of the Box-Jenkins approach is that of parsimony, or selection of the least number of parameters. Noting the proximity of the fourth value to the critical  $2/\sqrt{n}$  point, or .214, and the possible influences of seasonality and trend would suggest a lower number might be used, say  $p=2$ .

An examination of the ACF plot should specify an AR model or indicate the order of the MA process. The behavior of ACF is just the opposite of PACF. An exponential decay for increasing time lags indicate an AR process; a drop to zero after  $q$  time lags indicates an MA process of the order of significant points before a drop to zero. Figure 6 demonstrates differences in behavior of particular AR and MA models. The ACF plot for the total study group shows 2 significant values before the high initial magnitude drops to zero. A value of  $q=2$  is indicated.

Using approximately the same reasoning process for the seasonality effects, i.e., values for time lag of about 12, would indicate  $P=1$ . It is difficult to separate seasonal trend from normal trend. An initial estimate of  $D=0$ , assuming the observed growth is all normal. The seasonal pattern in ACF shows an exponential decay for 12 month lag, and therefore a seasonal AR process is indicated, i.e.,  $Q=0$ .

**Figure 3.5 Autocorrelation and Partial Autocorrelation Functions**

The final tentative model then would be ARIMA (2 1 2) (1 0 0) S=12. It must be stressed that this is a

tentative model. It may or may not be accurate for a variety of reasons, such as the existence of a noise level lowering or raising the theoretical values of ACF or PACF, or the unknown variation due to randomness. The identification process is not mechanical; human judgment plays a strong role. The final model for the study group, based on minimum MSE with no significant values of residual ACF was found to be ARIMA (2 1 2) (1 0 1) S=12. The trial-and-error approach required several iterations before the 'best' model was determined.

As a means of providing a guideline for model identification, the following summary of the procedure used above is provided:

1. Review the data. Visual observations of seasonality and trends will assist coming estimations.
2. Obtain a stationary series. If possible, this should be done next. However, if software capabilities allow, this can be included within step 3.
3. Examine the remaining correlations, i.e., those that do not drop off to zero, to determine the order of AR, MA, or ARMA processes. Figure 6 show the expected behavior of ACF and PACF for AR(1), AR(2), MA(1), and MA(2) models that may aid in determination of order.
4. Identify seasonality effects. A repeat of steps 1-4 procedures, looking at the ACF and PACF at the seasonal time intervals. Intervals may not always be exactly 12, allowing for weather variations to compress or expand the actual interval.

## 2. Phase II: Estimation and Testing

Estimation of parameters, according to the Box-Jenkins approach, is the next step of the process. The coefficients of the underlying mathematical equations would

be specified to give a minimum value of MSE. The parameters would then be entered into the computer for computing diagnostic information. Not all software packages require parameter specification as input, however. MINITAB, for example, requires only an ARIMA specification, such as ARIMA (2 1 2) (1 0 1) S=12, for a seasonal model, or simply ARIMA (2 1 2) if the model is not seasonal. Other software packages, such as IDA, do require parameter specification. Such specification requires a mathematical understanding of the underlying equations of the model which is beyond the scope of this paper, and would be difficult to apply at the operational command level. Thus, it will be assumed here that parameter selection is not required, or that textbooks for the basic level of mathematical theory necessary to estimate the parameters, are available. This will enable a more general presentation of methodology. The simplicity of the methodology is important to any expected application within DOD or DON. The MINITAB software package simplifies the entire approach to model building so that a thorough treatment of the identification process is not even entirely necessary. Arbitrary models can be selected, entered, and computed in a matter of seconds. The penalty for being too arbitrary is that the user loses direction. An improper initial model selection resulted in misdirection several times during the development of the models for these samples.

Diagnostic checking of the estimated model is based on two checkpoints. The first check is to see whether the ACF of residuals exhibit randomness, i.e., 95% of the ACF points should lie within 2 standard deviations of the mean. The second check is that MSE is minimal. The rigidity in applying these criteria is similar to that discussed for regression models. The existence of one or two points

outside the confidence limits may be unacceptable in view of the effort required to modify the model. The magnitude of MSE may be small enough that a change in MSE by a more complex model would be of little consequence, or the relative ease of improving the ARIMA model for even a slight improvement might justify additional complexity.

In fitting the models for the samples of this study, three models were chosen for illustrative inclusion in Part D of Appendices A-M. The first model attempted may or may not have been the model indicated during the identification phase. A second model is shown for comparative purposes as attempts to improve the ACF pattern and MSE magnitude were made. The final model shown was used to forecast.

NRMC Jacksonville can be used as an illustration. An initial model was developed on observations from ACF/PACF plots that, (1) PACF dropped to 0 after 1 time lag, (2) ACF fell to zero after 3 time lags, (3) visual survey of MBTU/SF showed nonstationarity, (4) seasonal PACF did not drop to 0 until after two seasonal time lags, (5) ACF showed some trend, and (6) ACF fell to 0 after 1 time lag. Thus an initial model of ARIMA (1 1 3) (1 1 2) S=12 was attempted. Only one ACF point was significant; an MSE of 11.518 was determined. Simplifying the model to an ARIMA (1 1 2) (1 1 1) S=12 only decreased the significance of the first point and increased an insignificant point to significance. MSE increased to 12.063. At this point, either model would be acceptable, although the second model would be preferable. The second model suggests that a seasonal adjustment might improve the model, since the significant points were at t-24, and t-37. The model ARIMA (1 1 3) (1 0 2) S=12 did improve the ACF pattern and had an MSE of 11.121. It was accordingly determined as the 'best' model for forecasting at that activity.

### 3. Phase III: Forecasting

The summary statistics for the NRMC Jacksonville ARIMA (1 1 3) (1 0 2) S=12 model display a 12 month forecast of electricity use (FY 82). The forecast, based on the historical patterns and trends of use at NRMC Jacksonville is its expected electricity use in FY 82. The fitted model and forecasted values are shown in Part F of Appendices A-M. The resultant curve is really not such easier to visually interpret than the initial electricity use curves, except that forecasted FY 82 values have been added. An imposed plot of actual FY 82 use and/or baseline use might afford a useful and easy means for comparing actual FY 82 use.

Since the basic intent of energy measurement is to compare change from the baseline, it would be useful to interpret the model results in this same light. With the fitted model values still in the computer memory bank, it is fairly simple to regress the fitted values against time to develop a curve of trend. This provides a very clear interpretation of the time model affording calculations of percentages of change anywhere along the curve.

Part E of Appendices A-M provide a statistical summary of such a regression. The value of these statistics is minimal relative to the normal information given by regression. Normal interpretation of  $R^2$  and MSE are relatively meaningless in this application. But the curve does represent the best fit of a straight line through the fitted data points giving the trend of forecasted use. The trend line is shown in Part F of these Appendices.

A composite curve of actual use, fitted model, and trend of use is shown in Part G. The fitted curve of expected values provides a benchmark for comparison of actual use. The May 1978 spike in energy use previously discussed could now be more effectively evaluated. The

model curve indicates expected use. In fact, a fairly large increase from April would have been expected. The magnitude of the difference between expected and actual use be a potential target of investigation.

The FY 82 forecast has been drawn with 95% confidence limits, calling attention to the fact that the model curve is an expected value estimate of a 'true' function. There will be allowances for error. A confidence interval around the entire fitted curve of the model could have also been plotted. However, the loss of clarity resulting from the extra lines would not be justifiable. The forecast interval will have control system applications to be discussed in Chapter V.

A numerical summary of actual use, model forecasts, and trend projections for each sample is provided as Appendix N. At the end of each activity summary is a comparison of particular use with the baseline. The first column is the actual use reported and resultant change. The FY 81 target was -12%. The second column shows the forecast values for FY 81 and FY 82 with the percent change from FY 75. The final column is similar to column 2 but is based on trend comparisons. For the study group, for example, a 9.3% increase was forecasted for FY 81 by the time series model. A 10.3% increase was actually reported. However, the trend of use, 10.8% might at least indicate the rate of growth from FY 75 had slowed. There are numerous applications of these results, such as relative comparisons with other activities, comparison of activities in a particular weather zone, comparisons by size, patient occupancy, or facility age, that could be meaningful to an evaluator. An extension of trend identification could be to use different origins. For example, NRMC Orlando showed a greater trend of increase after FY 79. Such trend would have been averaged out over

the FY 75 - FY 82 data period. Regression of model values against time from FY 79 would show the trend of use from FY 79. The effects of a particular event, such as facility expansion or technological innovation, could then be isolated for meaningful evaluation.

#### IV. USE CATEGORY MODELS OF ELECTRICITY USE

Models of electricity use by category codes using regression techniques will be examined in this chapter. The development of coefficients of use for various categories of use, and their application in a modular baselines, will be demonstrated. The average monthly electricity use and buildings relating to that use for FY 75 for the 12 NRHC sample will be the basis of this study.

The previously discussed problems of changing missions, growth of electronic technology, and the corresponding building use changes to accommodate such changes serve to confuse, if not distort, the basis of energy reduction comparisons. If the purpose of measuring electricity use on a per square foot basis is only to prorate energy use for different size bases, it would seem unreasonable then, in light of the technological growth, to expect a 20% reduction by FY 85. If, on the other hand, the goal of measurement is to effect an increased efficiency of use, there must be a means of making allowances for the changes in mission and building uses.

Conversion of a low energy intensity warehouse for installation of a greater energy intensive aviation trainer was discussed in Chapter II as a distortion of meaningful energy usage comparisons. Capital improvements for insulation, lighting, etc., may have been highly effective in raising the energy efficiency of the warehouse. However, the trainer equipment installation would probably dominate use such that the total energy use would be increased. The value of comparing the energy efficiency progress has been lost.

In other cases, building use has been downgraded as more modern, accommodating facilities have been constructed. Rather than demolish an inherently energy inefficient building, a common tactic is to use the building for a different purpose, such as office space, warehouse/storage space, or recreational space. The selection of these particular uses is common inasmuch as priority of limited construction funds is usually lower than mission essential project funding. As a result, there is usually a backlog of such projects awaiting funding. Vacated buildings easily become a target for innovative, resourceful managers to ease particular requirements. In fact, this may be a very practical action with large benefits to morale. The effect on energy use comparisons is less beneficial. The new facility may have much greater energy efficiency. The activity's overall use per square foot may improve. The converted facility may also have a lower energy use per square foot but not necessarily as a result of any efficiency improvements, though. As would be noted by TEM advocates, energy would be wasted by the building's inefficiency even though end use would have decreased.

Only if a building's functional use remained generally constant during the period of comparison can any valid conclusions be made at present. The problem is in providing a basis of comparison when changes have occurred. A means of effecting relatively simple changes in the baseline to reflect the changed uses would be useful.

A modular construction of the baseline would offer such a means of adjustment. In the case of the warehouse-to-trainer conversion, a standard use value for warehouses could be deducted from the baseline use, and be replaced by a standard use value for a trainer facility.

An example of the opposite effect would be the conversion of a World War II vintage Butler building from an industrial shops area to a recreation center. The conversion might have taken place as the result of a new Public Works facility which had expanded to meet an increased activity mission. The Butler building with its characteristic thin, sheet metal outer walls and concrete floors would be highly energy inefficient. The replacement of the industrial equipment with recreational equipment would certainly lower the energy use. Adjustment of the baseline by replacing an FY 75 standard industrial use with a personnel support use standard would allow a valid comparison of the change. At present, however, the energy baselines are fairly rigid and rarely adjusted.

#### A. DATA CONSIDERATIONS

The data necessary to support a development of such standard uses is not readily available at present. The NAVFAC P-164, Detailed Inventory of Naval Shore Activities, was examined as a possible source of data. The P-164 lists all the buildings at every location throughout the Naval Shore Establishment by category code, year of construction, floor area, dimensions, cost data, and various other details of inventory data. Changes, such as would occur by new construction of facilities, alterations, demolitions, or redesignated uses, are required to be done on a timely basis. However, this reporting function generally has low activity priority. Reviews are sporadic; submissions may be several years out of date.

Activities were originally tasked with developing their own baseline areas. Then, any changes to be made were requested via official channels. It is therefore difficult to reconstruct the baseline anywhere beyond the activity

level. The areas actually shown in the P-164 may be assigned to a particular station, but its energy use accountable to another command. Thus, identifying a building's existence in FY 75 by the P-164 does not necessarily mean that it has been included in the baseline area of the plant property record holder. Family housing, for example, is listed on the plant property records of the applicable activities but energy use is reported to the Housing Management Centers.

The functional use of a building or area within a building is identified in the P-164 by a 5 digit use code. Such a code is not necessarily related to its energy use. For example, 610 as the first three digits of the category code identifies an administrative use. 610-10 further identifies office spaces, while 610-20 identifies data processing centers-two very different types of energy use. Living spaces are broken down between categories of officer (724) and enlisted (721). Further distinction is made by paygrade groups, such as E1-E4 (724-11) and O3 and above (724-12). The differences in these category codes reflect only construction criteria, although energy use characteristics would be similar. In the NRNC sample there were over 80 significant category codes that would be considered as contributors to energy use. It was felt that a grouping by category codes of energy use characteristics vice functional use code would thus be more feasible. The degree of refinement within the groupings would be a matter of practicality. Subcategories of use by construction type and/or year would be specific possibilities.

Thus, P-164 data alone is insufficient to develop accurate area baselines because of its lack of timeliness and lack of energy reporting detail. The P-164 is the most complete and widely available data source available and was

thus used for purposes of this study. A more refined data base would be needed to provide the accuracy desired in an actual application.

## B. METHODOLOGY

The general approach taken was to test whether average monthly electricity use (MBTU) could be forecast as a function of the component areas for types of functional uses of total floor space. The derived coefficients of a regression model used for such a forecast being in units of MBTU/SP, suggest that the coefficients will be an average, or expected value, of use for the selected categories. Interpretation of the coefficients as standard values would then have useful applications where the energy use of particular areas are being evaluated.

The selection of the categories of functional use would be made relative to the information desired. It must be recognized that the coefficients of a regression model are relative to the applied context. The coefficients may change as variables, i.e., categories of use, are added or deleted, or input data is changed. Thus, the value of a derived coefficient will depend on the input data and what other variables are present. The implications of this recognition limit use to a particular time frame, to a particular activity, or to a particular group of activities, dependent upon the context of application.

The average monthly electricity use in FY 75 was selected as the dependent variable to enable a determination of standards of use in the baseline year. This meant use of only 12 data points for the total sample group. The consequence of the small sample size was that the corresponding 12 degrees of freedom allowed a maximum of only ten use categories, allowing 2 degrees of freedom for statistical results.

The sample was accordingly sorted into ten major energy use categories using the following categories and criteria:

1. Mission. Hospital space, as a large portion of the baseline area, would be of major interest.
2. Labs. Outpatient clinics, dental clinics, as well as designated lab areas for which specialized equipment would be required. Full time occupancy would not be expected.
3. Personnel Living Spaces. Unaccompanied officer/enlisted personnel housing (UOPH/UEPH), regardless of paygrade of occupants, and temporary living facilities.
4. Maintenance/Industrial. Shops areas, including vehicle maintenance shops, utilizing a higher energy use per square foot by virtue of machinery and installed equipment.
5. Data Processing Centers.
6. Administrative. Offices, family services centers, and other areas providing spaces for performance of managerial, clerical and counseling functions.
7. Commercial Areas. Areas which involve commercial sales and support such as the various functions of the Navy Exchanges (barber/beauty shops, snack bars, retail stores) which would entail various operating hours and medium energy intensive equipment.
8. Morale and Welfare-Community Services. Areas which would have relatively few hours of use by groups of personnel, such as chapels, theaters, and child care centers, but would not involve unusual equipment support.
9. Morale and Welfare-Recreation. Bowling alleys, gymnasiums, and hobby centers which would have more regular hours of occupancy and would require some specialized equipment support.

10. Storage. Areas in which minimal equipment installation, low personnel occupancy, and minimum heating/cooling standards would be maintained continually. Subcategorization to reflect differences in temperature standards for storage of equipment vice medical supplies would be suggested.

The results of the 'full' 10 variable model are shown in Table 3. These results indicated that the standard use for a hospital space was only .0003 MBTU/SF. The t-tests, in fact, showed no significance in any of the individual variables. It was concluded, by use of the F test, that all coefficients were insignificant. The very high  $R^2$  value of .998 would be expected from the use of 10 variables and only 12 observations.

A stepwise regression was then attempted. It was determined that a three variable model using hospital space, storage, and maintenance/industrial categories would provide significant values for the resultant coefficients. Test results are shown in Table 4. The  $R^2$  value was still reasonable at .908.

### C. RESULTS

The results of this attempt to demonstrate model use for this sample were inconclusive overall. The full model was unable to provide any significant coefficients. The 'best' model, i.e., one which provided significant coefficients, could provide values for only three coefficients. These coefficients would only be relevant in the presence of the other two variables. That is, the standard use for the three categories could not be concluded to be the values seen, with the other categories assumed to be zero. One explanation is that the data base was too small to support a test for 10 categories of use; a smaller number of groupings

might yield better results. However, it was felt that further generalization of the groupings would have seriously detracted from the desired results. The derived coefficients would have been more general than practical.

Although the results were inconclusive, there is reason to believe that the proposed method merits further consideration. The results suggest that coefficients of use based on energy use categories could be developed by regression techniques. The apparent limits imposed by the size of the

data sample might impose certain limits. Although this study was limited to particular NRHCs, in an expansion of this method, coefficients of use for the general categories of storage, maintenance, commercial, etc., could be studied for a large sample.

The issue of accuracy can not be overlooked. The data base used in this study was recognized to be susceptible to various errors. Refinement of a data base for application to a large sample would be challenging. However, it must also be considered that even 'ball park' values might be of value. 'Standards of use', with only minimal accuracy, would still permit implementation of modular adjustments to baselines, or to any other comparison years. The basis of comparisons would be improved to at least some degree. It

is thus felt that the modular concept of adjustment and the use of regression models to develop standards of use warrants further consideration.

## V. SUMMARY AND CONCLUSIONS

Energy reduction is a very significant and necessary goal in today's environment. The cost of energy has risen from a relatively insignificant level to one of major consideration. The era of cheap energy has resulted in a multitude of energy inefficient buildings that will require varying degrees of modifications.

The trend of rapidly rising costs will keep a strong focus on economizing energy use. The Arab oil embargo of 1973 not only touched off an era of spiralling energy costs, but brought about a realization of the serious consequences of our strong dependence on oil. The vulnerability of national security and the economy to supply and price manipulations were clearly demonstrated by the actions of the OPEC cartel.

Government policies and actions along with the normal market forces of supply and demand interactions would be expected to expand domestic oil supplies. These initiatives have also forced corporate and private energy users to examine the large amounts of energy being used, and wasted, as well as to search for alternate energy sources. Executive Order 12003 was issued to force the federal government-the largest single energy user-to reduce its energy use. It established the federal energy goals at a 20% reduction from FY 75 to FY 85, and a 35% reduction by FY 2000. The goals appear ominous in view of the failure to achieve yearly target levels though FY 81. A greater level of capital investment will be needed just to meet the 2% per year expected rate of reduction, and an even greater rate of investment to achieve the FY 85 overall goal. With the

limited availability of capital investment funds, effectiveness of investment becomes a vital issue. It is an issue which requires a full recognition of how energy is being used, identification of areas of greatest reduction potential, and the cost effectiveness of implementation actions.

This thesis questioned the ability of the present Defense Energy Information System (DEIS II) to provide the necessary valid comparisons of energy use as a means of identifying targets of reduction potential and evaluating the effectiveness of corrective actions. Distortions caused by noncontrollable factors, such as weather, and the particular functional uses and changes in use of buildings were shown to impair the ability of a decisionmaker to correctly evaluate reported energy uses. Electricity use at 12 Naval Regional Medical Centers was specifically studied. Regression and time series methodologies were demonstrated as means of improving the effectiveness of evaluating energy uses.

Regression models were shown to be a means of explaining a system output by means of particular stimuli, or predictor, variables. The techniques of selecting variables, evaluating the appropriateness of the stimuli, and interpreting the results were applied to weather effects on energy use. Weather factors of average temperature, heating degree days, cooling degree days, and precipitation (rainfall equivalent) were specifically studied. While weather would not be a good sole predictor of electricity use, the relative significance of various factors could be studied. Knowing the effects of weather on electricity use would in turn allow the decisionmaker to assess action to minimize such effects. Cooling degree days was seen to have a strong relative impact on energy use. Identifying this

factor and the relative magnitude of its effects would suggest certain actions to a decisionmaker. Load balancing, increased insulation, and/or use restrictions might be accordingly evaluated for implementation. A comparison of a similar regression model after implementation of corrective action would provide a further means of evaluation.

In an expanded model, weather variables would be only one type of variable. Hours of occupancy, ages of the buildings, air conditioning capacity, etc., might be other variables of interest. The results of the expanded model would be beneficial in further evaluation of system interrelationships, and relative significance among selected variables.

Time series models were shown to be a less technically oriented method of forecasting. This type of model uses historical patterns and trends in forecasting expected system outputs. Plots of the four previously cited weather factors were seen to have variations in expected levels. Of particular concern was the higher average temperatures and corresponding decrease in heating degree days experienced at most of the 12 activities during the winter months of the baseline year. Under the DEIS II system, the various effects of differing weather conditions are also being measured in the percentage of change calculations. Weather would be only one of several possible influences that could be reflected in such energy use comparisons. The time series model, in forecasting expected values, provides a more standardized basis of comparison.

The forecasts of expected values facilitate identification of variations. Comparison of a current use with an expected value, or expected value adjusted to a reduction target, might show a large variation which should be investigated promptly for corrective action. The present

system, with its potential of distortion, would only show a relative change rather than a variation from expected value. The decisionmaker can not readily assess the impact of unusual conditions on the observed change, nor assess whether a favorable change was in fact favorable. Similarly, an unfavorable variation might not be identified for a period of time due to particular conditions resulting in a lower energy use, thereby missing an opportunity for reduction.

Regression was further applied to a time series model to develop a linear trend of use. This method would allow an identification of a long term average rate of change. Although the trend of use between FY 75 through FY 82 projections was developed, the method is applicable over any time period, or from any reference point.

The results of the time series forecasts and trend projections for FY 81 are compared to actual reported uses in Table 5. It can be seen that the forecasted uses and actual uses are relatively close. The forecasted values, however, have been shown to be less subject to distortion and a more reasonable basis of comparison. Comparisons within Table 5 give a more appreciable picture of progress in meeting an established target. For example, NRMC Corpus Christi reported a 1.2% reduction from FY 75 use. Its expected use would have shown a 0.6% decrease. Thus, the activity showed a favorable variation from expected use of 0.6%. Comparison of reported results with a 1.0% trend of increase shows a 2.2% favorable variation from the long term trend of use. A similar comparison for NRMC Orlando shows a 15% unfavorable variation from expected FY 81 use, and almost no difference from the trend of increase. Comparisons can be made at the activity level or at a higher echelon of command. The total group, as might be viewed by

its major claimant, showed a 1% unfavorable variation from expected use but a 0.5% favorable variation from trend. Since these comparisons are less influenced by unusual variations of operations, weather, etc., they provide a more standard basis of comparison.

A final regression model was attempted to explain average monthly electricity use by the functional categories of use for building areas. The categories of functional use were established by identifying particular electricity use characteristics. The coefficients of the proposed model, in units of MBTU/KSF, can be interpreted as a standard of use for its corresponding category variable. It was shown that changes in a building use, or uses of areas within a building, would alter the normal energy use per square foot, thus distorting further comparison to the baseline year. By means of a modular concept of the baseline, the baseline could be adjusted by replacement of a standard use of the former designation with a standard use value of the new designation. The results of a ten variable (energy category) model were found to be inconclusive by virtue of the insignificance of the coefficients. The small size of the data base was inadequate to support the development of the necessary ten significant coefficients. The data base was capable of explaining use by three significant predictors, however. Concern for the accuracy of the data, which was based on often outdated, inaccurate property record submissions, was expressed. Further consideration of the model and modular baseline concept was felt to be justifiable, however, on the basis that even a small improvement of the present system by use of 'ball park' estimates would be useful.

The proposed methods of energy use models all have applications, either individually or in combination, in

\*Electricity use in MBTU/KSF

developing an energy use control system. In general, there is no real control system within DEIS II. Targets are established by end-use restrictions based on on FY 75 use. Baseline use, susceptible to the various influences of the

conditions at that time, may not be a valid comparison for uses without those similar influences. Variation, if identified, may actually not be variation at all; if unidentified, the causes of unfavorable variation may go uncorrected for undesirable lengths of time.

Regression models using explanatory variables such as connected load factors and weather would be used to forecast expected use. A comparison of expected use with target use would indicate a degree of desired change. Analysis of the coefficients of the model would suggest opportunities for achieving desired reductions. Comparison of actual use with forecasted expected use would identify variation that should be investigated for corrective action.

Time series models would be of similar use in a control system. Targets could be developed for expected use. A comparison of actual use with target use would also identify variation for possible investigation. A particular advantage of the time series model is its ability to forecast use over a period of time. An imposed plot of actual use provides an easy, visual means of display. In contrast, regression models dependent on observed inputs such as weather would be less convenient. Expected values would require individual calculation before a plot comparison with actual use could be made. The application of regression techniques to a time series model to develop a trend of use provides a further means of useful comparison.

Application of reduction targets to the forecasts of use would be a means of establishing control targets. In Table 5, for example, a control target of a 5% reduction in expected FY 81 electricity use might have been established. Variation from that level could be used in identification of possible investigation. Similar application of targets to trend of use forecasts could be made.

A regression model based on categories of use provides at least a potential for a control system. Comparison of actual use per square foot with a standard of use would be useful in identifying the energy efficiency of a building. This method, however, would require a great deal of effort to implement. Measurement of actual use in itself is a current problem with the necessity for submetering. Meters to provide such measurement are not in general use, at least not yet, within the shore establishment. However, the cost effectiveness of such meter uses has increased rapidly and should be in greater use in the near future.

The refinement of data necessary to develop accurate standards of use would be a further obstacle to implementation of this type of model. The use of 'ball park' estimates could be of limited application in modular adjustments to the baseline. It is not known whether engineering estimates could provide more accurate or more cost effective standards.

The choice of models would depend upon the decisionmaker's needs and capabilities. Regression models of technical factors would appear to be of greatest benefit to engineering staffs such as the NAVFAC Engineering Field Divisions. Such models would provide the technical information needed to evaluate the value of particular projects. Their technical review function for ECIP and ETAP projects could be facilitated by such models. Their access to a broad range of data would be beneficial to development of the models. The variety of technical expertise readily available would also be significant in developing and applying such models.

Time series models would appear to represent the greatest general value to an activity or upper echelon command for forecasting energy use for budget purposes as

well as for control systems. Models could be developed for, or by, bases depending on the availability of computers and appropriate software.

It is highly recommended that the implementation of energy use models be pursued within the energy management program of the Naval Shore establishment. Energy use models have been shown to be valuable tools in the measurement and evaluation phases of DEIS II.
