ABSTRACT

A Universal Interface Device (UID) was constructed for the TRS-80 Model I microcomputer that enables it to perform a wide variety of digital and analog data acquisition and control functions within the Department of Aeronautics. The system was tested and validated for low frequency data acquisition and control in a wind tunnel experiment and higher frequency applications were predicted with the development of additional software.

The UID consists of a collection of off the shelf and author designed components assembled within a common enclosure to provide eight channels of analog to digital input, a single channel of digital to analog output, eight bit TTL level digital to digital input and output, and eight power relay outputs all under software control of the host microcomputer.

Applications software, calibration tables, and a validation experiment were prepared and included within the appendices. The UID produced results within one percent of manual observations.

I. INTRODUCTION

A. BACKGROUND

The age of the microprocessor (U-P) is upon us. The relentless and geometrically accelerating advances in U-P technology are blurring the distinction between large and small computer with quantum leaps in memory capacity and speed of execution. Coincident with these developments has been the increasing application of the U-P first as a purely high cost scientific and research tool and now in low cost consumer electronics and the video game and microcomputer explosions. The microcomputer is the obvious and so far ultimate application of the U-P and is now revolutionizing the workplace and home. It is not outrageous to predict that by the end of the decade, as technological advances continue and economies of scale lower unit prices, the microcomputer should be as common in the workplace as the typewriter and, in the home, as the television.

In regard to scientific data acquisition, the marriage of the microcomputer to the family of concurrently developed analog to digital (A/D) and digital to analog (D/A) integrated circuits has made low cost, easily implemented electronic data acquisition and control an accomplished fact. This paper describes one such application utilizing a TRS-80 Model I microcomputer

interfaced to a collection of commercially available and author designed circuits to provide a portable and universal data collection and automatic control station for the various test instruments located within the Department of Aeronautics at the Naval Postgraduate School (NPS).

B. DISCUSSION

The resulting hardware for the application under discussion has been named the Universal Interface Device (UID) and will be referred to by this name. The host microcomputer is a TRS-80 Model I manufactured by the Tandy Corporation, Fort Worth, Texas and hereafter referred to as TRS-80 and/or Model I. Other models of the TRS-80 are made but are not discussed in this paper. The UID consists of an eight channel analog to digital input port, an eight bit relay output port, an eight bit TTL (transistor-transistor logic) input port, an eight bit TTL output port, and a single digital to analog output port all housed within a common enclosure. Two commercially available, off the shelf devices, the Analog-80 and Interfacer-80, both manufactured by the Alpha Products Company, Woodhaven, New York were used to implement the analog input port, digital input port, and relay output ports. The analog output and digital output ports were constructed from scratch. Subsequent chapters

describe the TRS-80 microcomputer and its operation, the UID and its interface between microcomputer and the outside world, implementation of the combined system for both analog and digital steady state/low frequency I/O (input/output), suggested software routines for various applications, results of preliminary testing of the system, and conclusions and recommendations for further development.

The scope of this discussion assumes some familiarity with microcomputer architecture and digital electronics, but not necessarily a prior knowledge of the TRS-80 system in particular. A comprehensive bibliography is included to direct the user to appropriate topics for review or closer interest. The mastery of the interpreted BASIC high level language resident in the TRS-80 operating system should be a major goal of the user of the UID since this language allows a highly flexible real time interaction with the data acquisition and control process. While it is not possible for this paper to be a comprehensive manual on the BASIC language, suitable attention has been devoted to the subject to provide the user with concepts for developing custom software to drive the UID in a variety of applications. The bibliography references several sources of information for both BASIC and interfacing techniques. Other languages for the TRS-80 are available but not within the scope of this paper; however,

of note for future reference is the fact that the TRS-80 is capable of direct execution of Z80 machine code which would allow high frequency measurements. This application is left for a separate investigation.

The author's purpose is not only to provide an operating manual for the TRS-80/UID system but also stimulate interest and provide a core reference for extended applications of the UID. Thus, it would be an injustice to refer the user to the TRS-80 documentation as the sole source of information for operating the TRS-80 hardware, so there is appropriate attention devoted to describing the operation of the TRS-80, including experiences gained by the author, that are not in the instruction manuals. A certain amount of this is subjective; but, as the project has developed, the author has become highly impressed with the TRS-80 in view of the capabilities implemented, especially since it is generally regarded as a lightweight in professional circles. Of course, no official endorsement of the TRS-80 is intended, but to observe a hobby-grade microcomputer perform as this one has inspired the imagination for the capabilities of those of loftier reputation.

The UID was designed with expansion in mind with both the physical room for additional circuitry and appropriate documentation to allow its future use as a building block for an even more ambitious data acquisition and control station.

II. SYSTEM DESCRIPTION

This section describes the physical and operational characteristics of the TRS-80 Model I and the UID. Where applicable, the various reference manuals and technical documentation listed in the bibliography are cited and will provide additional information beyond the scope of the discussion.

A. TRS-80 MODEL I MICROCOMPUTER

The TRS-80 Model I, first introduced in 1977 by the Tandy Corporation, is a Zilog Z80 microprocessor based microcomputer utilizing an 8 bit word, capable of direct memory access of 64K (kilobytes) of memory, and addressing 256 external ports. It has capacity for up to four 5.25" floppy disk drives, dual cassette drives, a parallel interfaced printer, and a serial RS-232 standard interface in its most standard and complete configuration. The above described peripherals are entirely optional. Of modular design, its main components such as keyboard, CRT monitor, and its various peripherals are separately enclosed and connected to one another by means of ribbon and other multiconductor cables. Resident in the first 16K of memory is the BASIC interpreter in ROM (Read Only Memory) which gives the TRS-80 its built in high level language; the remaining 48K is RAM (Random Access Memory) and is

accessible by the user for either program or data storage. The Model I is frequently referred to in terms of its memory capacity in 16K increments with the first 16K omitted since it is the ROM interpreter and transparent to the user. Thus, the maximum capacity is referred to as 48K even though the Z80 addresses 64K and technically that is what is actually in use. The standard four disk drives are capable of a minimum of 275K of additional storage, and non-OEM (original equipment manufacturer) sources market drives with double density and/or dual heads with capacities extending up to 1M (megabyte) for a four drive installation and hard disk systems capable of up to 10M. The BASIC interpreter is called Radio Shack Level II BASIC and is a variation of Microsoft BASIC, a widely accepted dialect of the BASIC language. Level I BASIC, a distinctly limited subset of Level II BASIC, was also available on some models but is not sufficiently sophisticated for serious application. The standard DOS, the program that interfaces the Model I to its peripheral disk drives, is TRSDOS, now in version 2.3; and other DOS's are available from non-OEM sources.

The TRS-80 Model I is probably the most widely recognized and supported microcomputer in the western world to date. But problems, the most offensive of which were rectified, tarnished its reputation at an early stage and created a somewhat adverse opinion of it as a serious

contender in the business and scientific communities. As an example, early models used an economy keyboard that lacked a professional feel and had severe debounce problems. Likewise, as with many products in the highly competitive computer electronics industry, the hardware was placed on the market before adequate support, both software and service, was available all in the face of an aggressive advertising campaign. The early TRSDOS disk system had a number of bugs that caused great consternation among the first purchasers. Small businesses and professionals expecting instant computing power for the masses were greatly disappointed. Later editions of the Model I, however, corrected these problems with the result that, although identical in outward appearance, they operated almost like a completely different machine. This fact does not seem to be widely known outside the body of dedicated TRS-80 users. But there were other shortcomings, some intentional, that were not corrected including the use of corrosion-prone non-gold plated connectors in the cable assemblies, a non-standard 64 column monochrome CRT display, low resolution graphics capability, and the incompatibility with CP/M (CONTROL PROGRAM/MONITOR), the defacto standard microcomputer DOS for business applications [Ref. 1]. As a result, periodic cable disassembly and contact cleaning is necessary, high resolution graphics are not possible, and a great body of

professional software is unusable by the Model I by virtue of its incompatibility with CP/M.

However, limitations aside, the later versions of the Model I are quite capable in their own right; and, because of its mass marketing through the nationwide Radio Shack franchise, the Model I made the microcomputer available on a heretofore undreamed of scale. In contrast, Tandy envisioned the Model I as a strictly experimental product expecting to sell no more than 1000 units during the first year [Ref. 2]. By the end of 1980, however, when production of the Model I ceased due to Federal Communications Commission restrictions on the RFI (radio frequency interference) caused by its unshielded interconnecting cables, over 300,000 units had been sold [Ref. 3] with a multi-million dollar support industry supplying peripheral hardware, software; and two nationally circulated monthly magazines with circulation in excess of 110,000 and devoted exclusively to the TRS-80 were being published [Ref. 4]. Since 1980, the Model I has been replaced by the Model III, a single enclosure unit without the RFI problems of the unshielded Model I but essentially an improved packaging of its design. Although now out of production and obsolete in the face of new products, so much has been and is still being published about the TRS-80 Model I and both the manufacturer and ad hoc user groups encourage and support experimentation and creative applications of it, that it is an ideal platform

on which to base a project such as the UID. A TRS-80 Model I was available in the Department of Aeronautics for this project, as were many salvaged parts used in the construction of the UID. The TRS-80/UID system replaces obsolete and non-functioning data logging equipment in the Department and adds control capabilities not heretofore available with the older equipment. The following subsections describe the various modules which make up the TRS-80 Model I.

1. TRS-80 Model I Architecture

The heart of the TRS-80 Model I is the Zilog Z80 microprocessor which is an MOS technology LSI (large scale integration) device that is manufactured in a standard 40 pin DIP (dual in-line package). Ciarcia, Build Your Own Z80 Computer describes the internal architecture of the Z80 with its pin out which is repeated in Appendix A. The pin-out shows that the Z80 has single power connection, a single clock connection, 8 data lines, 16 address lines, and various control lines as described. The collection of data and address lines are termed the data bus and address bus respectively, and it follows that the 16 address lines can define $2^{16} = 65,536$ separate and distinct addresses. Likewise, the eight bits of data can be encoded into $2^8 = 256$ distinct values within each address. Each data and address line is referred to as a bit and is assigned a corresponding binary weighted value. Eight bits are defined

as a byte and $2^{10} = 1024$ is defined as a kilobyte or K. Thus $65,536 = 64 \times (2^{10}) = 64K$, and the Z80 is said to address 64K of on-line memory. The Z80 is also capable of addressing 256 external input or output devices, called ports, via the lower 8 address lines. Data in and out of the Z80 is controlled by pins 19 to 22 which serve to gate the data from or to memory or port addresses [Ref. 5].

The arithmetic operations which the Z80 is able to perform are confined to single and a limited subset of double byte binary integer addition, subtraction, and logical operations with greater range and more complex operations implemented with software. Within the TRS-80, the Z80 chip is connected through buffers to external circuitry. The result is a 40 conductor edge connector termed the TRS-80 bus, or simply bus, for short. Its pin-out is described in Appendix A and a complete schematic of the TRS-80 is found in Radio Shack, TRS-80 Microcomputer Technical Reference Handbook. While the TRS-80 bus is not a pin for pin image of the Z80, its functions essentially the same. It is accessible from the rear of the keyboard unit or the left side of the expansion interface.

The other main feature of the TRS-80 is its collection of memory chips which together comprise the 64K of on-line memory. Since all the Z80 is able to do is add, subtract, compare, and move binary numbers between 0 and

255, a program is required to translate these operations into the decimal arithmetic and alphanumeric character strings that humans can readily understand. In the TRS-80, the first 16K of memory is permanently dedicated to this program which is called the interpreter. The first 12K of the 16 is ROM which, as the name implies, can be read from but not written to. The remaining 4K is RAM which may be written to as well. Within the ROM portion, the interpreter program, in directly executable Z80 machine code, resides static and unalterable save for chip failure, even when power is not applied. On power-up, the Z80 chip begins to execute the permanent ROM steps starting at address zero. This initializes internal parameters and jump addresses in the 4K of RAM which acts as a scratch pad for the interpreter and ultimately causes the TRS-80 to begin accepting input from the keyboard and from which all other operations are initiated. This is termed the direct or command mode, and from it programs may be entered from keyboard, disk, or tape; execution of an existing program may be initiated by entering the run mode; or an existing program may be altered by entering the edit mode. The syntax accepted by the ROM interpreter is called BASIC and is the familiar high level language common to microcomputers and through which the fairly simple machine/operator communication is accomplished. The remaining 48K of memory in the TRS-80 is RAM; and all programs, variables, and the DOS if a disk system is used,

are stored in it above the first 16K. The TRS-80 will execute BASIC programs using the interpreter and will also directly execute Z80 machine code. Actually, the interpreter translates a BASIC program step by step into Z80 machine code because, as previously explained, that is all the Z80 is capable of executing. Other high level languages, both compiled and interpreted, are available for the TRS-80; but nothing but the resident BASIC interpreter can occupy the lowest 16K of memory. Thus programs in other languages usually require overhead as a run-time module, or in other words, another interpreter, in addition to the program itself.

Minor components of the TRS-80 architecture include the floppy disk controller, printer interface, cassette interface, real time clock, video circuitry, and RS-232 port. Communication between the Z80 and its external components may be done by tying the device to a reserved memory address, called memory mapping; or to a port address, called port mapping. With one exception, all TRS-80 components including the keyboard and CRT display are memory mapped within the previously mentioned 4K of RAM reserved for the interpreter. The exception is the cassette interface which is mapped to port 255. Thus, for example, each character position on the CRT screen is tied to a discrete address between 15360 and 16383 decimal [Ref. 6]; and the keyboard is similarly mapped in a portion of RAM. The

interpreter in a predetermined sequence scans the keyboard memory block, updates the video memory block, triggers the video circuitry, and executes program steps, among other tasks, and then begins again. All of this, including the allocation and management of memory is transparent to the operator. Radio Shack, Level II Basic Reference Manual; Blattner and Mumford, Inside Level II; and Farvour, Microsoft Basic Decoded describe in detail the use of the BASIC interpreter, the mapping of peripherals, and physical layout of the TRS-80.

The TRS-80 Model I system is thus seen to be suitably complex from both a hardware and software standpoint. Through the execution of the BASIC interpreter, the operator is able to control the Z80 microprocessor with the simple English-like commands of BASIC syntax and also use Z80 machine code or combinations of both.

2. Keyboard Enclosure

The TRS-80 keyboard enclosure contains the Z80 microprocessor, interpreter ROM and RAM, supporting circuitry, plus the first 16K of program RAM on a single board located underneath the keyboard assembly. The keyboard is a familiar typewriter-like arrangement with additional keys for the four directional arrows used in carriage control, a clear screen key, and a break key which returns the computer to the command mode when

depressed. Later editions of the Model I have a twelve key numeric keypad to the right of the main keyboard which duplicates the top row of numeric keys. On the side facing away from the operator are located three connectors on the right for connection of the CRT display, power supply, and cassette drive #1; and an on/off button for the keyboard. On the left side of the same face is the 40 conductor edge connector which is the TRS-80 bus. If the expansion interface is installed, this is connected to it by a short ribbon cable; otherwise, it is available for connection of direct connect peripherals. Adjacent to the bus edge card connector and not within direct view of the operator is the reset button which will cause the CPU to reinitialize itself and return to the command mode. The power supply is contained in a separate sealed module external to the keyboard which has connections for the 110 AC power line and a plug with the proper DC voltages to the keyboard. The keyboard assembly connected to the CRT display and power supply is all that is necessary to operate the Model I in its simplest configuration.

3. CRT Monitor

The CRT monitor is a monochrome white on black cathode ray tube with associated circuitry which displays 16 lines in 64 columns (characters). The signal from the keyboard to the monitor is direct video from the character generator within the keyboard unit and is connected by a

short cable and multiconductor plug. Power for the monitor is supplied directly from the AC line by a cord and wall plug. Besides an on/off control, only two other controls, one for contrast and the other for brightness level, are present on the monitor. The monitor resembles a conventional portable television set in both outward appearance and operation.

4. Expansion Interface

The expansion interface is the second half of the Model I system; and, although the keyboard unit and monitor will operate without it, such a system is limited in capacity. The enclosure contains the additional 32K of program RAM, the floppy disk controller, parallel printer interface, and optional RS-232 interface. It is designed to be placed immediately behind the keyboard with the CRT monitor atop it to form a keyboard station of similar dimension and appearance to single enclosure units. Immediately opposite the bus connector on the keyboard is a corresponding connection to the expansion interface which links the two via a short ribbon cable. On the left side face are two additional edge connectors, the rearmost for a parallel standard printer cable; and the foremost, the extension of the computer bus. On the rear face of the left side is still another edge connector for the disk drive cable to the separate and optional four disk drives; and, in the center, sockets for cassette drives 1 and 2.

The socket for drive 1 is in parallel with that on the keyboard unit and provides a convenient place to connect both drives; either can be used. Finally, if the optional RS-232 port is installed, the edge connector protrudes through the center front face.

The expansion interface is powered by an external power supply module identical to that of the keyboard unit. A compartment in the bottom of the expansion interface is provided to house both power supply modules thereby reducing the number of discrete components adrift. Only one control, the on/off button on the front face, is necessary. Once energized, all control emanates from the keyboard.

5. Floppy Disk Drive

Up to four 5.25" floppy disk drive units can be connected to the cable which connects to the rear of the expansion interface. Drives are numbered 0 through 3. 1, 2, and 3 are identical but drive 0 has additional circuitry, termination resistors, required for impedance matching of the transmission line. The disk drive connecting cable has four in-line connectors along its length for attachment to the drive units; any number up to four may be connected. Proper connection of drives is described in Radio Shack, TRSDOS & Disk BASIC Reference Manual. The floppy diskettes are loaded through doors in the front of each drive. Additional software, the DOS, is required to operate a disk

system; and it must be present on the diskette in drive 0 for the system to operate when disks are in use. On power up, the DOS is written into RAM immediately above the 16K interpreter. This reduces the amount of RAM available for program and variable storage, but the increased mass storage of the disk compensates for this loss. The DOS is actually a machine language program which manages the disk space and adds additional commands to the BASIC interpreter. Its operation is transparent to the user and typically requires 10K of overhead if running BASIC; or 5K, if machine language. A number of disk drives of different manufacture are available as are non-OEM DOS's for the TRS-80. Their capacities differ but they operate similarly with the variety of enhancements as their discriminating factor. The DOS causes the disk drive to divide the diskette into concentric tracks typically 35, 40, or 80. Each track is further divided into ten sectors of 256 bytes. The sector is the basic unit of disk space management. Five sectors or half a track is referred to as a gran. Hardware modifications can enable increased data density above the 256 bytes per sector. As an example, an unmodified 40 track system will typically have the capacity to store slightly less than 100K per drive; the exact amount is dependent upon the manner in which the information is written to the disk and the number of files on the disk because a certain amount of the space on each disk is required by the DOS for

housekeeping. Data files may be either random or sequential. Also, the DOS in drive 0 requires approximately 25% of that disk's capacity which reduces the storage available on that drive. There is enough variety in both the disk hardware and software available that it is not practical to go beyond the above general description without unwarranted detail. The user should consult the documentation for the system in use for specific information.

Proper handling of disks and other magnetic media is of prime importance if their operation is to be reliable. Periodic cleaning of disk drive heads, similar to cleaning of audio recording heads; and a clean, grease, smoke, dirt, and electromagnetic field free environment is essential.

6. Tape Drives

The TRS-80 is also capable of using standard audio cassettes for storage of both programs and sequential data files, but the slow speed of tape storage makes it less desirable than a disk system. The bare keyboard unit has provision for one drive; and the expansion interface, a second. Any high quality audio cassette deck may be used and the Model I comes equipped with one as standard. The decks are connected to the computer via supplied cables with a multi-contact plug on the end to the computer and miniature phone jacks to the AUX, EXT, and REMOTE plugs on the tape decks. Operation of the tape decks is straight

forward, and the operator must manually set the transport controls before operation. Since the recorder is an analog device; and the computer, a digital, there is sensitivity in the conversion process particularly in regard to the volume control setting of the tape deck. This is a weak link in the tape system; some experimentation is often required to adjust the volume control for proper tape operation. As with all magnetic media, cleanliness and proper handling of the tape is of prime importance for reliability.

7. Line Printer

A variety of serial and parallel interface printers are available from both the manufacturer and non-OEM sources. Parallel interface printers connect to the previously mentioned slot on the expansion interface and are directly supported in BASIC. Serial printers are connected via the RS-232 port and required additional software drivers. Printers may be dot matrix where the characters are formed by a series of dots imprinted from a moving carriage; or impact, where discrete type, similar to that of a typewriter, creates each character. Many dot matrix characters support the Model I graphics set. Also, modified IBM selectric typewriters are available as are keyboard solenoid arrays which attach to and operate a standard electric typewriter under TRS-80 control. Printer

speeds vary with 80 cps (characters per second) a nominal speed for dot matrix printers; and 25 to 60 cps, for impact printers.

8. Other Peripherals

A wide variety of additional peripherals are available from both the manufacturer and other sources. These include plotters, fast tape systems, analog to digital devices, modems, EPROM programmers, speech synthesizers, voice recognition units, ad infinitum. These products are regularly advertised in the periodicals listed in the bibliography and in Radio Shack catalogs.

9. TRS-80/UID System

At the present writing, the TRS-80 installation available to drive the UID consists of a 16K Model I with 32K expansion interface (total memory = 48K). The keyboard unit is an early model without numeric keypad, and an RS-232 port is installed in the expansion interface. One cassette drive is available for program storage. Disk drives and a printer were borrowed to validate the software for this project and recommendations were made to obtain this additional hardware. All documentation was assembled in a loose leaf binder for ready reference and left in the custody of the Department of Aeronautics laboratory technicians. Appendix B contains various photographs, diagrams, and statistics relative to the TRS-80/UID installation.

B. UNIVERSAL INTERFACE DEVICE

1. General Description

The UID is a collection of circuits housed within a common enclosure that enable a variety of digital and analog I/O from the TRS-80. Those selected were done so after research into the types and characteristics of the applications that would be encountered within the Department of Aeronautics. As part of this, the UID was designed so that its external connectors match those used by the various transducer setups present on the wind tunnels and testing machines within the Department. To maintain compatibility with TRS-80 port notation, all associated port, switch, jack, and connector designations are numbered zero to seven.

The UID enclosure is a standard metal electronics cabinet measuring 22" x 13" x 15". Within it, all circuits are mounted on 44 conductor plug boards mating to sockets mounted within a common card cage. Appendix B contains a table of slot assignments; component orientation is to the right facing the front panel. Connections from the plug board sockets are tied into bundles and run to the front and back panels attaching with quick disconnect push-on connectors. The back panel contains a series of multi-conductor and BNC connectors for convenient connection of signals. The front panel is divided down the middle with the left side containing analog circuitry; and the right,

digital. On the analog side are controls and connections for eight A/D (analog to digital) channels, a single D/A (digital to analog) channel, and a jack and rotary select switch for single point connection of an external meter to monitor any channel in positions zero to seven. The meter jack and selector also provide the output for the D/A channel in position eight. On the digital side are banana jacks for connection to an eight bit TTL level input port, an eight bit TTL level output port, and an eight bit SPDT (single throw double throw) relay port all under control of the TRS-80 host. All digital channels are monitored by panel mounted LED's (light emitting diodes) which show the on or off status of each bit. The center section of the front panel contains ten banana jacks arranged two by five which connect directly to the last two 5 pin connectors on the back panel. With these connectors, non-standard hookups with 5 conductor plugs may be connected directly to the back panel and then patched to the appropriate circuit with jumper cables on the front. Likewise, along the bottom of the front panel are banana jacks which tie to ground, +/- 15 volts, and +5 volts, the standard voltages used within the UID. The UID connects to the TRS-80 by means of a 40 conductor ribbon cable extending from the back panel. Inside the cabinet, the cable continues to a 40 pin DIP jumper which plugs into a mating socket on the port decoder card. Two in-line connectors are also attached to the

internal cable for attachment of the Interfacer-80 and Analog 80 which are designed for direct connection to the TRS-80 bus. The UID power supply is external and connects via four banana jacks on the back panel. Photographs of the front and rear panels are included in Appendix B.

2. Subcomponents

a. Analog Input Port

The analog input port consists of an 8 channel A/D converter, buffer amplifiers, and signal flow and conditioning controls as described in the following:

(1) Analog-80 A/D Converter. The heart of the analog input port is the Analog-80 A/D converter manufactured by the Alpha Products Company, Woodhaven, New York. This unit is an eight bit resolution, eight channel, port mapped, voltage measuring device with a range from zero to five volts in 20 mV increments and directly connectable to the TRS-80 bus. To adapt it to the UID, it was mounted on a standard 44 conductor plug board with its inputs connected to the plug board connectors and its computer bus ribbon cable and edge connector attached to the internal lead-in ribbon cable from the TRS-80. The Analog-80 port address is jumper selectable to ports 0 to 7; port 0 was selected for the UID application. The Analog-80 only decodes the three least significant bits of the port address so that higher addresses containing a

multiple of the selected port are in conflict and thereby unuseable. The Analog-80 input is unprotected from signals outside of its range of measurement which will cause it catastrophic damage. The Analog-80 receives power from a regulated 9 volt supply on the buffer amplifier board. The manufacturer's operating manual for the Analog-80 is included in the separate documentation binder.

(2) Buffer Amplifier Card. To protect the Analog-80 from under/over voltage, monopolar L8148 OPAMP circuits connected for unity gain were placed between the input signal and the Analog-80 inputs. The OPAMP output signal follows its input signal as long as the input is within the range of the power supply but cannot exceed its supply voltage or drop below ground potential. By providing an adjustable supply for the OPAMP circuits, it is thus possible to prevent the OPAMP output from exceeding the Analog-80 input rating. On the buffer amplifier card, a trim pot is provided to enable the adjustment of this power supply. A second power supply circuit provides +9 volts for operation of the Analog-80 and Interfacer-80; both supplies are powered from the +15 volt external supply.

(3) Input Conditioning Amplifiers. Eight circuit cards with gain selectable OPAMP conditioning circuits are included, one for each A/D channel, to provide for the amplification of small signals to within

the useful range of the Analog-80. Coarse gain is adjustable by a DIP switch located on the amplifier card with fine gain adjustable from precision potentiometers, AMP RANGE 0 to 7, located on the front panel. A second set of potentiometers, AMP BIAS 0 to 7, adjust the signal bias to any level so that an input signal can be conditioned to fit within the 0 to 5 volt dynamic range of the Analog-80 and thus attain maximum resolution.

The input conditioning cards also contain circuitry to drive a diaphragm/strain gauge pressure transducer; each has an isolated and regulated +5 volt supply for this purpose. The supply and return signals are connected to the first eight 5 conductor jacks on the back panel. The conditioning amplifiers receive power from the +/- 15 volt external power supply. Conditioning amplifier circuit board pinout and DIP switch gain code are included in Appendix B.

(4) Signal Flow. The analog input port was primarily designed to measure small, millivolt level signals from strain gauge sensing pressure transducers hence the inclusion of the input conditioning amplifiers. However, the capacity to monitor other signals was recognized as desirable, so the signal flow into the A/D converter was designed so the user could inject the signal at a point in the system ahead of the buffer amplifiers. Other devices, such as an analog computer, can thus be utilized

to condition analog input signals as well as the option to not employ signal conditioning at all. Also, recognizing that other A/D devices could be installed in the UID in the future, a DEVICE SELECT rotary switch was included in each channel. The input to the Analog-80 buffer amplifier is tied to position 1 of each of the device select switches; the other unconnected positions are for future expansion. The common pole of the device select switch is connected to the corresponding A/D IN banana jack underneath the device select switch. At the A/D IN jacks an input signal may be injected directly into the analog input port bypassing the internal conditioning amplifiers. Likewise, just underneath the A/D IN jacks are the corresponding AMP OUT jacks which are controlled by the LINE IN switches. With the appropriate LINE IN switch in the down position, the AMP OUT jack is connected to the output of its input conditioning amplifier which is in turn receiving its signal through its five pin connector and a suitable transducer. With the LINE IN switch in the up position, the AMP OUT jack is connected directly to the corresponding BNC connector, on the back panel. To route the AMP OUT signal to the A/D converter, a jumper is inserted between the AMP OUT and A/D IN jacks. This signal flow is illustrated in Appendix B.

b. Analog Output Port

A DAC0801LCN digital to analog converter chip is used in conjunction with a unity gain OPAMP circuit to

provide a D/A output port with a nominal range between zero and five volts in 20 mV increments. The maximum current output of the D/A output port is 10 mA. Greater voltages and power levels must be obtained through external amplification provided by the user. The D/A output port is mapped to port 2 through the bus decoder card described in another section. The D/A output is connected to position 8 of the METER SELECT switch. The D/A output receives its power from the +/- 15 volt and +5 volt external power supply and is colocated with the digital output port. The technical specification sheet for the DAC0801LCN chip is included in the separate documentation binder.

c. Digital Input Port

The digital input port is contained within the Interfacer-80 manufactured by the Alpha Products Company, Woodhaven, New York. It is a TTL level, 8 bit (single byte), port mapped device that returns a decimal integer value between 0 and 255 to the host computer based on the binary weighted value of the signal present in the bit pattern at its input. It is directly connectable to the TRS-80 bus. Also contained within the Interfacer-80 is the relay output port. To adapt the Interfacer-80 to the UID, it was mounted on a standard 44 conductor plug board with its inputs connected to the plug board connectors and its computer bus ribbon cable and edge connector attached to

the in-line connector on the internal lead-in ribbon cable to the TRS-80. The Interfacer-80 port address is jumper selectable to ports 0 through 7; port 1 was selected for the UID. As with the Analog-80, the Interfacer-80 also decodes only the three least significant bits of the port address so that higher addresses containing multiples of the selected port cannot be used.

The digital input port is connected directly to banana jacks TTL IN on the front panel, and panel mounted LED's above the jacks display the status of each bit. The Interfacer-80 is powered by the 9 volt regulated supply on the buffer amplifier card; its operating manual is included in the separate documentation binder.

d. Digital Output Port

A modified version of the circuits contained in Titus, TRS-80 Interfacing Book 1 were used to construct a TTL level, 8 bit (single byte), digital output port. The circuitry is colocated with the D/A output port. The output is available at banana jacks TTL OUT on the front panel and LED's monitor the status of each bit. The bit pattern corresponds to the binary weighted value of the decimal output argument. The digital output port is mapped to port 3 through the port decoder card. The port will drive 10 TTL loads (16 mA) and receives power from the +5 volt external power supply.

e. Relay Output Port

The relay output port is contained within the Interfacer-80 previously mentioned and is mapped to port 1. The eight SPDT relays are connected to banana jacks RLY COM (common), RLY NC (normally closed), and RLY NO (normally open) on the front panel. Eight other jacks, LINE IN, are connected to BNC connectors on the back panel. Panel mounted LED's display the status of each relay. The relay contacts may be connected in any configuration through the connecting jacks; maximum ratings are recommended not to exceed 25 volts, 500 mA. The relays are latched according to the binary weighted value of the output argument. The operating manual for the Interfacer-80 is included in the separate documentation binder.

f. Miscellaneous Components

(1) Bus Decoder Card. The analog and digital output ports require additional interfacing to the TRS-80 bus whereas the Analog-80 and Interfacer-80 have their own internal decoding. The bus decoder card is provided for this purpose and is a modified version of the circuits found in Titus, TRS-80 Interfacing Book 1 which not only decode the port I/O but buffer the bus from harmful signals from the interface. The circuit decodes the four least significant bits of the port/address bus for a total of sixteen available ports. The Analog-80 and Interfacer-80

circuits, however, each require two ports, one the designated port address and one made unuseable because of the three significant bits used in decoding; therefore, there are a total of twelve remaining ports available from the bus decoder. Two are used, one for the analog output port; and the other, for the digital output port, with ten remaining for future expansion. The buffered control signals from the TRS-80 bus are likewise available on the bus decoder card. The bus decoder card receives its power from the external +5 volt supply.

(2) LED Indicator Driver Card. A small circuit board using 7404 IC drivers is mounted on the reverse side of the front panel toward the upper center. The LED indicators are driven by these circuits which serve to isolate the LED's from the TTL level I/O signals. The LED indicator driver card is powered by the +5 volt external supply.

(3) Power Supply. An external power supply was used to avoid duplication of effort, and several were available within the Department for this use. The power supply connects to the rear panel via four banana jacks supplying +/- 15 volts, +5 volts, and ground.

III. SYSTEM IMPLEMENTATION

Implementation of the TRS-80/UID system involves five phases: software design, hardware setup, power up, signal calibration, and program execution.

A. SOFTWARE DESIGN

1. General

All port I/O between the TRS-80 and UID is accomplished with the two BASIC statements, INP and OUT, with the following syntax:

10 OUT port, arg

20 A = INP (port)

Statement 10 is an output statement where "port" is the port address and "arg" the argument sent to the port. Both "port" and "arg" can be a constant, arithmetic expression, or variable. The binary weighted value of "arg" is assigned to the eight bits of "port." Likewise, in statement 20, an input statement, the variable, A, is assigned the decimal value of the signal present at the eight bits of "port." Here "port" can also be a constant, arithmetic expression, or variable. Since the port address and data are both eight bits in length, the values of "port" and "arg" must be between 0 and 255 or an error occurs. Likewise, "port" and "arg" are dimensionless, integer numbers; the relationship between the values passed and the parameters

they represent must be scaled and calibrated by the programmer. In the TRS-80, the INP and OUT statements may be executed in both the command and run modes.

2. Analog Input

Analog input is accomplished by executing the following statements:

```
10 OUT 0, channel
```

```
20 A = INP(0)
```

where "channel" is a constant, arithmetic expression, or variable with a value between 0 and 7 corresponding to the desired analog channel to be read. The analog port, as previously explained, is mapped to port 0; a variable or arithmetic expression equal to zero could also have been used in the program statements. In this example, an integer value between 0 and 255 will be returned in the variable, A, corresponding to approximately 20 mV of input voltage per unit of A. A may be converted directly to volts by multiplying by .20. In the general case, the variable, A, will represent some other parameter than voltage; and the scale factor of 20 mV per unit will not be exact due to any number of analog errors in the transmission line. The calibration and scaling of analog input is discussed in a succeeding section.

3. Analog Output

Analog output is accomplished by executing the following statement:

```
10 OUT 2, arg
```

where "arg" may be a constant, arithmetic expression, or variable with a value between 0 and 255. The analog output port, as previously explained, is mapped to port 2; a variable or arithmetic expression equal to 2 could also have been used in the statement. The voltage impressed on the output port will be approximately 20 mV per unit of "arg." As with analog input, the correspondence between the argument value and the output voltage must be calibrated and scaled as described in a succeeding section.

4. Digital Input

Digital input is accomplished by executing the following statement:

```
10 A = INP(1)
```

The digital input port is mapped to port 1, as previously explained; an arithmetic expression or variable equal to 1 could also have been used in the program statement. A decimal integer value will be returned in variable, A, corresponding to the binary weighted value of the bit pattern signal present at the TTL In jacks. Thus, for example, if bit 0 and bit 3 are both above 2.4 volts (corresponding to a TTL level "1" value) and the others are at ground potential (corresponding to a TTL level "0" value) then the value returned in A will be:

$$A = ((2**0)*1) + ((2**3)*1) = 9.$$

The signal present at the digital input port could represent the on/off status of eight binary parameters, a single

binary encoded value, or some other coded combination of parameters; but the value returned in A is a single decimal number. Deciphering the bit status from the decimal value to decode the input is called masking and is required whenever the input parameter represents something other than a single binary encoded value. Masking of digital information is analagous to the calibration and scaling of analog information and is treated in greater detail in a succeeding section.

5. Digital Output

Digital output is accomplished by executing the following statement:

10 OUT 3,arg

where "arg" may be a constant, arithmetic expression, or variable with a value between 0 and 255. As previously explained, the digital output port is mapped to port 3; an arithmetic expression or variable equal to 3 could also have been used in the program statement. A binary weighted signal corresponding to the decimal value of "arg" will be impressed across the TTL OUT jacks and remain until a similar statement is executed to change it. Thus, as in the preceding example, if the value of "arg" is 9 then bit 0 and bit 3 will be above 2.4 volts (corresponding to a TTL level "1" value) and the remaining digital output jacks will be at ground potential (corresponding to a TTL level "0" value). The masking of digital output information is

analagous to digital input and is discussed in the aforementioned succeeding section.

6. Relay Output

Relay output is accomplished by executing the following statement:

```
10 OUT 1,arg
```

where "arg" may be a constant, arithmetic expression, or variable with a value between 0 and 255. As previously explained, the relay output port is mapped to port 1; an arithmetic expression or variable with the value 1 could also have been used in the program statement. The action of the relay output port is identical to that of the digital output port except that the output manifests itself at the relay jacks instead of the TTL output. The relays latch according to the binary weighted value of the argument passed and remain so until a similar statement is executed to change them. Thus, as in the two previous examples, if the value of "arg" is 9, then relays 0 and 3 will close; and the rest, open. Masking is also required.

B. HARDWARE SETUP

The UID may be used to monitor any physical parameter that can be converted into an analog or digital signal within the operating range of its various ports. Likewise, the UID can control any device that will respond to a properly conditioned analog or digital signal. BASIC is

suited to steady state applications with time constants on the order of one second or greater. Higher frequency applications would be possible using machine language but is beyond the scope of this investigation. It is the user's responsibility to ensure that the hardware connected to the UID fits within the bandwidth of the system.

Suggested setups for transducer hookup and control applications are listed in Appendix C. Also, a wind tunnel evaluation of a two dimensional NACA 66(215)-216 wing section is also included as Appendix H as part of the validation and testing of the UID. Obviously, the user must be familiar with the signals under investigation, their conditioning, and the logging and control algorithms. Other sections of this paper discuss these topics as do several of the bibliography references.

All hardware connections should be made using good engineering practices and before any power is applied to the TRS-80/UID system. Analog connections must be especially secure to prevent contact losses. Test runs of the application should be made and monitored with conventional measuring instruments before the TRS-80/UID is energized to ensure no damaging signals will be applied to the UID.

C. POWER UP

The integrated circuitry within the TRS-80 and UID is susceptible to permanent damage from surges in the lines

between components. Inadvertent application of a supply or unusually high signal voltage to the computer bus could have catastrophic results. Likewise, the initial values at the output ports are indeterminate at power up. Devices controlled by the UID could be overdriven by erroneous input signals if energized when power is applied to the TRS-80/UID system. For these reasons, a simple but precise power up procedure is recommended as follows:

1. Make all physical and electrical connections prior to energizing any equipment. Test the set-up to ensure the input signals are safe for the UID.
2. Energize all input devices to the UID.
3. Energize the UID.
4. Energize all TRS-80 peripherals (printer, disk drives, expansion interface, monitor, etc.); a multi-plug AC bus strip is recommended.
5. Energize the TRS-80 keyboard unit.
6. Assign the desired initial values to the digital and analog ports from the keyboard in the command mode.
7. Energize all devices controlled by the UID.
8. Calibrate and scale parameters as required.
9. Load and execute the application program.
10. Power down in reverse order.

D. SIGNAL CONDITIONING

Signal conditioning is the amplification/attenuation and biasing of both input and output signals to levels acceptable to the UID and the devices under its control.

The methods described in this section are illustrated in Appendix C.

1. Analog Input Conditioning

While the analog input port is protected from signals not within its operating range, such signals will be meaningless if accepted as valid data. Likewise, if the dynamic range of the input signal is not of the same order as that of the A/D port, 5 volts, resolution in the A/D process is lost. For these reasons, it is necessary to condition an analog signal.

For analog signals processed through one of the internal conditioning amplifiers, the sensing transducer should be excited to a level slightly less than the expected minimum signal of the application run. This may have to be determined by experimentation. The voltage output from the amplifier is measured and recorded at the AMP OUT jack with a suitable voltmeter. Next the transducer is excited to a level just slightly higher than the maximum expected and this voltage also noted. Then, with the transducer still excited at the higher level, the corresponding AMP RANGE potentiometer is adjusted so the difference between the minimum previously measured and the maximum is within the linear range taken from the channel calibration plots in Appendix G. The transducer is then excited to the former minimum level and the corresponding AMP BIAS potentiometer is adjusted until the signal present at the

AMP OUT jack is slightly above the lower boundary of the linear region. The transducer should be checked again at the higher level and the process repeated until the signals present at the minimum and maximum excitation are within the linear range of the channel. The precise values are not critical as they will be calibrated with software, but it is important that the input signal span the linear range of the A/D channel for maximum resolution.

Signals not processed through the internal amplifiers should be conditioned with external circuitry in a similar manner if not within the range and bias previously mentioned. The user may decide to accept a lesser resolution if the application can tolerate such a condition.

An analog computer is a convenient device for external conditioning; Peterson, Basic Analog Computation describes the setup and operation of analog computers that are available within the Department.

2. Analog Output Conditioning

The analog output is capable to supplying 10 mA at five volts and is intended to operate as a dry (low power consumption) control voltage source. An analog computer may be used to condition the analog output signal which may then be amplified by a power amplifier if necessary. Peterson, Basic Analog Computation describes the setup and operation of analog computer available within the Department.

3. Digital Input Conditioning

The TTL logic family is directly cascadable, noise immune, relatively fast (20 MHz typical), and monopolar [Ref. 7] in operation. The high or one state is represented by a signal of 2.4 volts or higher (3.3 typical); and the low or zero state, .8 volts or lower. A +5 volt power supply is standard. Not explicit in the above description is the tendency of TTL connections to "float" or assume the "on" state when left unconnected. This characteristic makes it convenient for the digital input port to monitor mechanical switch contacts because no external excitation voltage is required. With the opposite pole of the contact returned to ground, an open contact represents a high or "1" state; and a closed, a low or "0" state. Such a scheme can be used with the digital input port as can direct connection of other TTL devices. Other logic families may require buffering. Lancaster, TTL Cookbook treats the subject of TTL interfacing in detail.

4. Digital Output Conditioning

TTL devices will source or sink up to 16 mA; that is, the output will supply 16 mA in its on state to an external load returned to ground or will return 16 mA to ground in its off state from an external load supplied from the power source. Thus, from a 5 volt supply, the impedance of any TTL load should not be less than 312 ohms. Many common devices such as LED's (with limiting

resistor), small incandescent lamps, and low power relays fall in this category and can thus be driven directly from a TTL output. Loads requiring higher output can often be driven by transistor amplifiers as the TTL level output is also within the range of the typical input signal to a common emitter amplifier. Finally, the TTL level output of the digital output port can directly drive up to ten TTL inputs.

5. Relay Output Conditioning

The output relay contacts of the UID are completely isolated from the internal computer circuitry and can thus be connected in any relay application subject to the limitations listed below. The relays are physically located within the Interfacer-80 enclosure with the contacts rated at 120 volts, 2 amps. The manufacturer, however, does not recommend voltages higher than 25 volts due to the inherent danger of such levels and the potential for catastrophic circuit failure should inadvertent contact be made between a high voltage line and the computer circuitry. The author further recommends limiting the contact amperage to less than 500 mA due to the thin gauge connections between the Interfacer-80 output terminals and the relay output jacks on the front panel. Switching of larger loads can be done through an isolation relay supplied by the user.

E. PROGRAM EXECUTION

Successful program execution is the obviously desired end result of all the above preparations. Proper interfacing and correctly designed software are required, or the old adage of garbage in/garbage out will apply. Therefore, a calibration routine allowing the user to pause in the execution of the program to calibrate and examine the initial response of the TRS-80/UID is always recommended. Accurate calibration will ensure accurate data and control. Likewise, any program should be validated by testing its performance against known results.

Loading and execution of a TRS-80 program is straight forward from the previously cited reference manuals. At the appropriate step in the power up procedure, the program is loaded from tape, disk, or keyboard and execution begun by typing RUN <enter> from the keyboard.

Errors may be encountered during program execution especially from new and untested programs. The user must be aware of the progress of the program and prepared to abort it if problems occur. The first source of error comes from without the system in the form of transducer malfunction or signals exceeding the calibrated range. Parallel monitoring of the input signals with a suitable voltmeter is recommended. The second source of error comes from within the program itself. The most typical are typographical errors in program or data entry, syntax errors

in BASIC usage, mismatch of variables, exceeding the range of a variable, or exceeding the capacity of available memory. The BASIC interpreter contains error handling routines which halt program execution in this case and inform the user of the type of error and the line number in which it occurred. BASIC can also be programmed to internally handle errors or ignore them completely, although this can often be a greater source of program bugs than the error itself. Editing of the program to correct the error is the remedy. The last and an often hidden source of error is incorrect application of the algorithms within the program such that the program executes but does not do what it is supposed to do. Validation of the program against known results is the best source of insurance against this type of problem.

The end result for the TRS-80/UID user will be the successful execution of an applications program. The release from the tedium of manual data collection will allow a more thorough evaluation of the data; and automatic control, greater creativity in the application.

IV. BASIC APPLICATION PROGRAMS

A. GENERAL

Well written software will maximize the interactive capabilities of the TRS-80/UID system and be easier to debug and enhance. A structured, modular approach will result in such programs and has been used in the examples and application programs presented in this section. BASIC is FORTRAN-like in its syntax and, since FORTRAN is a language with which the UID user is likely to be familiar, comparisons between the two have been made. The following sections describe the characteristics of BASIC and present the application software.

B. CHARACTERISTICS OF BASIC

BASIC is an acronym for Beginners All-Purpose Symbolic Instruction Code which was developed at Dartmouth College. As the name implies, it is less formidable than FORTRAN but lacks some its capabilities while adding a few that FORTRAN does not have. In most microcomputers of current design, and the TRS-80 is no exception, BASIC is interpreted rather than compiled. It is still an evolving language with no recognized standard as yet, but its wide acceptance has caused efforts to be made in that direction [Ref. 8]. BASIC's used in microcomputers of different manufacture thus tend to differ slightly in syntax and

minor adaptation is usually required to transport programs from one to the other. The main strength of BASIC is that it is relatively easy to learn and use yet sophisticated enough for serious application. It's weakness lies in its interpretive nature which means that it is relatively slow in execution. What is slow to the computer, however, is often imperceptible to the human senses; and this is often the case. The controversy over BASIC as an acceptable language for sophisticated application rages on and is beyond the scope of this paper. Suffice to say that BASIC is certainly an appropriate medium for the steady state applications of the UID.

BASIC assignment statements, arithmetic expressions, and functions will be recognizeable to the FORTRAN programmer. BASIC supports single and double precision real variables (6 and 14 decimal places) and integer variables but does not support complex variables. These, however, can be synthesized if required. Alphanumeric variables, called string variables, are supported in BASIC where they are not in FORTRAN. The string variable makes possible many applications such as word processing and facilitates interactive English-like communication between the user at the keyboard and the program output on the CRT monitor. Logical and a special set of string operations in BASIC are supported where they are not found in FORTRAN. BASIC supports multi-dimension arrays in all variable

types. BASIC variable labels are two significant characters in length as opposed to the six of FORTRAN and are all global; this can be a minor inconvenience as the selection of label combinations that mnemonically resemble the parameter name are reduced. Thus, the programmer must be careful not to use the same label for a different parameter in another part of the program. Conditional and unconditional transfer statements, IF and GOTO, are also similar to FORTRAN; but the PRINT and INPUT statements replace the WRITE and READ statements of FORTRAN and offer a simpler and wider variety of syntax. Unlike FORTRAN, all BASIC statements must be numbered as the BASIC interpreter uses the line number to locate the program code during execution. BASIC programs are stored as condensed text files in memory above the BASIC interpreter; during execution, the interpreter deciphers each statement as it is encountered and executes a block of its own machine code based on the evaluation of the BASIC statement.

The user is advised to read and gain comprehension of Radio Shack, Level II Reference Manual and Radio Shack, TRSDOS & Disk BASIC Reference Manual for detailed information on the Level II BASIC used in the TRS-80. Both manuals are comprehensive and contain numerous examples illustrating the use of the language. Other references listed in the bibliography may also be useful to the first time BASIC programmer.

C. STRUCTURED BASIC

Structured programming is characterized by easy to follow, step by step program flow with transfer out of the physical statement order not allowed except within defined constructs. Several such constructs are recognized as standard and represent natural steps in decision making and iteration. Examples are: IF-THEN, DO FOR, CASE OF, and others further developed in Appendix D. A group of program statements arranged within these constructs and designed to accomplish a specific purpose is called an algorithm. Program flow enters at the top of the algorithm and exits at the bottom; and, thus, complex program operations may be grouped into algorithms and visualized as discrete modules, a much more manageable method of organizing the program. One construct, the subroutine CALL, causes the program to execute an algorithm located elsewhere within the program and return to the CALLing point when finished; thus transfer of program control in structured programs is not lost, it is just more orderly. Together with internal documentation in the form of REMARK statements, structured programming greatly simplifies the programming task and allows easier debugging and enhancement. All application programs written for the UID have been done so using structured techniques. Graham, Introduction to Computer Science treats the subject of structured programming at great length and is the inspiring source of the methods used in these examples.

The Level II BASIC used in the TRS-80 is not a structured language per se; its various conditional and absolute transfer statements allow the programmer complete freedom in program flow control. However, the structured constructs can be synthesized using combinations of BASIC statements and these translations also appear within the examples of Appendix D. These can be used to build algorithms which obey the logic of the given construct even where there is no BASIC statement that directly applies. Likewise, the indentation of nested constructs in the program listing is a common practice that facilitates readability of the listing but is not an inherent function of Level II BASIC. The program LIST/BAS, Appendix E, has been written to list structured BASIC programs following the indentation conventions and also limits one construct to a page. The program is internally documented and will prompt the user as to its use; it will list to a line printer in structured format any program that has been written following the translations in Appendix D and has been used to supply the listings for the applications software for the UID.

There are, however, two disadvantages to using the above described format with the TRS-80. The first stems from the fact that the added non-executing REMARK statements occupy real memory space which may cause a conflict

in larger programs; any memory byte occupied by a REMARK cannot be used by executing statements or for variable storage. The problem typically becomes acute when large amounts of data must be stored internally in arrays. The solution is to remove the REMARK statements or subdivide the data into smaller modules, often inconvenient. The second disadvantage stems from the manner in which the BASIC interpreter executes transfer statements. Although in theory the structured approach does not use transfer statements, the translation does in synthesizing them; an examination of Appendix D will show this to be evident. When BASIC executes a transfer to a specified line number, the interpreter must search the program text file for it, beginning at the top of the program, because the line numbers are not absolute memory addresses but merely labels of significance only within the program. The label search can occupy perceptible periods of time particularly if the program is long, the label located towards the end of the program, and the transfer executed frequently. The result is a program that executes slowly. The remedy is to place frequently called constructs toward the top of the program.

The user is in no way required to use structured methods with the UID, and at times a judicious combination of structured and non-structured techniques may be optimum. These topics were presented because the application software was

written using them and the user may find the frequently encountered logical patterns of the structured technique of value in BASIC programming efforts. With imagination, the structured approach may be used to produce well documented BASIC programs that execute in reasonable amounts of time.

D. CALIBRATION, SCALING, AND MASKING

1. General

The values passed between the UID and the TRS-80 with the INP and OUT statements are dimensionless integer numbers which require interpretation to be of any value to the program. For example, an A/D input channel with 2.0 volts across it would return approximately the integer value 100 to the program. This corresponds to the 20 mV resolution of the A/D converter and is said to be only approximate because the gain of the buffer amplifier may not be exactly unity and other analog losses may be present. The important thing is that the relationship be linear; determining the scaling factor is the process of calibration. Thus, this value of 100 is at first meaningless in terms of the 2.0 volts that it represents; but if it is multiplied by .02, the estimated scale, the result is 2.0, the measured value. An analogous process exists for digital information where a byte may represent a single binary weighted value, multiple values encoded by some scheme, or the binary status of up to eight discrete

parameters. Deciphering and setting the bit pattern to evaluate or send digital information is called masking. The two following sections develop calibration, scaling, and masking for practical application to the UID.

2. Analog Calibration and Scaling

The A/D process, as previously explained, returns a dimensionless integer value to the computer based on a to be determined scale factor of so many volts per unit of the integer. There may also be present an offset error voltage wherein zero potential across the input channel returns a small but non-zero value to the computer. If the A/D process is assumed to be approximately linear, then these two scaling parameters can be represented by the familiar linear equation:

$$Y = M \cdot X + B$$

where Y is the measured voltage in volts; M, the unknown scale factor in volts per unit of X; X, the dimensionless value returned by the A/D conversion; and B, the unknown offset error in volts. If two samples of X and Y are taken at opposite ends of the dynamic range, the result is two equations in two unknowns which can be solved for M and B. Thereafter, Y can be calculated from any value of X. Likewise, if the measured parameter has units other than volts, then stating the calibration samplings of Y in those units will result in values of M and B that give Y relative to X in that desired unit. The actual gains and

losses in the transmission path between the analog parameter and the A/D converter need never be known as long as the relationship is linear. Operating the A/D converter in the center of its dynamic range will typically give performance that approaches linearity. Likewise, D/A output is essentially the same except the scaling and calibration process is reversed with X as the dependent variable. Specific calibration and scaling algorithms are included in the subroutine library of Appendix F.

3. Digital Masking

If the parameter monitored by a digital port represents a single valued binary weighted bit pattern, then the decimal value sent or returned by the program corresponds directly to the bit pattern; otherwise, masking to decipher the encoded information is required. As an example, two other common encodings which are often encountered are BCD (binary coded decimal) and discrete binary.

BCD requires four bits to represent the ten decimal digits; four bits can represent sixteen values, but BCD only uses the first ten. The least significant bit corresponds to two to the zeroeth power; the next, two to the first; and so on. The combination of the four bits can thus represent 0 to 9, and multiple bit combinations can represent multi-digit decimal numbers. Thus, a single byte

with eight bits can represent two decimal numbers with values from 0 to 9 or a single decimal number with values from 0 to 99.

Discrete binary corresponds to eight separate parameters represented by on/off or yes/no states. There is no weight to the bit pattern since each parameter is separate from the other. Combinations of BCD and discrete binary can also be encoded on a single byte as long as the number of bits required does not exceed the eight available in the byte. Numbers may also be represented in other than BCD format; Hexadecimal (base 16) and Octal (base 8) are two additional examples.

Digital masking in BASIC is directly supported with the AND and NOT operators. If X is the decimal number to be masked and Y the bit position to be determined, then execution of the following statement will return a zero or one in B corresponding to the off/on state of bit Y:

$$10 B = (X \text{ AND } 2^{**}Y) / 2^{**}Y$$

The statement may also be inverted to solve for the value of X that will set bit Y.

The NOT operator returns the complement of the argument and is useful in inverting logic. Whereas the previous example returned a value of one when bit Y was one, the following returns a zero if one and vice versa:

$$B = \text{NOT}((X \text{ AND } 2^{**}Y) / 2^{**}Y)$$

Since binary inputs may represent the complement of the desired parameter; the NOT statement is useful for inverting such logic.

Masking algorithms are also included in the subroutine library, Appendix F, for the various examples of this section.

E. SUBROUTINE LIBRARY

A subroutine library has been composed and included as Appendix F. These subroutines are designed to be integrated into any driving program to accomplish their stated operations many of which have been described throughout the text. They include analog and digital I/O through the UID, calibration and scaling of analog information, masking and coding of digital information, delay loops, and a menu driver for interactive programs, and others. The subroutines are written in structured format and use mutually exclusive line numbers; they may be merged into any program as long as the host program line numbers do not conflict with those of the subroutines. A subroutine is called by assigning its input parameters, if required, and executing a GOSUB statement to the appropriate line number. In general, variable labels beginning with the letter V have been used for passing parameters to and from subroutines; and labels beginning with T, for internal calculations. Use of variable labels beginning with

letters other than these two in the host program will avoid inadvertent variable conflict and the hard to find error of having the same label representing two parameters. Each subroutine listing is internally documented with REMARK statements explaining any information necessary for its execution; the REMARK statements may be omitted in an application to conserve memory if desired.

V. TESTING AND VALIDATION

Each circuit of the UID was tested for proper operation and the results included within Appendix G. To demonstrate the TRS-80/UID in practical operation, the system was connected to the 32" x 45" academic wind tunnel in Halligan Hall and used to evaluate a NACA 66(215)-216 two dimensional wing section. The results are included as Appendix H.

A. TESTING

Testing of the UID circuits involved separate techniques for the analog and digital circuits. For the digital, the operation of each bit could be observed from the LED indicators mounted on the front panel; and each of the three circuits responded by setting the correct bit pattern for the entire range of 8 bit I/O possible. A truth table for the digital circuits is included in Appendix G. For the analog circuits, the analog output was first excited through the entire argument range of 0 to 255 and the resulting output voltage measured, tabulated, and plotted. The calibrated analog output was then used to drive each analog input channel and the corresponding results tabulated and plotted for each channel. These tables and calibration curves are included in Appendix G.

B. VALIDATION

The TRS-80/UID was used to investigate the NACA 66(215)-216 wing section in the following manner. The test wing section with 36 predrilled pressure taps distributed over its surface was mounted in the wind tunnel and the port taps connected to the tunnel mounted scanivalve/pressure transducer and the tunnel manometer array. The relay output port was used to drive the scanivalve controller; and the digital input port, to monitor the BCD encoded scanivalve address. An EAI TR-20 analog computer was used to condition the output from the pressure transducer whose output was applied to channel 0 of the analog input port. A driving program which included the chord/camber/pressure tap coordinates of the test section in internal statements was composed to first calibrate the UID to the pressure transducer and then record the pressure field around the test section by stepping the scanivalve through its ports. Coincident with the TRS-80/UID run, a photograph of the manometer array was taken and the same pressure field tabulated manually. The entire report is included in Appendix H. Agreement of the comparisons was within one percent.

VI. RESULTS AND CONCLUSIONS

The TRS-80/UID has been described and demonstrated in practical application in the previous sections for steady state data logging and low frequency control applications. Included are calibration curves for the analog circuits and truth tables for the digital as well as a demonstration of a practical application with the wind tunnel evaluation. The analog calibration curves show linear behavior and the manual and UID tunnel observations agreed within one percent. The TRS-80/UID is considered validated for the above use.

The system is capable of expansion, and ten additional port addresses are easily accessible from the bus decoder card. Of particular utility would be a multi-byte resolution A/D channel for greater accuracy in the analog input port which the author had hoped to implement but regrets that time constraints forced him to abandon. Likewise, high frequency data logging is also a possibility with the use of machine language programs, and that capability remains to be investigated. The applications are only limited by the imagination.

The TRS-80/UID project has been a true challenge. In building it, the author hopes to have provided a powerful and useful test instrument for the Department of Aeronautics

and also has realized a large amount of personal satisfaction in working with the equipment and expounding ideas of keen interest. As demonstrated, the microprocessor is revolutionizing the world in which we live.

STRUCTURED BASIC

The following pages describe the logical constructs of structured programming and list skeletal methods for implementing them in BASIC. They are:

1. IF-THEN-ELSE (conditional execution)
2. DO FOR (unconditional iteration)
3. DO UNTIL (conditional iteration)
4. DO WHILE (conditional iteration)
5. CASE OF (conditional execution)
6. LOOP UNTIL (conditional iteration)
7. CALL (unconditional transfer)

IF-THEN-ELSE

Executes the succeeding statement(s) if the given condition is true. Optional multiple conditions and default ELSE. The first set of statements whose condition is true are executed (or the ELSE statements) and none others.

Structured Abstraction

```
IF (condition 1) THEN
    (program statements)
ELSE IF (condition 2) THEN
    (program statements)
ELSE IF .....
    .
    .
    .
ELSE IF (condition n) THEN
    (program statements)
ELSE
    (program statements)
END IF
```

BASIC Translation

```
100 'If (condition 1) THEN
102     IF (NOT(condition 1))THEN 110
        (program statements)
109     GOTO 199
110 'ELSE IF (condition 2) THEN
112     IF(NOT(condition 2))THEN 120
        (program statements)
119     GOTO 199
120 'ELSE IF .....
    .
    .
    .
1N0 'ELSE IF (condition n) THEN
1N2     IF(NOT(condition n))THEN 190
        (program statements)
1N9     GOTO 199
190 'ELSE
        (program statements)
199 'END IF
```

DO FOR (index) = (p1) TO (p2) STEP (p3)

Executes the statements within the construct a given number of times determined by setting the index to parameter 1 and incrementing (decrementing) it by parameter 3 for each iteration until $\text{ABS}(\text{index}) \geq \text{ABS}(\text{parameter } 2)$. Index may be used on right, but not left, side of an assignment statement within the construct. Index may be a real or integer simple variable (no arrays); parameters may be real/integer simple or array variable, arithmetic expression, or constant. STEP (parameter 3) is optional; '1' is default.

Structured Abstraction

```
DO FOR (index) = (param 1) TO (param 2) STEP (param 3)
    (program statements)
END DO
```

BASIC Translation

```
100 'DO FOR (index) = (param 1) TO (param 2) STEP (param 3)
102     FOR (index) = (param 1) TO (param 2) STEP (param 3)
        (program statements)
198     NEXT (index)
199 'END DO
```

DO UNTIL (condition)

Executes the statements within the construct until the condition is true. Executes at least once even if condition is initially false. Assignment statement within loop must cause condition to converge to true or infinite loop will result.

Structured Abstraction

```
DO UNTIL (condition)
    (program statements)
    (condition) <= TRUE
    (program statements)
END DO
```

BASIC Translation

```
100 'DO UNTIL (condition)
      (program statements)
1XX   (condition) <= TRUE
      (program statements)
198   IF(NOT(condition))THEN 100
199 'END DO
```

DO WHILE (condition)

Executes the statements within the construct while the condition is true; skips the construct altogether if condition is initially false. Assignment statement within loop must cause condition to converge to true or infinite loop results.

Structured Abstraction

```
DO WHILE (condition)
    (program statements)
    (condition) <= TRUE
    (program statements)
END DO
```

BASIC Translation

```
100 'DO WHILE (condition)
102   (IF(NOT(condition))THEN 199
      (program statements)
1XX   (condition) <= TRUE
      (program statements)
198   GOTO 100
199 'END DO
```

CASE OF (index) = 1 TO (constant)

Executes the index'th set of statements within the construct or optional ELSE default. Index must be integer variable and constant be integer greater than '1'.

Structured Abstraction

```
CASE OF (index) = 1 TO (constant)
CASE 1:
    (program statements)
CASE 2:
    (program statements)
CASE 3: . . . . .
    .
    .
CASE (constant):
    (program statements)
ELSE:
    (program statements)
END CASE
```

BASIC Translation

```
100 'CASE OF (index) = 1 TO (constant)
102     IF (index) < 1 OR (index) > (constant) THEN 190
104     ON (index) GOTO 110,120, . . . ,1C0
110 'CASE 1:
        (program statements)
119     GOTO 199
120 'CASE 2:
        (program statements)
129     GOTO 199
130 'CASE 3: . . . . .
        .
        .
1C0 'CASE (constant):
        (program statements)
1C9     GOTO 199
190 'ELSE:
        (program statements)
199 'End case
```

LOOP UNTIL (condition)

Executes the statements within the construct until condition is true. Exits the loop immediately upon a true evaluation of condition (unlike the DO constructs which exit at the bottom). Assignment statement within loop must converge to true condition or infinite loop will result.

Structured Abstraction

```
LOOP UNTIL (condition)
    (program statements)
    (condition) <= TRUE
    (program statements)
    IF (condition) = TRUE THEN QUIT
    (program statements)
END LOOP
```

BASIC Translation

```
100 'LOOP UNTIL
      (program statements)
1XX   (condition) <= TRUE
      (program statements)
1YY   IF (condition) THEN 199:'QUIT
      (program statements)
198   GOTO 100
199 'END LOOP
```

CALL (subroutine)

Transfers program control to subroutine and resumes execution at CALLing point when subroutine is ENDED.

Structured Abstraction

```
ALGORITHM MAIN PROGRAM
    (program statements)
    CALL (subroutine) (parameters)
    (program statements)
END MAIN PROGRAM
.
.
.
SUBROUTINE (subroutine) (parameters)
    (program statements)
END (subroutine)
```

BASIC Translation

```
100 'ALG MAIN PROGRAM
    (program statements)
1XX   (parameters) <= (calling parameters)
1YY   GOSUB 200: '(subroutine)
1ZZ   (returning parameters) <= (parameters)
    (program statements)
198   END
199 'END MAIN PROGRAM
.
.
.
200 'SBR (subroutine)
202   (local parameters) <= (calling parameters)
    (program statements)

APPENDIX G

SYSTEM CALIBRATION RESULTS

The following pages contain the digital truth tables, calibration tables for the D/A and A/D ports, and associated plots of these data.

In the D/A tables, the output port is represented in the first two columns labeled ARG and VOLTS. The remaining eight columns are not used. ARG is the non-dimensional integer argument sent to the D/A output port and VOLTS is the resulting analog output voltage in volts at the METER SELECT jack position 8 measured to four places with a digital volt meter.

In the A/D tables, the D/A output port was used to drive each of the A/D input channels through an external conditioning amplifier biased to sweep through the range of the channels. ARG is the non-dimensional integer argument to the D/A port, the VOLTS column is the amplified input to the A/D channels in volts, and the CH 0 to CH 7 columns are the returned non-dimensional integer parameters from the respective A/D channel.

D/A CAL PLOT

A/D CAL PLOT

APPENDIX H

SYSTEM VALIDATION RESULTS

The TRS-80/UID was validated by evaluating a NACA 66(215)-216 wing section in the 32" x 45" academic wind tunnel as described in Section V. The results are compared against manually collected data from the tunnel manometer array.

Airfoil Characteristics

Wind Tunnel Description

Type: AEROLAB 90 Series, 32" x 45", lowspeed; located in Halligan Hall, Naval Postgraduate School, Monterey, California 93940

Pressure Transducer: capacitive, amplified to +/-15 volts analog output

Scanivalve: 48 channel (1-48) single step & home (ch 48)

Parameters:

P0 = ambient static pressure

P1 = tunnel plenum static pressure

P2 = test section static pressure

V = test section velocity

RHO= density

Pressure/Velocity Relationship:

$$V = \text{SQR}((2*(P2-P1))/\text{RHO})$$

Manometer Array Configuration

40 tubes

S.G. of Fluid = .939

APPENDIX I

GLOSSARY

1. Address bus: that group of lines from the CPU which it uses to vector data to/from memory locations by means of binary electrical signals.
2. Assembly language (code): a low level computer language which uses mnemonics and higher order number systems to represent the binary operation codes and absolute addresses of the CPU but is otherwise a one for one translation of the CPU machine code.
3. A/D: analog to digital
4. Baud: the data transmission rate expressed in bits per second.
5. BCD: Binary Encoded Decimal. A 4 bit binary bit encoding representing the decimal digits 0 to 9.
6. BIT: Binary digit: single unit of information representing a one/zero, on/off, or yes/no state.
7. Bug: any software or hardware error/malfunction that causes the computer/program to operate in a manner other than intended.
8. Byte: a group of eight bits which are processed as a single quantity.
9. CPU: Central Processing Unit. The area of a computer which computes all logic and arithmetic functions and sequences the flow of the program.
10. CRT: Cathode Ray Tube. Used as the generic name for television type I/O devices.
11. Data bus: that group of lines from the CPU on which the information that is processed is vectored from CPU, memory, and I/O devices as binary electrical signals.
12. DIP: Dual In-line Package. The standard integrated circuit housing characterized by two rows of symmetric pins in a low profile, rectangular package.

13. D/A: digital to analog; the inverse of A/D.
14. D/D: Digital to Digital, from one logic family to another or from the clocked data bus under CPU control to a latched I/O device.
15. HEX (hexadecimal): the base 16 number system. The digits 10 to 15 are represented by the letters A to F. Thus, 12 decimal = C hex; FF hex = 255 decimal.
16. I/O: input/output.
17. K: a suffix which indicates a group of 1024 (2^{10}) items as in '16K of memory' meaning 16384 memory locations.
18. LED: Light Emitting Diode. A type of diode that emits visible light in its forward biased condition; used frequently as an indicator because of low voltage/power requirements.
19. Machine language (code): the binary bit patterns, represented by electrical signals, used by the CPU to carry out its programmed functions.
20. Nibble: the upper or lower four bits of a byte.
21. OPAMP: Operational Amplifier. An extremely stable linear amplifier capable of precise gain.
22. RAM: Random Access Memory. Volatile memory the contents of which can be changed by the CPU.
23. ROM: Read Only Memory. Non-volatile memory the contents of which may not be changed by the CPU but may be Read Only.
24. Software: the program that resides in the micro-processor memory.
25. Structured Programming: a modular programming technique characterized by top to bottom program flow with transfer out of the statement order not allowed except within defined, logical constructs.
26. TTL: Transistor Transistor Logic. A family of digital logic and IC's characterized by a +5 volt monopolar power supply, high noise immunity, high speed (20 MHz typical), and with directly cascadeable I/O. A signal above 2.4 volts represents an on or '1' state; below .8 volts, an off or '0' state.

27. Word: a group of one or more bytes which the CPU is capable of treating as a single quantity; the binary order of the data bus expressed in bytes or bits.
28. Z80: a third generation microprocessor using an eight bit word, sixteen bit address bus (64K), and requiring a single +5 volt supply voltage.
