ABSTRACT

The project is concerned with the investigation of quantization, charge transport and applications in two dimensional subbanding systems including MOSFET and various junction field effect configurations. The degree of subbanding to be expected in various semiconductor materials has been characterized for different channel doping densities, temperatures and surface orientation. The materials treated here are (110) and (111) Si, n-GaAs, n-InP, n-InAs and n-InSb. Results for both buried conducting channels and surface conducting channels are presented. It is noted that subband separation in excess of 100 meV is to be expected for n-Si of appropriate surface orientation and doping concentration. Even larger separations may be expected for various compound semiconductors. The Fermi level has been calculated for different channel dopings at 4.2K, 77K and 300K. The channels are shown to be degenerate under certain conditions in spite of the fact that a 3D system would be non-degenerate at the same temperature and concentration.

Theory is presented for transverse voltage amplifying devices. This structure constitutes a new class of semiconductor devices.

FOREWORD

This is the first annual report for ONR contract N0014-76-C-1081 sponsored by the Office of Naval Research.

The personnel associated with the project this last year were Prof. J. W. Holm-Kennedy, principal investigator, and Mr. Daryl Motoda, technical assistant.

The contract supports the investigations of subbanding phenomena and related applications in various semiconductor subbanding systems. Emphasis in this report will be placed on the degree and nature of the subbanding to be expected in various semiconductors and the transverse voltage-amplifying device. Other proposed applications supported by the project will be treated at a later date.

Subbanding in Semiconductor Devices

In recent years there has been a growing activity in investigations of the physics of two dimensional subbanding in electronic devices. Heretofore the field has been limited to investigations of MIS structures with heavy emphasis on the common Si MOSFET. Although those investigations have proven fruitful, and there is still a good deal of intense activity surrounding this type of device, the MOSFET is not the only candidate for subbanding nor is it necessarily the best one for certain areas of study.

The principal investigator has proposed a completely separate and new class of two dimensional subbanding systems which promise to be more versatile in their applications. These devices use a p-n homo-junction to confine the free electronic charge in the semiconductor to conducting regions so narrow as to exhibit quantum effects (subbanding). This system is akin to the common J-FET but is designed to insure a sufficient degree of confinement to guarantee quantum effects.

The ideal band structure for a subbanding system is well known. It consists of sets of two dimensional ellipses in k-space. The subband members are separated in energy determined by the degree of confinement. For junction subbanding structures (J-SUBS), the bands in k-space will ideally have the same shape as for MOSFETs. However, J-SUBS may be expected in practice to vary markedly from the MOSFET nature. J-SUBS are more versatile and, except where an interface is used as a barrier on one side of the device, should not suffer from the presence of the SiO_2/Si interface, related surface charge and surface roughness.

Degeneracy

One effect of subbanding is to lift part of the degeneracy of the bulk three dimensional band structure. This results in finding fewer k states near the edge of the conduction (sub) band than for the 3D system. The degree of band filling is therefore stronger when electrons are introduced into the band. Fewer electrons are needed to fill all the lower states in the subband and as a result one may expect degeneracy in the two dimensional structure whereas a similarly doped three dimensional channel would exhibit non-degenerate behavior. The location of the Fermi level E_F depends on how the electrons are distributed throughout the subband and therefore on the temperature (for E_F below E_{c1}). For a parabolic 3D band, one knows that the density of states depends upon m^* ^{3/2}. In the 2D structure the density of states depends on m^* , i.e., on the mass to first power. Thus one may expect stronger degenerate effects in semiconductors having smaller effective masses, such as n-InSb and n-GaAs, than in materials with larger effective masses (such as Si). The valley degeneracy also affects the density of available states (contrast (111) n-Si with 6-fold degeneracy to n-GaAs with 1-fold degeneracy).

All of these effects may be treated quantitatively by considering the condition for conservation of carriers in the conducting channel. One can show that the population of the v^{th} subband is

$$n_v = 4 (m_{1v} m_{2v})^{1/2} \frac{kT}{h^2} \ln[e^{(E_F - E_{cv})/kT} + 1] \quad (1)$$

where m_{1v} and m_{2v} are the principle subband effective mass values in the non-confining directions, T is the temperature and E_{cv} is the subband edge for the v^{th} subband. The total number of carriers in the channel of width W_c doped at a concentration N_d is simply¹

$$n_o (\text{cm}^{-2}) = N_d W_c . \quad (2)$$

Carrier conservation yields

$$N_d W_c = \sum_v n_v \quad (3)$$

resulting in the expression

$$\prod_{i,j} [e^{-(E_{ij}-E_F)/kT} + 1]^{\alpha_j} = e^{N_d W_c / kT} \quad (4)$$

where

$$\alpha_j = \frac{4\pi}{h^2} n_j (m_{1j} m_{2j})^{1/2} . \quad (5)$$

Here v has been replaced by i,j to illustrate the contribution from the different subband sets (j) and all of their contributing members (i). n_j is the valley degeneracy factor (e.g., $n_j=6$ for (111)-n-Si).

Several interesting observations may be made here. If only one subband is occupied and it is clearly degenerate (i.e., $[E_F - E_{v1}]/kT \gg 1$), the expression for E_F becomes

$$E_F = E_{v1} + N_d W_c / \alpha_j . \quad (6)$$

If two different subbands are degenerate and only these are occupied, one finds

$$E_F = \frac{\alpha_2 E_{c2} + \alpha_1 E_{c1}}{\alpha_2 + \alpha_1} + \frac{N_d W_c}{\alpha_1 + \alpha_2} \quad (7)$$

and so on. Thus, for such conditions E_F becomes linear in W_c . One may expect to vary the degree of degeneracy in a very controlled way (linearly in W_c) by simply controlling W_c through the variation in the depletion width with applied gate voltage. An increasing W_c is therefore expected to increase the degree of degeneracy. This effect should continue to occur until, for large W_c , the subbands become so close together that the effective density of accessible states forces again a non-degenerate condition (approaches the 3D system).

At pinchoff the channel is empty ($W_c=0$) resulting in a non-degenerate condition. Thus one has a system, which, if it exhibits degeneracy effects, may

be varied between strictly non-degenerate conditions and strongly degenerate conditions while maintaining a number of other parameters unchanged. This is in stark contrast to the MOSFET.

The J-SUBS therefore present a very interesting and versatile physical system with which to probe fundamental physical phenomena of two dimensional systems. They also afford unique applications potential.

Appendix I is the text of a paper published in the proceedings of the Second International Conference of 2D Systems (Brechtsgaden, 1977) and describes an approximate method for computing the strength of the quantum effects.

Figures 1 through 58 and the associated tables show the results of a portion of our calculations of both subband edge energies and Fermi level E_F for (110) and (111) n-Si, n-InSb, n-InAs, n-InP and n-GaAs for various channel doping and channel width. (Similar analyses applies to p-type channels.) The quantum effects can be very pronounced under appropriate conditions, being 100's of meV in some instances as compared with values on the order of 10's of meV for Si MOSFETs. Of course, if the conducting channel is located at the surface, the confinement on the surface side of the channel is usually more abrupt than on the p-n junction side naturally resulting in sharper confinement and therefore stronger quantum effects (i.e., large subband separation). The separation for abrupt surface channel device is easily shown to be the same as for the symmetric channel in the bulk with simply every other subband removed (see Appendix I).

It is observed that the degeneracy effects are strongest for the lighter mass semiconductors, as expected. With appropriate design, the Fermi level is seen to penetrate several subbands.

Transverse Voltage Amplifier Device

For particular surface orientations, the subband structure exhibits an anisotropic character. Different subband sets have different energy separations due to their different transverse effective mass values. The effective mass tensors for transport in directions parallel to the confined conducting plane differ for the different subband sets (e.g., (110)n-Si). This results in different contributions to the anisotropic transport from the different subband sets.

Because of the energy separation of the subband sets, the relative subband populations are temperature dependent. The separation is gate voltage dependent through the effect of the gate voltage V_g on the degree of confinement. The transport anisotropy results in the generation of a voltage dependent transverse voltage V_T for non-principle directions. If $\partial V_T / \partial V_g > 1$, one has a differential voltage gain.

One can write, for two valleys separated by ΔE ,

$$\frac{\partial V_T}{\partial V_g} = \frac{\partial V_T}{\partial \Delta E} \frac{\partial \Delta E}{\partial W_c} \frac{\partial W_c}{\partial V_g} \quad (8)$$

Here W_c is the conducting channel width.

For the non-degenerate case, and where we neglect screening effects, one can write

$$\frac{\partial V_T}{\partial \Delta E} = \frac{\Omega(|\Gamma_A| + |\Gamma_B|)e^{-\Delta E/kT}}{kT[1 + \Omega e^{-\Delta E/kT}]^2} \cdot V_{SD} \frac{W}{L} F\left(\frac{W}{L}\right) \quad (9)$$

$$\frac{\partial x_n}{\partial V_g} = \frac{1}{2} \frac{x_n}{(V_g + V_B)} \quad (10)$$

$$\frac{\partial \Delta E}{\partial x_n} = -2 \frac{\partial \Delta E}{\partial W_c} \quad (11)$$

$$\Omega = (m_{1B}m_{2B}/m_{1A}m_{2A})^{1/2} \quad (12)$$

$$x_n = \left[\frac{N_a}{N_d} \frac{2k_s \epsilon_0}{q} \left(\frac{1}{N_d + N_a} \right) \right]^{1/2} [V_g + V_b]^{1/2} \quad (13)$$

and,

$$|\Gamma_{A,B}| = |(\gamma_{A,B} - 1)| \left| \frac{\sin \theta_{A,B} \cos \theta_{A,B}}{\sin^2 \theta_{A,B} + \gamma_{A,B} \cos^2 \theta_{A,B}} \right| \quad (14)$$

where

$$\gamma_A = \frac{\mu_{\perp A}}{\mu_{\parallel A}}, \quad \gamma_B = \frac{\mu_{\perp B}}{\mu_{\parallel B}} \quad (15)$$

and where A and B correspond to the lower and upper subband respectively. $\mu_{\perp}$ and $\mu_{\parallel}$ are the mobility values perpendicular ($\perp$) and parallel ($\parallel$) to the ellipse principle axes. m_1 and m_2 are the "free electron tensor effective mass components, V_B is the junction built-in potential, W_c is the width of the conducting channel, L the channel length, $F(W/L)$ accounts for contact shorting effects, V_{SD} is the source to drain voltage, N_d and N_a the doner and acceptor concentrations, k_s the relative dielectric constant and x_n is the depletion width on the n side of the junction, θ_A and θ_B are the angles the channel orientation make with the A and B ellipses $\partial \Delta E / \partial x_n = -2 \partial \Delta E / \partial W_c$ is computed from the expression for E_i in Appendix I.

A more general expression can be derived to include the effects of higher subbands and the effects of degeneracy. One finds that both E_F and $E_{c,i,j}$ are functions of W_c . Analyses for the transverse voltage gain for a system with two subband sets yields

$$\frac{\partial V_T}{\partial V_g} = \frac{\partial \Gamma}{\partial V_g} \cdot \frac{W}{L} F\left(\frac{W}{L}\right) V_{SD} \quad (16)$$

$$\Gamma = \left\{ \sum_{i,j} [4|\Gamma_A| n_{Ai} - 2|\Gamma_B| n_{Bj}] / \left\{ \sum_{i,j} (n_{Ai} + n_{Bj}) \right\} \right\} \quad (17)$$

$$N_d^+ W_c = \sum_{i,j} (n_i + n_j) \quad (18)$$

$$\frac{\partial \Gamma}{\partial V_g} = \frac{\partial \Gamma}{\partial x_n} \frac{\partial x_n}{\partial V_g} \quad (19)$$

$$\frac{d\Gamma}{dx_n} = \frac{1}{B^2} [B \sum_i \frac{dA}{du_i} \frac{du_i}{dx_n} - A \sum_j \frac{dB}{du_j} \frac{du_j}{dx_n}] \quad (20)$$

$$A \equiv \sum_{i,j} [4|\Gamma_A|n_{Ai} - 2|\Gamma_B|n_{Bj}] \quad (21)$$

$$B \equiv \sum_{i,j} (n_{Ai} + n_{Bj}) \quad (22)$$

$$\frac{dA}{dx_j} = -\frac{C_A}{T} \sum_i \left[\frac{1}{e^{(E_{ci}-E_F)/kT} + 1} \frac{du_i}{dx_n} \right] + \frac{C_B}{T} \sum_j \left[\frac{1}{e^{(E_{cj}-E_F)/kT} + 1} \frac{du_j}{dx_n} \right] \quad (23)$$

$$\frac{dB}{dx_j} = -\frac{D_A}{T} \sum_i \left[\frac{1}{e^{(E_{ci}-E_F)/kT} + 1} \frac{du_i}{dx_n} \right] + \frac{D_B}{T} \sum_j \left[\frac{1}{e^{(E_{cj}-E_F)/kT} + 1} \frac{du_j}{dx_n} \right] \quad (24)$$

$$C_A \equiv 4\Gamma_A \alpha_i kT \quad (25)$$

$$C_B \equiv 2\Gamma_B \alpha_j kT \quad (26)$$

$$\alpha_i \equiv 4\pi(m_{1A}m_{2A})^{1/2}/h^2 \quad (27)$$

$$\alpha_j \equiv 4\pi(m_{1B}m_{2B})^{1/2}/h^2 \quad (28)$$

$$D_A \equiv 4kT\alpha_i \quad (29)$$

$$D_B \equiv 2kT\alpha_j \quad (30)$$

$$u_{i,j} \equiv E_{c_{i,j}} - E_F \quad (31)$$

The above applies for any doping profile. If the device has n and p regions homogeneously doped and assumes the depletion approximation, the analysis is simplified by writing

$$\frac{dx_n}{dV_g} = \frac{x_n}{2} \frac{1}{(V_B + V_G)} \quad (32)$$

where x_n is the n-depletion width. Here n_i and n_j are the populations of the i^{th} and j^{th} members of the A and B subband sets, respectively.

For convenience, only results for the non-degenerate case assuming the lowest subband member of each set only is occupied will be presented here.

By considering Eqs. (9) through (15), several observations may be made for the simple case. To maximize the gain one wants to maximize $|\Gamma_A| + |\Gamma_B|$, x_n , $\frac{\partial \Delta E}{\partial x_n}$, $\Omega e^{-\Delta E/kT} / (1 + \Omega e^{-\Delta E/kT})^2 = \frac{1}{4} \cosh^2[\frac{1}{2}(\ln \Omega + \Delta E/2kT)]$, V_{SD} , $\frac{\partial x_n}{\partial V_g}$ and $\frac{W}{L} F(W/L)$ which has a maximum value of 1. $\frac{\partial x_n}{\partial V_g}$ can be maximized by setting $V_g = 0$ and maximizing x_n/V_b . This may be accomplished via doping $N_a > N_d$ and keeping the doping light. The latter is constrained however by the prerequisite for significant subbanding (dependent upon relatively heavy doping). There is an advantage in unequal densities of states with the B subband having a larger density of states. The mobility anisotropies γ_A , γ_B should be as large as possible and $\theta_B = \frac{\pi}{2} - \theta_A$ should be chosen for maximum values of $|\Gamma_A| + |\Gamma_B|$. The temperature enters the expression in a significant way. For $kT \ll \Delta E$, $G \equiv \partial V_T / \partial V_g \rightarrow 0$. For $kT \gg \Delta E$, $G \rightarrow 0$. There is clearly an optimal relationship between ΔE and kT and the gain may be expected to be quite temperature sensitive, perhaps displaying thermometric applications potential. We have performed extensive calculations on this system. They show that a differential gain is to be expected. The results will be reported at a later date.

Our other applications-oriented work has also progressed and will be described elsewhere. Effects of subband-washout will be discussed at a later date.

Publications

Ury, I. and Holm-Kennedy, J.W., "Two Dimensional Subbanding in Junction Field Effect Structures" presented at the Second International Conference on the Electronic Properties of Two Dimensional Systems held in Brechtesgaden, West Germany, September 19-22, 1977. The paper is found in Appendix I and in the Conference proceedings. It will also be published in a forthcoming issue of Surface Science.

Figures

The figures are representative of the subbanding study. The degree of subbanding is displayed as a function of device parameters and temperature. Following each figure is a set of tables showing the subband energies in meV, the Fermi energy in meV, and the relative subband populations at various channel widths ($\text{\AA}$). The calculations do not include the effects of screening.

The second set of figures show the differential transverse voltage gain for the Transverse Electric Field Field Effect Transistor (TEFFET) for various device parameters and temperature. It is noted that impurity band effects may be present and affect the mobility anisotropies. Also, any condensation effects have been ignored although they are expected to be present at low temperatures in some cases. Additional details may be added to the calculations at some future time.

Table 5D

NSI/III - Surface Channel

DONOR CONCENTRATION = .1E 20/CUBIC CENTIMETER
TEMPERATURE =300.0DEGREES KELVIN

The figure is a plot showing the relationship between Energy (eV) on the vertical axis and WC (degrees) on the horizontal axis. The vertical axis ranges from 1.2 to 300.0 eV, with major ticks every 10 eV from 1.2 to 100.0, and then 115.9, 140.2, 169.6, 205.1, 248.1, and 300.0. The horizontal axis ranges from -10 to 10 degrees, with major ticks at -10, -5, 0, 5, and 10. A horizontal line at the top of the plot is labeled 'ENERGY'. Data points are represented by dots and asterisks (*). The dots form a V-shape opening upwards, with the vertex at approximately (0, 1.2). Asterisks (*) are scattered around the dots, particularly at higher energy values and larger WC angles.

ABSTRACT

It is shown that confinement leading to substantial subbanding may be realized in the channel region of a junction field effect device. Two types of devices are considered: One having a doped surface channel the other having a doped buried channel. Useful approximate analytical expressions are presented for the values of the subband energy minima assuming a simple model for the electronic potential. The validity of these expressions are determined by comparison to a numerical calculation. Results for Si and GaAs devices are presented. The effects of a screened potential on the subband energies for a specific device are determined by numerically solving Poisson's and Schrödinger's equations. The devices appear to be interesting structures for the study of two dimensional phenomena in both the bulk and surface regions of semiconductors.

1. INTRODUCTION

Over the past decade there has been considerable study of two-dimensional subbanding in semiconductor devices [1]. The activity has been mostly centered about inversion and accumulation layers at semiconductor surfaces. A heterojunction structure has also been proposed and studied [2]. We show here that there is another class of structures, namely the junction field-effect devices, which are expected to exhibit strong quantum effects when appropriately designed [3,4,5].

2. CALCULATION

We treat here two types of junction field-effect devices, the buried channel device (BCD) and the surface channel device (SCD). The BCD (fig. 1a) consists of a thin conducting channel sandwiched between two p-n junctions. The SCD (fig. 1b) has one p-n junction with confinement on the other side of the channel provided by the surface. In either device the degree of confinement can be adjusted by varying the gate bias V_g . The nature of the potential well seen by the electrons in a homogeneously doped n-channel device is illustrated in fig. 2. The shape of the potential well seen by the electrons in the channel of the SCD (under flat-band conditions at the surface) is obtained by bisecting the potential well of the BCD and introducing an essentially infinite barrier at the surface [1]. When the applied bias is low enough to allow a substantial amount of free electrons to remain in the channel there will be a space-charge neutral region in the center of the channel whose nominal width is denoted by W_c . When the sum of the built-in and applied biases $V_b + V_g$ is sufficient to deplete essentially all the electrons from the channel the device is said to be

(a)

(b)

Figure 1. Two idealized devices considered in the analysis having (a) a buried channel (BCD) and (b) a surface channel (SCD).

in the "pinch-off" condition.

In the presence of a confining potential $V(z)$ the one electron energies will be restricted to discrete values E_i which are determined by the one-dimensional Schrödinger equation

$$-\frac{\hbar^2}{2m_3} \frac{d^2}{dz^2} \psi_i(z) + [V(z) - E_i] \psi_i(z) = 0 \quad (1)$$

where m_3 is the appropriate effective mass for motion in the z -direction [6]. Because the potential $V(z)$ for the SCD and BCD considered here are simply related, it is sufficient to solve eq. (1) for the buried channel structure. The solutions of eq. (1) for the SCD are easily seen to correspond to the antisymmetric solutions of eq. (1) for the BCD.

We first consider a BCD having a homogeneously doped n -region with a donor concentration N_d . Assuming the depletion approximation, the confining potential $V(z)$ in the n -region is given by

$$V(z) = \begin{cases} 0 & , |z| < \frac{W_c}{2} \\ \frac{q^2 N_d}{2\epsilon_r \epsilon_0} \left(|z| - \frac{W_c}{2} \right)^2 & , \frac{W_c}{2} < |z| < \frac{W_n}{2} \end{cases} \quad (2)$$

Although the depletion approximation is equivalent to neglecting the effects of Debye screening, which is precise in the limit of zero temperature, it is useful in determining the magnitude of the quantum effects. A more precise analysis including the effects of screening is presented below.

Using the form of the potential given by eq. (2) we apply the WKB method to determine the values E_i in eq. (1). The result of this approach is

Figure 2. The potential wells for a buried channel device and a surface channel device are shown. W_c is the conducting channel width; W_n is the width of the n-region; V_b the p-n junction built-in potential; V_g the gate voltage; ϵ_c the bulk semiconductor conduction band edge; and z is the dimension in the direction of confinement. The surface channel device consists of one half the full potential well with an essentially infinite potential barrier placed at $z = 0$. (a) shows the devices for $W_c > 0$ and (b) shows the devices at pinch-off.

$$E_i = (i + \frac{1}{2}) \hbar \omega_0 + \frac{m_3 W_c^2 \omega_0^2}{\pi^2} \left\{ 1 - \left[1 + \frac{2\pi^2 (i + \frac{1}{2}) \hbar \omega_0}{m_3 W_c^2 \omega_0^2} \right]^{\frac{1}{2}} \right\} \quad (3)$$

$$i = 0, 1, 2, \dots$$

where

$$\omega_0 = \left[\frac{q^2 N_d}{\epsilon_r \epsilon_0 m_3} \right]^{\frac{1}{2}} .$$

It is noted that at pinch-off ($W_c = 0$) the potential of eq. (2) has a parabolic shape and the Hamiltonian becomes that of the simple harmonic oscillator. Under these conditions the energies predicted by eq. (3) reduce to the familiar values for the energy of the simple harmonic oscillator

$$E_i = (i + \frac{1}{2}) \hbar \omega_0 . \quad (4)$$

For the SCD, the subband energies E_i may also be determined from eq. (3) where the value of W_c used in eq. (3) is understood to be equal to twice the actual surface channel width and where only odd values of i are allowed. This means that for a given channel doping concentration, the SCD would be expected to display twice the subband separation of the BCD at pinch-off. For $W_c > 0$ the subband separation for the SCD is still larger than the subband separation for the BCD due to the increased confinement created by the surface.

The Fermi level E_F for this subbanding system may be determined by considering the expression for the conservation of free carriers. The carrier concentration for the i th member of the j th subband set is

$$n_{ij} = \alpha_j P_{ij} \quad (5)$$

where the density of states is [6]

$$\alpha_j = \frac{4\pi}{h^2} n_j (m_{1j} m_{2j})^{\frac{1}{2}} \quad (6)$$

with n_j being the valley degeneracy, and where the occupation probability is [6]

$$p_{ij} = kT \ln[e^{-(E_{ij} - E_F)/kT} + 1] \quad (7)$$

The total density of carriers for the case under consideration is

$$n_{TOT} = \sum n_{ij} = N_d W_c \quad (8)$$

where N_d is the ionized donor density in the conducting channel [7].

Conservation of free carriers yields

$$\prod_{ij} \left\{ [e^{-(E_{ij} - E_F)/kT} + 1]^{\alpha_j} \right\} = e^{N_d W_c / kT} \quad (9)$$

The Fermi level is found by numerical solution of eq. (9).

Figs. 3 through 6 show E_i^{WKB} for $i = 0, 1, 2, 3$ and E_F as a function of W_c for n-GaAs and n-Si BCDs at various homogeneous channel doping concentrations. Several observations may be made from these figures:

1. The subband energy edge is strongly dependent on N_d .
2. The subband energy edge drops rapidly with W_c .
3. The adjacent subband separations for $W_c > 0$ increase for increasing quantum number i (in contrast to the results for MOS devices).
4. The two dimensional channel may be strongly degenerate with the Fermi level penetrating several subbands (e.g., see fig. 6).

These observations are easily understood. Larger values of N_d cause the potential to have a steeper slope in the space charge region thereby resulting in a higher degree of confinement and hence higher subband energies. The increasing separation of adjacent subband minima with increasing quantum number i for $W_c > 0$ occurs due to the similarity of the well to that of a "particle in a box." The increase in the Fermi

Figure 3. The first four subband valley minima vs. W_c for a (111) Si BCD doped with 10^{18} cm^{-3} donors. The system is non-degenerate at 300K.

Figure 4. The first four subband valley minima vs. W_c for a (111) Si BCD doped with 10^{19} cm^{-3} donors. The system is non-degenerate at 300K.

level with increasing W_c is a direct result of the low density of states in each subband and the linear increase in the electron concentration per unit area with increasing W_c which is expressed by [7]

$$n = N_d W_c \quad (10)$$

A numerical analysis has been performed for the solution of eq. (1) using the potential described by eq. (2) to test in the present case the validity of the WKB approach. Results for (111) n-Si with $N_d = 10^{18} \text{ cm}^{-3}$ and $m_3 = 0.258 m_0$ are shown in Table I. One observes that as the channel widens some error appears in the value for E_0^{WKB} . The error in the upper subbands decreases rapidly with increasing quantum number i . This is consistent with the semiclassical nature of the WKB approximation.

A better approximation to the ground state energy is provided by the Rayleigh-Ritz technique. The trial function was chosen to be

$$\psi(z) = \begin{cases} (z^2 - \alpha^2)^2, & |z| \leq \alpha \\ 0, & |z| > \alpha \end{cases} \quad (11)$$

where α is the variational parameter. The resulting ground state energy in terms of the dimensionless parameter C is given by

$$E_0^{\text{VAR}} = \frac{m_3 \omega_0^2 W_c^2}{8} \left[-\frac{1}{11} C^{-2} - \frac{63}{128} C^{-1} + 1 - \frac{105}{128} C + \frac{48 \hbar^2}{m_3^2 \omega_0^2 W_c^4} C^2 + \frac{21}{64} C^3 - \frac{9}{64} C^5 + \frac{5}{128} C^7 - \frac{7}{2816} C^9 \right] \quad (12)$$

where

$$C = \frac{W_c}{2\alpha} \quad (13)$$

lies on the interval (0,1) and is a root of the polynomial

TABLE I

$E_i^{\text{WKB}}/E_i^{\text{num}}$ for $N_d = 10^{18} \text{ cm}^{-3}$, $m_3 = 0.258 m_0$ - (111) Si.

$w_c (\text{\AA})$

i	0	60	120	180	240
0	0.998	1.2227	1.5378	1.8252	2.0423
1	0.9981	0.9842	1.0004	1.0425	1.0923
2	0.9970	0.9983	0.9901	0.9894	0.9997
3	0.9959	0.9968	0.9981	0.9933	0.9902

$$\begin{aligned}
& \frac{1}{11} - \frac{63}{256} C + \frac{105}{256} C^3 - \frac{48 A^2}{m_3^2 \omega_0^2 W_c^4} C^4 - \frac{63}{128} C^5 \\
& + \frac{45}{128} C^7 - \frac{35}{256} C^9 + \frac{63}{2816} C^{11} = 0.
\end{aligned} \tag{14}$$

For $W_c = 0$, $E_0^{\text{VAR}} = \sqrt{12/11} \frac{1}{2} \hbar \omega_0$ which is approximately 4.5% higher than the exact value. Comparison with the numerical results indicates that the error in the Rayleigh-Ritz result decreases with increasing values of W_c .

As mentioned above, the transition between the conducting channel and the depletion region is not abrupt at finite temperatures. To include the effects of screening exactly one must solve Poisson's equation for the electrostatic potential and Schrödinger's equation for the charge distribution self-consistently. Since such a solution requires very lengthy numerical procedures we employ here a less complicated approach which approximates the effects of screening on subband minima energies. The approximation consists of calculating the shape of the potential well assuming a three dimensional conduction band and a Boltzman distribution of carriers [8]. The resulting potential is then used to numerically calculate the subband minima energies. The subband energies calculated using this analysis on a specific device are displayed in Table II and compared to the subband energies for the unscreened potential. One observes that the inclusion of the screening in the analysis results in significantly higher subband energy minima for gate voltages below pinch-off. This effect occurs due to the smearing of charge at the edge of the conducting channel which gives rise to a rounding and effective narrowing of the potential well. At $V_g = 3.0V$, which under the depletion approximation corresponds to the pinch-off condition, one observes that the screened values are

TABLE II

Subband Energy Minima (meV) for a BCD: With screening; (KKB);
and [Rayleigh-Ritz]. $W_n = 960\text{\AA}$, $m_3 = 0.190 m_0$, $T = 300\text{K}$, $N_d = 10^{18}\text{cm}^{-3}$.

	V_g (Volts)			
i	0.0V	1.0V	2.0V	3.0V
0	1.32 (0.22) [0.62]	3.50 (0.70) [1.45]	7.98 (3.47) [4.70]	10.53 (12.30)
1	4.75 (1.84)	11.5 (5.22)	25.1 (17.3)	32.3 (36.3)
2	9.68 (4.81)	21.1 (12.51)	43.5 (34.0)	56.0 (61.5)
3	16.05 (8.91)	31.9 (21.7)	62.4 (52.1)	79.2 (86.1)
4	23.90 (14.0)	43.5 (32.2)	82.0 (71.15)	102.6 (111.0)

lower than the unscreened values. This is because with the more exact analysis some free electronic charge remains in the channel even at $V_g = 3.0V$. These remaining electrons compensate some of the ionic charge leading to a decrease in the steepness of the potential well.

3. CONCLUSION

We have shown that strong quantum effects are to be expected in appropriately designed J-FET structures. The effects are strongest at high channel doping concentrations and for semiconductors having a low effective mass. The SCD exhibits larger quantum effects than the BCD. A BCD has the advantage of being far from the semiconductor surface and is not dependent upon the availability of suitable insulators.

Although the channel free carrier concentration decreases with increasing confinement, substantial subband separation and carrier concentration (cm^{-2}) are simultaneously achievable. For example, a GaAs n-channel device having a donor concentration of $5 \times 10^{18} cm^{-3}$ and a channel width of $100 \text{\AA}$ will contain 5×10^{12} electrons cm^{-2} . Under these conditions the separation of the lowest two subbands will be 42.4 meV for the buried channel device and 68.3 meV for the surface channel device.

The magnitude of the subband separations appears to be adequate for experimental investigations using the transport and optical techniques which have been successfully employed in studying MOSFETs. Fabrication of BCD's and SCD's appears to be within the scope of current semiconductor device technology.
