19. ABSTRACT (Continue on reverse if necessary and identify by block number) Cosmic-ray nuclei that enter the atmosphere will subsequently breakup into lighter nuclei due to collisions with air particles. They also undergo a gradual loss of energy due to ionization. The fluxes and energy spectra of particles were calculated for several atmospheric depths and geomagnetic locations. The results of these radiation transport calculations are plotted as integral LET spectra showing the total number of particles that can contribute to energy lows in silicon above a given threshold value. The results can then be used to calculate the upset rate induced by cosmic ray nuclei for devices of known size and critical charge. <i>upsets, and single event upsets.</i>

COSMIC RAY EFFECTS ON MICROELECTRONICS

Part III: Propagation of Cosmic Rays in the Atmosphere

1.0. Introduction:

This report considers the propagation of primary cosmic rays through the atmosphere and assesses their effectiveness at producing single event upsets (SEU) in microelectronic components. The problem of soft upsets centers on the ability of a single charged particle, upon passage through a sensitive volume on a silicon chip, to cause the logical state of a memory circuit to change. Such upsets obviously have immense leverage in, for example, control circuit applications. Shielding against cosmic-ray-induced upsets is difficult because they are highly penetrating and have measurable fluxes at extremely high energies. The upset potential of cosmic rays is dependent on many factors including the solar cycle, geomagnetic field strength, atmospheric depth, and device orientation. In this report upset calculations in the atmosphere are described and computer code to perform these calculations is presented.

In Section 2 we consider the effect of passage through air on cosmic ray fluxes. The most prominent interactions with air are nuclear fragmentation reactions and ionization loss. Close collisions between air nuclei and cosmic rays cause breakup of the cosmic ray into lighter nuclides. Generally a few nucleons or alpha particles are emitted. The fragments retain roughly the same energy/nucleon as the incident nucleus. Secondaries, that is, accelerated fragments of silicon nuclei are not considered in this report although they are a potential source of upsets (Peterson, 1981). Leptons and mesons created in the collisions are also not considered.

Distant collisions between air molecules and cosmic rays do not change the composition. They generally cause ionization of the air. These collisions gradually decelerate the cosmic rays and modify their spectrum. The rate of energy loss, or stopping power, is proportional to the square of the cosmic ray charge. Thus the heavy ions which are most effective at causing upsets suffer greatest attenuation in the atmosphere. Nuclear decay need not be considered because propagation through the atmosphere takes a fraction of a millisecond while most decays occur on time scales of more than milliseconds.

In Section 3 results of cosmic ray propagation through air are integrated to give total flux levels at any altitude. This integration involves calculating flux levels as a function of zenith and azimuthal angles. These depend on the geomagnetic field and the amount of air to the top of the atmosphere in any direction. The latter is a sec θ effect for the altitudes considered in this report. The geomagnetic field effect results in an enhancement of fluxes to the west relative to the vertical. Total cosmic ray fluxes as a function of altitude and cutoff are displayed showing the roughly exponential decrease as a function of both variables.

Section 4 considers the conversion of cosmic ray spectra into LET (linear energy transfer) spectra and upset computations. LET spectra show the flux as a function of stopping power in silicon. Instead of

classifying according to energy, they are classified according to the rate at which they give up energy in silicon. As stated previously LET increases as the square of the cosmic ray charge. LET is not a monotonic function of energy. In fact the lowest LET occurs at high energies (a few GeV/nucleon) while the highest LET occurs at a few MeV/nucleon. The stopping powers vary by roughly a factor of 50 in this range. LET spectra for geomagnetic cutoffs ranging from 0 to 8 GV, and altitudes between 55,000 and 150,000 ft. are presented.

Given the device parameters, LET spectra may be converted into upset probabilities. In any environment the probability of upset depends on a critical charge and sensitive volume (device dependent parameters) in addition to the cosmic ray LET spectrum. The critical charge is the number of free electron-hole pairs necessary in the neighborhood of a junction to cause an upset. These pairs are created at a rate of one per 3.6 eV of deposited energy. The sensitive volume is characterized by a chord length distribution giving the relative frequency of each pathlength. The energy deposited is proportional to this pathlength.

Section 5 consists of descriptions of the programs developed to estimate soft upsets in the atmosphere.

2.0. Propagation of Cosmic Rays through Air

2.1 Master Propagation Equation

The cosmic ray flux at the top of the atmosphere consists roughly of 2500 proton/(m² sec ster), about one tenth as many He nuclei, and roughly 1 per cent heavier nuclei. The average energy of these particles is 1 or 2 GeV/nucleon. Within the magnetosphere and atmosphere they are subject to several attenuating processes. The most important are:

- 1) Fragmentation in collision with N and O nuclei in the air.
- 2) Energy loss by ionization of the air.
- 3) Deflection from the atmosphere by the geomagnetic field.

The first two of these processes are discussed in this section, while the third is discussed in Section 3.

The master equation for cosmic ray propagation with ionization loss and fragmentation (Ginzburg and Syrovatskii, 1964) is:

$$\frac{\partial J_i}{\partial t} = -nv\sigma_i J_i + nv \sum_{j>i} \sigma_{ij} J_j + \frac{\partial}{\partial E} \left(\frac{dE}{dt} \frac{J_i}{A_i} \right) \quad (2.1-1)$$

Terms in this equation are defined as follows:

J_i = Differential energy spectrum of cosmic rays of species i in particles/m² sec steradian (MeV/nucleon). If species are ordered by increasing mass, and within that by decreasing charge, then all reactions reduce the species index. For example, ${}^6\text{Li} < {}^7\text{Be} < {}^7\text{Li}$.

- σ_i = Total reaction cross-section for nuclei of species i in air.
 σ_{ij} = Partial fragmentation cross-sections for nuclei of species i to be produced in collisions of species j with air.
 n = Number density of N and O nuclei in air.
 v = Cosmic ray velocity which is related to energy/nucleon (MeV/nucleon) by

$$(v/c)^2 = \frac{E(E + 1863)}{(E + 931.5)^2}$$

A_i = Atomic mass of species i .

It is convenient to re-express eq. 2.1-1 in terms of pathlength, instead of time. The pathlength is the total number of grams of material in a cylinder of 1 cm² cross section traversed in time, t , by the particle. Thus,

$$x \text{ (g/cm}^2\text{)} = n v m t \quad (2.1-2)$$

where m is the average mass of an air atom. The pathlength between the top of the atmosphere and any point directly below is essentially equal to the air pressure at that point. However, pathlength has units of mass per unit area while pressure is force per unit area. The relation between pathlength and altitude is shown in Fig. 2.1. Data for this figure were taken from the 1962 U. S. Standard Atmosphere (NASA et al., 1962). A fit to the data valid between 50 and 150 kilofeet is also shown. Table 2.1 shows altitude vs. pathlength comparisons of special interest in this report. The composition of the atmosphere is essentially constant in the region of interest. We assume a mixture consisting of 79 per cent N and 21 per cent O by number.

Table 2.1
ALTITUDE vs. PATHLENGTH
(corresponding to computations in this report)

<u>Altitude</u>		<u>Pathlength</u>
kilofeet	kilometers	g/cm ²
150	45.7	1.33
125	38.1	3.59
100	30.5	11.1
85	25.9	22.0
75	22.9	35.0
65	19.8	56.5
60	18.3	72.1
55	16.3	92.2

In terms of pathlength Eq. 2.1-1 may be rewritten:

$$\frac{\partial J_i}{\partial x} = - \frac{\sigma_i J_i}{23954} + \sum_{j>i} \frac{\sigma_{ij} J_j}{23954} + \frac{1}{A_i} \frac{\partial}{\partial E} (w_i J_i), \quad (2.1-3)$$

where w_i is the stopping power of nuclei of species i in air. This fixes the cross section units to millibarns and the stopping power units to MeV/(g/cm²). The factor 23954 is the average mass in grams of an air nucleus divided by the unit conversion from cm² to mb.

For the purposes of further manipulation we express Eq. 2.1-3 in the condensed, matrix form:

$$\frac{\partial J}{\partial x} = M J + \frac{\partial}{\partial E} (\bar{W} J) \quad (2.1-4)$$

The fragmentation effects are contained in the modification matrix, M , and ionization loss effects in the derivative term; $\bar{W}$ is the energy loss per nucleon.

Approximating the ionization loss and backsubstituting for K we have the approximate solution:

$$J(E, x+\Delta x) = e^{M\Delta x} \left\{ \left[1 - \bar{W}(E) \frac{\Delta x}{\Delta E} \right] J(E, x) + \bar{W}(E + \Delta E) \frac{\Delta x}{\Delta E} J(E + \Delta E, x) \right\} \quad (2.1-5)$$

In this form the flux at a given pathlength and energy depends only on the flux at shorter pathlengths and greater (or equal) energies.

The flux at the highest energy, where ionization loss can be linearized (Letaw et al., 1983b), is:

$$J(E_{\max}, x) = e^{Mx} J(E_{\max}, 0) \quad (2.1-6)$$

where M now contains the term:

$$-(n\alpha - n + 1) \frac{Z_i^2}{A_i R_p} \quad (2.1-7)$$

R_p is the proton range in air, Z_i the charge of species i , n the range-energy index (~ 1), and α the spectral index (~ 2.7) of the differential flux at high energy. The relative importance of this term is gauged by comparison with fragmentation losses.

2.2 List of Isotopic Species

The most abundant cosmic rays have charges between 1 and 28. Heavier elements exist in much smaller quantities because they are beyond the stability point at iron for stellar nucleosynthesis. A list of 230 isotopes from H through Fe was extracted from the Table of Isotopes (Lederer and Shirley, 1978). Most of these isotopes are unstable but cannot decay during the fraction of a millisecond spent in the atmosphere.

To reduce the length of the list, a propagation through air (neglecting ionization loss) with pathlength of 30 g/cm² was performed. Elemental abundances were taken from Adams, et al. (1981). Isotopic abundances were estimated from recent data (Webber, 1981; Young et al., 1981; Garcia-Munoz et al., 1981). Unstable isotopes are created in fragmentation reactions. Those which did not achieve an abundance greater than or equal to 1 percent that of Fe were dropped from the list. Those which developed abundances between 1 percent and 5 percent of iron were regrouped with other isotopes of the same charge. In this way a reduced list of 104 isotopes was developed (Table 2.2).

2.3 Cross Sections

Two sets of cross sections, the total reaction cross sections σ_i and the partial fragmentation cross sections σ_{ij} , are needed to perform air propagation calculations. These cross sections are for reactions of the form:

Roughly 5500 partial cross sections and 104 total cross sections are required. These cross sections are incompletely known and are estimated using semi-empirical formulas.

The partial cross sections for many proton-nucleus reactions are given by the semi-empirical formulas (Silberberg and Tsao, 1973a,b; Silberberg and Tsao, 1977a; Tsao, et al., 1983). These are scaled up to air-nucleus interactions using procedures discussed in Silberberg and Tsao (1977b). The scale factor is roughly 2 with additional enhancement for light products.

The total cross sections are calculated using the Bradt-Peters (1950) overlap model:

$$\sigma = 49.88 (A_t^{1/3} + A_p^{1/3} - 0.4)^2 \quad (2.3-1)$$

where A_t and A_p are the target and projectile masses respectively.

When the projectile is hydrogen the cross section

$$\sigma = 44.9 A^{0.7} \quad (2.3-2)$$

(Letaw et al., 1983a) has been used.

Significant unknowns in the cross section data base are cross sections for production of light products ($A < 6$). These cross sections are not known even for proton-nucleus collisions. Errors of 20 percent or more in the proton and He abundances may result from ignoring the production of these nuclides in fragmentation reactions. Rough estimates of these cross sections for production of light nuclei were made based on data obtained by Freier and Waddington (1975).

We note here that uncertainties in the total cross sections are the single greatest uncertainty in these calculations. The error (~ 10 percent) in the total cross section for iron fragmentation causes at least n times that error in the flux after n mean free paths (1 mean free path = 16 gm/cm²). The error in partial cross sections, when averaged over the isotopes is similar in magnitude to that of the total cross sections.

We have neglected the variation of cross sections with energy in this computation and used the high-energy values. This does not result in significant error because the mean-free-path for fragmentation at low energies is much smaller than the range.

2.4 Ionization Loss

Loss of energy in the atmosphere due to ionization of air molecules is represented by the stopping power of the nuclide. The stopping power

$$w = - \frac{dE}{dx} \quad (2.4-1)$$

is the rate of energy loss [MeV/(g/cm²)] of material traversed. For protons the stopping power in air varies from roughly 200 MeV/(g/cm²) at 1 MeV down to about 2 MeV/(g/cm²) at high energies. For other particles it scales as Z^2 . Table 2.3 contains stopping powers of H, He, C, O, Ar, and Fe in air. This table was produced by programs discussed in Adams, et al. (1983a).

The range of particles in air is also required in this work. Range is defined by the integral:

$$\int_0^E \frac{dE}{w_1(E)} \quad (2.4-2)$$

and is calculated in g/cm². Table 2.4 contains ranges of H, He, C, O, Ar and Fe in air. Ranges for other nuclides may be interpolated from this table.

Table 2.3

2.5 Flux at the Top of the Atmosphere

The cosmic ray flux at the top of the atmosphere has been measured extensively. A compilation of these results and procedures for estimating the fluxes are given in Adams et al. (1981). These fluxes are dependent upon various solar system and near-earth environmental factors. Among these the 11-year solar cycle causes variations of up to an order of magnitude in fluxes. They are greatest at solar minimum, the most recent of which was late in 1977. Solar flares, which are of short duration and occur at unpredictable intervals, can cause increases of many orders of magnitude in the low energy flux. The magnetic field of the earth however can deflect all low energy charged particles below some cutoff which can be as high as 8 GeV/nucleon ($A/Z = 2$) and averages 1 or 2 GeV/nucleon.

The cosmic ray fluxes have errors of 30 percent or more. This error contributes to the overall estimate of upset probabilities, and is the most important error at high altitudes.

Isotopic abundances are not critical in estimating soft upset rates. They were taken from current data as mentioned in Section 2.2.

2.6 Results of Propagation

Vertical flux of several groups of cosmic rays as computed by the methods of this section are shown in Figure 2.2. They are compared with data of Webber et al. (1967). Good agreement with these data is found.

3.0 Cosmic Ray Fluxes in the Atmosphere

3.1 Integrated Flux in the Atmosphere

In this section the combination of differential energy fluxes into a total particle flux at any point in the atmosphere is discussed. The particle flux at any point is both zenith and azimuthal angle dependent. The two factors which determine the flux in any direction are geomagnetic cutoff and pathlength. The zenith angle, θ , is the angle the cosmic ray trajectory makes with the vertical. Pathlength in the atmosphere depends only on this angle. We may define a function $X(\theta, x_0)$ (see Section 3.2) giving the number of grams to the top of the atmosphere proceeding at a zenith angle θ from a point whose vertical depth in the atmosphere is x_0 g/cm². This function has the property:

$$X(0, x_0) = x_0 \quad (3.1-1)$$

The geomagnetic cutoff at a point depends both on the zenith and azimuthal angles. We define the azimuthal angle, ϕ , as the incoming direction of the cosmic ray as measured with respect to geomagnetic east. At any geographic point, the cutoff vs. zenith and azimuthal angles is completely determined by the vertical cutoff. Thus, the lower limit of rigidities allowed within the atmosphere at any place is given by a function $R(\theta, \phi, R_v)$ (see Section 3.3). The rigidity is related to energy/nucleon for a particular species i by:

$$R(\text{GV/c}) = \frac{A_1}{1000Z_1} \sqrt{E(E + 1863)} \quad (3.1-2)$$

where E is expressed in MeV/nucleon.

Given the pathlength and rigidity cutoff functions and the flux vs. energy and pathlength, $J(x, E)$, as computed in Section 2, the total flux at a point is:

$$F_T(x_0, E) = \int_0^\pi \sin \theta \, d\theta \int_0^{2\pi} d\phi \, J(X(\theta, x_0), E) \, g(\theta, \phi, E) \quad (3.1-3)$$

where $J(X, E)$ is the calculated particle flux (see Section 3) for energy E and pathlength X.

The function $g(\theta, \phi, E) = 1$ if the particle was able to enter the top of the atmosphere and $= 0$ otherwise. We evaluate $g(\theta, \phi, E)$ by comparing the range of the nuclide at energy E in air with the range at cutoff rigidity minus the pathlength. If

$$\text{Range}(E) \geq \text{Range}(R_{\text{cutoff}}) - X(\theta, x_0) \quad (3.1-4)$$

then the range at the top of the atmosphere was greater than the range at cutoff energy (implying the energy was greater than cutoff energy), and $g(\theta, \phi, E) = 1$.

The flux calculations are performed for a limited number of pathlengths (in this work, 7). The flux at any other pathlength is determined by interpolating between these fluxes (or extrapolating if $X(\theta, x_0) > 100 \text{ g/cm}^2$). The fluxes at two nearby points x_0 and x_1 are J_0 and J_1 respectively. Assuming an exponential decrease in flux with pathlength the flux at $x \text{ g/cm}^2$ is:

$$J(x) = J_0 \exp \left\{ \frac{\ln(J_0/J_1)}{(x_1 - x_0)} (x - x_0) \right\} \quad (3.1-5)$$

Figure 3.1 shows total flux levels for the altitudes of interest in this report versus geomagnetic cutoff. From the figure one sees that total flux can be reduced more than a factor ten by the geomagnetic cutoff. Roughly equal spacing of the curves corresponds to the roughly exponential drop in flux with pathlength.

3.2 Zenith Angle Dependence of Atmospheric Depth

The variation of pathlength with zenith angle and altitude is computed in this section. Figure 3.2 shows a schematic diagram of

earth's atmosphere at some altitude h . The vertical distance to the top of the atmosphere is denoted by x . We wish to calculate the distance, y , to the top of the atmosphere at a zenith angle θ . Applying the law of cosines we have:

$$y^2 + 2y(R_e+h) \cos \theta + (R_e+h)^2 = (R_e+h+x)^2 \quad (3.2-1)$$

therefore:

$$y = (R_e+h) \left\{ \left[\left(\frac{R_e+h+x}{R_e+h} \right)^2 - \sin^2 \theta \right]^{1/2} - \cos \theta \right\} \quad (3.2-2)$$

The square root may be re-expressed as:

$$\cos \theta \left[1 + \frac{2x}{(R_e+h) \cos^2 \theta} + \frac{x^2}{(R_e+h)^2 \cos^2 \theta} \right]^{1/2} \quad (3.2-3)$$

In this work, the altitudes under consideration are less than 64 km whereas the radius of Earth is ~ 6400 km. The third term in brackets may be neglected, while so long as $\theta < 80^\circ$ the remainder can be expanded to yield

$$y = x \sec \theta \quad (3.2-4)$$

Therefore, for zenith angles which encompass the majority of cosmic rays at a point, the relation between y and x is linear.

The linear relationship between x and y implies a linear relationship between the pathlength along the vertical to the pathlength at θ . In moving vertically between x and $x + dx$, a density $\rho(x)$ is encountered and a pathlength $\rho(x)dx$ is traversed. The corresponding move at an angle θ is over a distance $dy = dx \sec \theta$ and therefore involves traversal of precisely $\sec \theta$ times the vertical pathlength - independent of x . Thus, the pathlength vs. zenith angle relation is simply

$$X(\theta, x_0) = x_0 \sec \theta \quad (3.2-5)$$

At the point where this relation breaks down ($\theta = 80^\circ$) the cosmic ray flux is negligible, having passed through almost 6 times as much air as the vertical flux.

3.3 Geomagnetic Cutoff

Earth's magnetic field serves as an extremely effective shield of low to medium energy cosmic rays. This shielding action is characterized by a vertical rigidity cutoff at each geographical location (see energy/rigidity relation, eq. 3.1-2). Positively charged particles having rigidities below the cutoff cannot arrive at a point

vertically or from the east because they are deflected away. Arriving from the west they are deflected toward Earth and hence are able to penetrate at lower energies.

Vertical geomagnetic cutoffs have been computed at 20 km altitude by Shea and Smart (1975). For roughly 800 geographical positions, charged particles arriving vertically were propagated backward through a precise model of the geomagnetic field. Such trajectories, when the rigidity is below cutoff, eventually intersect the earth's surface. When the rigidity is above cutoff they escape earth. This method gives an accurate determination of the cutoff rigidity. A contour plot of the vertical cutoff data is presented in Figure 3.3. Note that more than half earth's surface has a cutoff rigidity of greater than 4 GV. Since the average cosmic ray energy is roughly 1 or 2 GeV/nucleon most cosmic rays are deflected from earth by its magnetic field.

The cutoff rigidity in directions other than the vertical depends on the angle of arrival (see Fig. 3.4). Low energy particles arrive predominantly west, while particles with energy much greater than the cutoff arrive from any direction. Exact arrival angles are described by the Stormer cones. The relation between the Stormer cone angle, γ , and cutoff is approximately

$$R = \frac{4R_v}{[1 + (1 - \cos \gamma \cos^3 \lambda)^{1/2}]^2} \quad (3.3-1)$$

where

$$\cos^4 \lambda = \frac{R_v}{17.6} \left(\frac{1 + \text{altitude (km)}}{6371} \right)^2 \quad (3.3-2)$$

Plots of the ratio of cutoff to vertical cutoff for various vertical cutoffs and Stormer cone angles are displayed in Fig. 3.4.

The Stormer cone angle, γ , is related to the azimuthal and zenith angles by

$$\cos \gamma = \cos \phi \sin \theta \quad (3.3-3)$$

Eq. 3.3-1 through 3.3-3 allow the geomagnetic cutoff for any arriving angle to be determined from the vertical cutoff and altitude. Further discussion of the geomagnetic field effect on cosmic rays is contained in Adams et al. (1983).

4.0 Single Event Upsets

4.1 LET Spectra

Up to this point we have discussed the calculation of cosmic ray spectra in the atmosphere for each charge species. There is no direct relation between these spectra and single event upsets because the rate of energy deposit by a cosmic ray bears a complicated functional

relation to its total energy. The LET (linear energy transfer) or stopping power of a charged particle is its rate of energy loss in matter. Table 4.1 shows the stopping power in silicon for several elements in MeV/(g/cm²). It is notable that the stopping power is at a minimum and roughly constant above 1 GeV/nucleon.

The transformation from energy spectrum to LET spectrum is:

$$J(L) = \sum_i J_i(E) \left(\frac{dL}{dE_i} \right)^{-1} \quad (4.1-1)$$

where the sum over species is necessary because the stopping power is charge dependent. The differential LET spectrum represents the energy transfer characteristics of all species in one spectrum. Because L is not a monotonic function of E its derivative can be zero, thus $J(L)$ has singular points corresponding to stopping power minima and maxima for all the elements. These singularities are avoided in numerical applications by using LET and energy bins, and defining the LET spectrum by

$$J(L) = \sum_i J_i(E) \frac{\Delta E}{\Delta L} \quad (4.1-2)$$

In our work we have divided the LET interval ($1 \leq L \leq 10^5$ MeV/(g/cm²)) and the energy interval ($1 \leq E \leq 8$ GeV/nucleon) into 500 bins with special treatment of particles above 8 GeV/nucleon.

In practice it is convenient to use the integral LET spectrum

$$N(L) = \int_L^{\infty} J(L) dL \quad (4.1-3)$$

because it does not fluctuate, but decreases monotonically from $L = 0$. Integral LET spectra for cosmic rays at various altitudes and geomagnetic cutoffs are shown in Fig. 4.1-4.9. Interpolation allows the spectrum to be found at any altitude between 50 and 150 thousand feet at any location. For example, Fig. 4.10 shows the integral LET spectrum at 10^3 MeV/(g/cm²) for all altitudes and cutoffs.

Figure 4.1 shows the typical behavior of the LET spectrum as a function of altitude. At 150,000 ft., where very little slowing down has taken place, the geomagnetic field essentially eliminates ions with $LET > 2 \times 10^3$ MeV/(g/cm²). This occurs because all heavily ionizing (i.e., low energy) Fe are deflected while higher charge species are extremely rare. By 85,000 ft. many high energy Fe ions have slowed down because of ionization loss and the spectrum is appreciable to 10^4 MeV/(g/cm²).

4.2 Soft Upsets

The relation between soft upsets and the LET spectrum is governed by the critical charge of the device, Q_c , and the geometry of the sensitive volume. An energy deposition in the sensitive volume causes

Table 4.1

free electron-hole pairs to be created at a rate of 1 pair per 3.6 eV deposition. This charge is then, by definition of the sensitive volume, able to accumulate and cause a change in device state. Device sensitivities are discussed in a number of articles (Pickel and Blandford, 1980; Petersen et al., 1982; Ziegler and Lanford, 1979). The critical charge is a few pC for devices with length scales on the order of 10-20 μm . It varies roughly as the inverse square of the length scale. Radiation hardened devices have a critical charge about twice as large. The total charge freed when ΔE is deposited is

$$Q(\text{pC}) = \frac{\Delta E (\text{MeV})}{22.5} \quad (4.1-4)$$

Thus the upset rate is the number of particles per unit time which deposit an energy greater than or equal to

$$\Delta E_c = 22.5 Q_c \quad (4.1-5)$$

Since ions lose energy linearly at a rate equal to their LET (in thin slabs of matter), the upset rate depends only on the LET spectrum and the distribution of chord lengths in the sensitive volume.

The chord length distribution $C(p)$ is a probability density. Assuming the sensitive volume is subject to an isotropic cosmic ray flux, $C(p) dp$ is the probability that a cosmic ray will pass through between p and $p + dp$ of the region. This is a purely geometric quantity which is known exactly for any rectangular parallelepiped (Pickel and Blandford, 1980). The energy deposited by a charged particle over the length p is

$$\Delta E = \rho L p \quad (4.1-6)$$

where ρ is the density of silicon (2.32 g/cm³). For a chord length p any charged particle with LET greater than

$$L_{\min} = \frac{22.5 Q_c}{\rho p} \quad (4.1-7)$$

causes a device upset. The total number of upsets/sec is therefore

$$U = \bar{A}_p \int_0^{\infty} N(L_{\min}) C(p) dp, \quad (4.1-8)$$

where $\bar{A}_p$ is the mean projected area of the sensitive volume, equal to one quarter the surface area of a rectangular parallelepiped, and $C(p)$ is the chord length distribution. $N(L_{\min})$ is given by Equation 4.1-3.

Figures 4.11 through 4.14 show typical upset rates and their variation with parameters of the calculation. In Figure 4.11 the variation with altitude show that upset rates for a sensitive volume $5 \times 10 \times 10 \mu\text{m}$ and critical charge between .1 and 1 pC are strongly dependent on atmospheric depth. At the top of the atmosphere the cutoff excludes highly ionizing Fe, while at lower altitudes ionization loss restores the low energy iron flux. At 75,000 ft. the variation with cutoff is shown in Figure 4.12. Highly ionizing Fe are restored from a cutoff of 1 GV, but not at the 4 GV level. The breakdown into element

groups (Figure 4.13) shows that for critical charges above 0.02 pC, the heaviest ions contribute most to soft upsets. Lighter ions are of importance in proportion to their charge. Figure 4.14 shows the variation of several orders of magnitude possible with varying device sensitivity.

5.0 Computer Code

In this section the computer code developed to estimate soft upset rates in the atmosphere is presented. These programs may be classified as follows:

- (i) Data Files and Data File Preparation Programs
- (ii) Air Production Programs
- (iii) Post-processing Programs
- (iv) Command File Generator

Classes (i) through (iii) are VAX-11 FORTRAN programs and data files. This FORTRAN version is an extension of the standard FORTRAN-77 and the programs may not be compatible with other systems. The structure of this system of programs and data files is shown in Figure 5.1. The Command File Generator is written in the VAX/VMS command language, DCL (Version 3.2). This file generates a command file which associates the programs and data files correctly and requests all required input data. The command file may be submitted for execution when convenient.

5.1 Data Files and Data File Preparation

There are four input data files required for execution of these programs.

1) SILPOW - Stopping powers of H, He, C, O, Ar, and Fe in Si (same as Table IV.1). Format (F8.3,6(3X,1PE9.3)).

2) ASTPOW - Stopping powers of H, He, C, O, Ar and Fe in air (same as Table II.3). Format (F8.3,6(3X,1PE9.3)).

3) ARANGE - Range of H, He, C, O, Ar and Fe in air (same as Table II.4). Format (F8.3,6(3X,1PE9.3)).

4) SOURCE3 - List of Isotopic Species (same as Table II.2), Format (5(I3,A2,I3),F6.3).

In addition, four data file preparation programs create the remaining four files:

5) QAIR3 - List of partial cross sections for production of lighter nuclides from heavier nuclides in collision with air, produced by the program, QAIR, which requires the subroutine YIELDX (IZ, IA, JZ, JA, E, S). YIELDX returns the partial cross section, S, for the process $N_i + p \rightarrow N_j + p + \text{anything}$ at energy, E (MeV/nucleon).

6) FLUXES - Fluxes at the top of the atmosphere for the isotopic species in SOURCE3. The program FLUX uses Adams et al. (1981) model of cosmic ray fluxes as modified by recent experimental work.

7) RANGIN - Produced by RANGER and contains data on flux loss in passing through $.1 \text{ gm/cm}^2$ air.

8) POWIN - Produced by POWER and contains stopping power data on the nuclides in SOURCE3, interpolated from ASTPOW.

The data file preparation programs are listed in Appendices 1 through 9. A subroutine, CUBSPL, which performs cubic spline interpolation is required for execution of RANGER. This subroutine is shown in Appendix 5.

5.2 Air Propagation Programs

The techniques used in the air propagation programs are discussed in Section 2. The procedure is separated into two parts. In the first (APROP) propagation through all but the last gram of air is performed. Only fragmentation for the last gram is performed. In the second (GRAM) the last gram of ionization loss is performed, meanwhile extending the minimum energy from 30 MeV/u to 1 MeV/u. These programs are shown in Appendices 6 and 7.

The two subroutines of APROP (appended to the program) are AIRMAT and ILOSS. AIRMAT constructs the matrix of total and partial cross sections. The partial cross sections are read in from QAIR3 while the total cross sections are calculated using 2.3-1 and 2.3-2. In ILOSS the coefficients in 2.1-7 pertaining to ionization loss are calculated as needed.

5.3 Post-Processing

The three post-processing programs exhibited in Figure 6.1 are found in Appendices 8, 9 and 10. These programs take the results of air propagation and convert them into the quantities of interest in this report.

ATMOS interpolates the seven flux files at 0, 5, 15, 30, 50, 75, and 100 gm/cm^2 and integrates them over zenith and azimuthal angles to get the total integrated flux. These procedures are discussed in Section 3. The functions RANGE and STPOW estimate the range-energy and stopping power relations in air using the Bethe-Bloch theory. These are used in combination with CUTFACT to evaluate the inequality 3.1-4. CUTFACT determines the angular dependence of the geomagnetic cutoff. The subroutine ALTGRM computes the altitude vs. grammage relation of Fig. 2.1. FLUX performs the exponential interpolation (Eq. 3.1-5).

LETINTT performs the conversion from flux to LET spectrum for all species. It calls the cube spline subroutine, CUBSPL. Methods are discussed in Section 5.1.

UPSET converts the LET spectrum into an upset vs. critical charge profile. It depends on geometrical properties of the sensitive region which is assumed to be a rectangular parallelepiped. The function DIFPLD evaluates the analytic form of the differential pathlength distribution.

Figure 2.1 Altitude vs. pathlength in the atmosphere between 50,000 ft. and 150,000 ft. Pathlength is proportional to pressure and varies roughly exponentially with altitude.

Figure 2.2 Comparison of vertical cosmic ray fluxes in the atmosphere (Webber et al., 1967) with computations of this work.

INTEGRAL FLUX vs. CUTOFF FOR VARIOUS ALTITUDES

Figure 3.1 Integral cosmic ray flux (mostly protons) as a function of altitude and geomagnetic cutoff. Equal spacing of curves shows roughly exponential decrease with increasing depth in the atmosphere.

Figure 3.2 Schematic diagram of relation between vertical pathlength, x , to a point in the atmosphere and the pathlength, y , at zenith angle θ .
