ABSTRACT

This thesis presents a microcomputer based, computer-aided design program for tactical military tropospheric scatter radio systems. The program has the capability of predicting the system performance and reliability for both analog (FM/FDM) and digital troposcatter radiolinks. Propagation gain generated by elevated tropospheric ducting is called height gain. A height gain computational model for specific elevated tropospheric ducts is derived from statistical radiosonde data. A terrain profile plot, real-time radiosonde data analysis, and the probability of error for digital radiolinks are provided as program options.

I. INTRODUCTION

A. PURPOSE

The development of digital transmission techniques in military communications systems has generated a renewed interest in tropospheric scatter. Digital troposcatter radio systems have required changes in the present planning and engineering design methods. The military design engineer has the responsibility to predict system performance and reliability within limited planning time. Under certain tactical situations, the urgency to restore vital communications has forced the engineer to provide several alternative designs for a single communications link. These requirements have justified the need for an efficient, computer-aided design method to accomplish the task. The purpose of this thesis research is to develop a tropospheric scatter communications system design program. The objective is to design a microcomputer-based program which will predict the path reliability and system performance for troposcatter radiolinks. This program will introduce

several improvements over the manually generated, nomograph-based design methods. Specifically, the program will estimate the height gain at the average system antenna height for specific elevated tropospheric ducts. Other features include a terrain profile plot, radiosonde weather data analysis, and the calculation of the probability of error for binary and orthogonal digital signaling techniques.

B. BACKGROUND

Tropospheric scatter communications systems propagate microwave energy beyond line-of-sight (LOS) or "over the horizon" by taking advantage of the refraction and reflection phenomena in a section of the earth's atmosphere called the troposphere. Typical military troposcatter systems use transmitter power outputs from 1 to 10 kW, parabolic type antennas, and sensitive broadband FM receivers with front-end noise figures (NF) between 2.0 - 4.0 dB. These systems are most often employed in military applications because of the limited available channel capacity [Ref. 1:pp. 253-254]. Several system advantages are summarized as follows:

1. Fewer terminal and/or relay stations are required to cover the same transmission path as compared to tactical microwave line-of-sight radiolinks.

2. Reliable multichannel communications can be installed across long distances of hostile or inaccessible terrain.
3. Standard transmission ranges are suitable for the tactical military field environment for radiolinks from 30 to 200 miles.

A fundamental design parameter for troposcatter links is the allocation of allowable channel degradation to each link making up the total communications system. In analog scatter systems, the quality parameters are system availability and signal-to-noise ratio in the voice channel. However with the deployment of digital troposcatter radio systems the performance of the digitized voice channels under fading conditions is significantly different than the performance of analog voice systems under the same conditions. The primary measure of transmission quality for a digital system is its error performance. There are two main sources of transmission errors: (a) long-term error rate which will occur because of equipment degradation, channel interference, and long-term power fading; and (b) multipath fading [Ref. 2:pp. 4-5].

C. RELATED WORK

1. Performance Models for Troposcatter Links

Monsen [Ref. 3] has derived performance models for analog FDM/FM and digital quadrature phase shift keying (QPSK) systems on troposcatter communications links. The analysis included the effects of signal level variations and multipath delay dispersion. His performance criterion was the outage probability rather than either average error rate or median signal-to-noise ratio (SNR) values. Outage probability performance in a digital system was derived for two different modems: the Decision-Feedback Equalizer (DFE) and a transmitter time-gating technique, the Distortion Adaptive Receiver (DAR). Analog system performance was determined for the percentage of the time that the voice channel SNR including thermal noise and multipath delay dispersion effects were below a specified threshold.

The performance test results for a Distortion Adaptive Receiver (DAR) was presented in a paper by Zawislán [Ref. 4]. The critical problem with digital troposcatter is intersymbol distortion produced by the multipath dispersion of the fading channel. To resolve this problem, the distortion adaptive receiver was

implemented. The DAR modem employed QPSK modulation with adaptive matched filter demodulation. A complete functional description was explained in the reference. The advantage to this approach was that it did not require equalization at the receiver to correct intersymbol interference and it provided near optimum performance using the adaptive matched filter receiver.

Typical bit error rate performance for the DAR on a troposcatter channel is shown in Figure 1-1 for different values of rms multipath delay dispersion. For low multipath spread, the fading on each diversity channel has a Rayleigh distribution and the performance is indicated by the "flat. fading" marked curve. Note that the performance improves rapidly with increasing multipath spread and, at a 10^{-5} error rate a 10 dB improvement is achieved for multipath curve [B]. However, as the multipath spread increases (with increased path length), a irreducible error rate occurs as shown in curve [C] due to the transmitter time-gate limitation. To compensate for this problem, the DAR is modified by utilizing a dual frequency pulse waveform. This technique is also used in the modem employed by the AN/TRC-170 tactical digital troposcatter radio set.

SINGLE PULSE DAR PERFORMANCE

Figure 1-1 Distortion Adaptive Receiver Performance
(After Zawislan, Ref. 4:p. 3)

2. Tropospheric Elevated Duct Models

Several mathematical models have been developed to calculate the ducted signal field strength based on the refractivity profile and by modeling the tropospheric duct as a laterally homogeneous-layer atmospheric waveguide [Ref. 5:pp. 22]. A detailed mathematical analysis was presented by Marcus and Stuart [Ref. 6]. These authors have developed an effective modal solution computer program, called "DUCT", which requires a large processing capability of a main-frame computer [Ref. 7]. A version of this program, called "PDUCT", is available at the Naval Postgraduate School Computer Center [Ref. 8] and [Ref. 5:pp. 23-24].

Weston [Ref. 5:pp. 58-70] has proposed a statistical model, based on "PDUCT" predictions for selected ducts of interest. The height gain data, for these ducts, was used to derive model coefficients. These unique coefficients were stored according to their respective transmitter and receiver heights in a matrix form. Thus, given a receiver height and range from the transmitter for a selected duct/frequency data point, the coefficients for each receiver height are obtained and used to produce the corresponding height gain curve.

This approach required a significant number of main-frame computer "PDUCT" computations to establish height gain data for all the ducts of interest.

In December 1983, a microcomputer-based program, called "MINIDUCT" Version 1.1, based on Knorr's mathematical model was developed by Nagel, [Ref. 9], at the Naval Postgraduate School to calculate elevated ducted signal levels at various frequencies. This program used either historical radiosonde data or current elevated duct information [Ref. 10]. The radiosonde data represented the atmospheric temperature, pressure, and humidity at specific altitudes over a five year recording period. This model was valid for the case where the transmitter is at the optimum duct coupling height and the receiver is located either below, within or above the duct. The optimum coupling height is the altitude above the surface where the gradient of the modified refractive index becomes negative.

II. TROPOSPHERIC PERFORMANCE CONSIDERATIONS

A. SCATTER PROPAGATION

1. General

At frequencies above 30 MHz three propagation mechanisms can carry energy beyond the horizon: (a) variations in the refractive index in the troposphere can scatter radio energy, (b) horizontally-stratified abrupt changes in the refractive index can cause reflection, and (c) atmospheric regions of negative modified refractive index gradients can introduce ducting. Refractive index and tropospheric ducting will be thoroughly discussed in the following section. The forward scattering of radio signals is the most dominant propagation mechanism at the frequencies of 0.3 to 10 GHz. [Ref. 11:p. 1]

2. Received Scattered Field

The index of refraction depends on pressure, humidity, and temperature. Slight variations in these quantities, caused by atmospheric turbulence, will produce random fluctuations in the refractive index. When an electromagnetic wave propagates through this

inhomogeneous medium, energy will be scattered out from the original incident direction. The turbulent-scattering theory, [Ref. 12:p. 345], has shown to a first approximation that the index of refraction fluctuations can be replaced by a model of so-called "blobs", inhomogeneities of different dielectric constants randomly distributed. If these "blobs" are in the common volume formed by the transmitter and receiver antenna beams, the complex received field can be described by [Ref. 13:p. 146]:

$$Re^{j\theta} = \sum_{i=1}^m A_i e^{j\phi_i} \quad (2-1)$$

where m is the number of "blobs" in the scattering volume, A_j is the amplitude, and ϕ_j is the phase of a wave scattered by a single "blob". Assume m to be very large and the blobs are spherical and uniformly distributed through the scattering volume. Then the phase difference of the waves scattered by the inhomogeneities at the top and bottom of the volume will be [Ref. 13:p. 147]:

$$\Delta\Phi = \frac{4\pi h \sin\gamma}{\lambda} \quad (2-2)$$

where γ = transmitter, receiver antenna elevation angle

h = mean thickness of the scatter volume (m)

λ = transmitter wavelength (m)

The variables in Equation 2-2 are described in Figure 2-1.

By observing the volume geometry, it can be determined that more "blobs" exist in the central volume region than at the top or bottom. This indicates a non-uniform "blob" distribution.

Many phase variations will occur over many phase cycles of length 2π . The antenna elevation angle will be less than 2 degrees for most systems and the ratio of scatter volume thickness to operating wavelength will be very large. These conditions make the scattered phases uniformly distributed from zero to 2π [Ref. 13:p. 148].

The amplitude distribution will now be determined. The real and imaginary components of the complex received field, Equation 2-1, were resolved into two random variables X and Y . The number of blobs, m , is assumed to be large, so by the Central Limit Theorem, both X and Y will approach a normal "gaussian" distribution. Finally it was shown that these variables

Figure 2-1 Scatter Volume Geometry

(After Beckmann, Ref. 11:p. 147)

are also uncorrelated and independent. Then their two-dimensional normal distribution can be transformed into the Rayleigh distribution.

Turbulence, mixing, and wind continuously change the positions and structure of the inhomogeneities making the random terms of Equation 2-1 functions of time. The reality of nature is the inhomogeneities do not vary isotropically because the index of refraction changes more rapidly with altitude than with distance. There can also be a stratification or layering of inhomogeneities near a particular height (or heights) that changes the assumed spherical shape of the so-called "blobs". Under these conditions the uniform phase distribution may change to an unknown distribution.

B. TROPOSPHERIC DUCTING.

The index of refraction, n , of air is defined as the ratio of the velocity in a vacuum of electromagnetic (EM) radiation to the velocity in the medium. A convenient parameter is refractivity, N , defined as [Ref. 11:p.14]:

$$N = (n - 1) \times 10^6 \quad (2-3)$$

Another parameter called modified refractivity, M , is defined as [Ref. 10:p.9]:

$$M = N + 0.157 h \quad (2-4)$$

where h is the altitude in meters above the surface. The modified refractivity accounts for the curvature of the earth so the presence of ducting can be easily determined by observing the M -gradient on the M versus height plot.

Refraction of incident radio waves across a discontinuity of refractivity is described by the principles of Snell's Law. It is important to remember that the wave "bends" towards the higher value of refractivity, and the more dense a material the higher its n . Since the density of the atmosphere decreases with height, we expect that a wave will bend back downward from a geometric straight path. Whenever the refractive index decreases sharply with height, radiowaves can be trapped and experience low-loss propagation for long distances. This condition is known as tropospheric ducting [Ref. 11:p. 29].

The following conditions must be satisfied for a duct to occur: (1) the modified refractive index gradient shall be equal to or more negative than 0 M-units/km, and

(2) this gradient should continue over a height of many wavelengths. The important duct parameters are the duct thickness, D , the intensity, M , and the optimum coupling height, H_{opt} . A piecewise linear approximation to the modified refractivity (tri-linear) profile for several types of ducts are shown in Figure 2-2. There are three types of ducts: (1) surface or ground-based ducts, also called evaporation ducts when formed over water, Figure 2-2a; (2) surface-based ducts from elevated refractive layers, Figure 2-2b; and (3) elevated ducts from elevated refractive layers, Figure(s) 2-2c and d. Note that all positive M -gradients are assumed at 118 M -units/km which corresponds to a standard atmosphere. Once the slopes are identified, the important duct parameters are quickly determined [Ref. 9:pp. 9-12].

Tropospheric ducts more often occur as ground-based ducts because of both evaporation and advection. Evaporation of water vapor from the surface of the sea may create a zone of high humidity (i.e. high refractive index) below a region of drier air. Advection, defined as the movement of one air type over another, may cause hot dry air (from the land) to be blown over cold wet air, producing a region of low refractive index above a region of high refractive index. Such a duct may also

Figure 2-2 Tropospheric Duct Descriptions
(After Marcus, Ref. 7:p. 2-5)

form when warm dry air is blown over cold ground. Radiation cooling can produce temperature gradients which cause ground-based ducts. Air next to the ground becomes cooler and the duct becomes thicker as the night continues.

When morning solar heating warms the air next to the ground, a region of rapid decrease of refractive index with height produces an elevated duct. However these ducts quickly disappear because continued ground heating increases convection mixing and destroys the stable elevated layer. Elevated ducts may form for several days by a subsidence inversion. Hot air rises at the center of a high pressure region and spreads out horizontally, cooling as it slowly descends. This produces a boundary with the slightly colder air near the surface. The increasing temperature with height at the boundary forms the subsidence (temperature) inversion. Changes in temperature and/or humidity may cause related changes in the refractive index within the boundary interval [Ref. 11:pp. 33-35].

Figures 2-3a thru d illustrate propagating rays within ground-based ducts. Rays leaving the transmitter at elevation angles close to the horizontal will parallel the earth's surface, while other departing rays will

Figure 2-3 Propagation Effects of Ducts
(After Hall, Ref. 9:p. 31)

either travel upward or downward. If the M-gradient is negative and assumed uniform within the duct, rays beginning at elevation angles below the critical angle, defined as [Ref. 11:p. 31]:

$$\theta_c = \sqrt{(2 \Delta M \times 10^{-6})} \quad (2-5)$$

will strike the surface, and those above the critical angle will leave the duct. If ground reflection is neglected, Figure 2-3a, a shadow region depicts minimum propagated energy. In the case where surface reflectivity is high, Figure 2-3b, the rays launched within the critical angle range will travel beyond the radio horizon. Figure 2-3c describes the situation when the M-gradient is not constant within the duct. If a transmitter is positioned in the height region h , then rays within the $\pm \theta_1 = \pm \sqrt{(2 \Delta M_1 \times 10^{-6})}$ range ^a will remain in the duct with bounces as depicted in Figure 2-3b. Similarly rays transmitted within the $\pm \theta_2 = \pm \sqrt{(2 \Delta M_2 \times 10^{-6})}$ range are trapped within the height range h . Finally a surface-based duct from an elevated layer over rough terrain is illustrated in Figure 2-3d. In this case the refractive "bending" takes place at the top of the duct [Ref. 11:pp. 30-32].

For elevated ducts formed by advection or subsidence, the position of the transmitter and receiver relative to the optimum coupling height, H_{opt} , will influence the propagation effects. The means in which energy enters or leaves an elevated duct can be described by the duct acting as a "leaky" waveguide. Energy is "leaked" or coupled into the duct from the transmitter, and "leaks" out as the energy propagates along the duct [Ref. 11:p. 36].

Because of the non-permanent characteristic of elevated ducts, their effects are seldom an influence to troposcatter links, especially if they form above the common scatter volume. But the presence of tropospheric ducts can degrade the overall performance of troposcatter systems by changing the predicted transmission loss. The term that will change the total path loss is the duct's height gain, which is derived in Chapter IV.

C. MULTIPATH CONSIDERATIONS

The multipath fading model for a tropospheric scatter channel produces received signal fading. The received signal consists of the sum of a large number of time-variant, complex vectors having amplitudes and phases. The fading is caused by randomly time-variant

phases variations. At times the received signal vectors add destructively to decrease the mean received signal amplitude. While at other times, the vectors add constructively, so the received signal is large. Thus the amplitude variations, or signal fading, are due to the multipath characteristics of the tropospheric channel. The channel can be modeled as a zero mean, complex-valued gaussian process, with the envelope of the instantaneous signal level being Rayleigh-distributed. This Rayleigh fading channel describes the short-term fading. When there are fixed constant regions of refractivity or stratified refractive layers in the vicinity of the common scatter volume the channel cannot be modeled as having a zero mean. In this case, the Rayleigh distribution does not apply and the channel approaches a Rice distribution [Ref. 14:pp. 456-458]. All performance predictions in this study will assume Rayleigh "short-term" fading as the channel model.

Channel performance will be degraded during periods of severe multipath fading. With digital systems, the voice user is unaware of any increase in background noise until the PCM (Pulse Code Modulation) outage threshold is broken. Once this threshold is passed the complete multichannel circuit will be unusable due to noise. The

characteristics of fade outages for a typical digital troposcatter circuit can experience three (3) primary categories of fade outage. The first category occurs when the voice user is subjected to a single fade outage of duration less than 200 milliseconds. This outage will be hardly noticed. The second category of outage will have an outage duration ranging from 1/5 second to 5 seconds. The user will detect this distortion but will continue to communicate following the outage. When a recurrence of short duration outages take place (e.g. 2 to 4 outages per minute) annoyance rather than total disruption will occur. The third category are fade outages that exceed a subjective level of user patience. The Defense Communications Agency (DCA) [Ref. 15] has specified five (5) ranges of fade outage conditions, refer to Table I. DCA has defined the fade outage in terms of a diversity signal-to-noise ratio threshold corresponding to a 10^{-4} bit error probability.

Techniques used to counter multipath propagation are frequency diversity, space diversity, amplitude equalization, and channel equalization. If a modulated signal is simultaneously transmitted over the same troposcatter radiolink on two or more frequencies, the correlation between the individual received signals will

TABLE I

be small. This method of signal diversity is called frequency diversity. The important advantage of frequency diversity is that it requires a single antenna at each site. But the need for additional frequencies can increase the probability of co-channel interference among other operating transmitters.

Uncorrelated short-term fading can also be achieved by separating the receiving antennas in space. This is known as space diversity. Horizontal and vertical polarization can be used to distinguish between two space-separated signals. However horizontal and vertical polarization do not provide a satisfactory degree of noncorrelation of signal fading for efficient diversity.

The multiplicity of signals provided by these diversity methods must be combined. The diversity-combining techniques are classified into: (1) selection or switching; (2) combining a desirable weighted combination of received available signals; and (3) a combination of selection and combining.

In the selection techniques the diversity channels are scanned until one is found whose level exceeds a selected threshold. This may not necessarily select the best available signal. In the combining techniques, all

diversity channels are simultaneously monitored and equally weighted. This is called equal-gain combining. In maximal-ratio combining, the weighting factor of each channel is automatically adjusted to yeild the maximum signal-to-noise ratio for the total of all the diversity channels [Ref. 12:pp. 453-454].

Amplitude equalizers are designed to properly equalize the propagation channel for minimum phase fading. Channel equalizers balance the channel for amplitude and mutlipath delay distroction. They are typically adaptive transversal equalizers that consist of tapped delay lines (TDL) with tap-weight multipliers (i.e., amplifiers or attenuators); and control circuitry that adaptively vary the tap-weights in response to temporal channel variations [Ref. 16:p. 11-12].

III. TROPOSCATTER SYSTEM DESIGN PROGRAM

A. GENERAL PROGRAM ALGORITHM

The main program, named "TROPO", is presented as Appendix B. Figure 3-1 illustrates the program flow and the primary computational program modules. The program development and mathematical approach for the Radiosonde Data Analysis and Height Gain modules are described in Chapter IV. The remaining modules are formulated in this chapter. A program tutorial and compilation instructions are contained within the program.

B. PREDICTION OF PATH LOSS

1. General

The basic median transmission loss will be the sum of several additive losses, expressed in decibels, [Ref. 17]:

$$L_T = L_s + L_d + L_c + L_a + L_w - G_t - G_r + HG \quad (3-1)$$

where L_s = free-space propagation/scatter loss (dB)

L_d = knife-edge diffraction loss (dB)

L_c = medium-to-aperture coupling loss (dB)
 L_a = atmospheric absorption loss (dB)
 L_w = waveguide/connector loss (dB)
 G_t = transmit antenna gain (dB)
 G_r = receive antenna gain (dB)
 HG = height gain (dB)

2. Surface Refractivity

An adjustment to the average surface refractivity N_o , refer to Figure 3-2, is made for the elevation at each terminal site. The adjusted surface refractivity, N_s , is [Ref. 18:p. 2-12]:

$$N_s = N_o \exp(-0.03222h_s) \quad (3-2)$$

where N_o = minimum monthly average refractivity
 h_s = average antenna height (kft)

If the surface refractivity at each site is significantly different, an option to calculate the respective N_s for each site can be selected and an average path surface refractivity can be calculated. The average antenna height is calculated by averaging the transmit and receive antenna heights.

Figure 3-2 Monthly Surface Refractivity (Sea Level)

(After Panter, Ref. 12:p. 375)

3. Effective Earth's Radius

Changes in the surface refractivity will effect the radio-ray path curvature as the wave propagates over the earth. To accurately represent the ray-path an effective earth's radius is calculated as [Ref. 12:p. 374]:

$$a = a_o \left[1 - 0.04665 \exp(0.005577N_s) \right]^{-1} \quad (3-3)$$

where a_o = actual earth's radius (6370 km)

4. Terrain Profile Plot

Several methods are available to plot a troposcatter system terrain profile. The most fundamental method is to plot the successive path terrain elevations along the great circle path. Special 4/3 earth plotting graph paper is required for this method. Alternatively, computer graphics techniques which obtain terrain information from topographical databases, can rapidly plot the profile.

The program provides a dot-matrix printer plot. The terrain profile is linearly plotted by modifying the terrain elevations, in meters, to include the effect of

the average curvature of the radio-ray path and the earth's surface. Elevations, h_i , of the terrain are manually obtained from topographical maps and tabulated versus distances, x_i , from a selected reference terminal. The terrain data points are keyboard entered into the program. The modified elevations are computed as [Ref. 12:p.380]:

$$y_i = h_i - \frac{x_i^2}{2a} \quad (3-4)$$

where a = effective earth's radius (Equation 3-3)

Figure 3-3 illustrates a typical linear terrain plot.

5. Calculation of the Angular Distance

The terrain profile can now determine various path geometries. The three (3) path configurations considered are:

- a. Smooth Earth Horizons at Both Terminals
- b. Obstacle Horizons at Each Terminal
- c. Smooth Earth and Obstacle Horizons

The terrain geometries are depicted in Figure(s) 3-4a, 3-4b, and 3-4c. The respective terminal take-off angles are calculated for the predicted path type as [Ref. 12:pp. 385-337]:

Figure 3-4a Smooth Earth Path
(After Panter, Ref. 12:p. 385)

Figure 3-4b Near Obstacle Path
(After Panter, Ref. 12:p. 386)

Figure 3-4c Near Obstacle/Smooth Earth Path
(After Panter, Ref. 12:p. 385)

a. Type I Radio Horizon/Radio Horizon

$$\theta_{et} = - \frac{\sqrt{2ah_{ts}}}{a} \quad (3-5a)$$

$$\theta_{er} = - \frac{\sqrt{2ah_{rs}}}{a} \quad (3-5b)$$

where h_{ts} , h_{rs} = transmitter, receiver terminal elevation

b. Type II Obstacle Horizon/Obstacle Horizon

$$\theta_{et} = \frac{h_{lt} - h_{ts}}{d_{lt}} - \frac{d_{lt}}{2a} \quad (3-5c)$$

$$\theta_{er} = \frac{h_{lr} - h_{rs}}{d_{lr}} - \frac{d_{lr}}{2a} \quad (3-5d)$$

where h_{lt} , d_{lt} = transmitter obstacle elevation, distance
 h_{lr} , d_{lr} = receiver obstacle elevation, distance

c. Type III Obstacle Horizon/Radio Horizon

$$\theta_{et} = (\text{Same as Equation 3-5c})$$

$$\theta_{er} = (\text{Same as Equation 3-5b})$$

The path type combination may be reversed to satisfy a Radio Horizon/Obstacle Horizon configuration. Referring to Figure 3-5, the angles α_{oo} and β_{oo} are calculated as:

Figure 3-5 Typical Path Geometry
(After Ref. 18:p.8-6)

$$\alpha_{oo} = \frac{d}{2a} + \frac{h_{ts} - h_{rs}}{d} + \theta_{et} \quad (3-5e)$$

$$\beta_{oo} = \frac{d}{2a} + \frac{h_{rs} - h_{ts}}{d} + \theta_{er} \quad (3-5f)$$

These angles are modified by correction factors, $\Delta\alpha_o$ and $\Delta\beta_o$ to allow for the effects of a non-linear refractivity gradient [Ref. 12:p. 383]. The correction factors can be obtained from Appendix A, Figure A-7, however for most transhorizon, "over the horizon", paths these factors are negligible.

The angular distance (often called scatter angle) is:

$$\theta = \alpha_{oo} + \Delta\alpha_o + \beta_{oo} + \Delta\beta_o \quad (3-5g)$$

The ratio α_{oo} and β_{oo} defines the path symmetry factor [Ref. 18:p. 4-7]:

$$S = \frac{\alpha_{oo}}{\beta_{oo}} \quad (3-5h)$$

The following equation will calculate the height of the intersection point of the transmit and receive antenna beams. This result will estimate the bottom of the common scatter volume (Refer to Figure 3-6) as

Figure 3-6 Common Scatter Volume Dimension

(After Du Castel, Ref. 19:p. 145)

[Ref. 18:p. 8-8]:

$$h_o = \frac{s d \theta}{(1 + s)^2} \quad (3-5i)$$

where S = symmetry factor

Du Castel, [Ref. 19:p 146], approximates the dimensions of a typical common scatter volume. The volume height is:

$$H = 2h_o \frac{\theta_1 - \theta_o}{\theta_o} \doteq 0.3h_o \quad (3-5j)$$

where $\theta_1 = 1.15\theta_o$

θ_o = scatter angle

The maximum longitudinal dimension, L, is:

$$L = \frac{d H}{2 h_o} \doteq 0.15d \quad (3-5k)$$

where d = great circle path distance (m)

The center of gravity of the scatter volume is approximated as:

$$H_{cg} \doteq h_o + 2/3H \quad (3-5l)$$

6. Diffraction Loss

Propagation paths having a common obstacle horizon, such as a mountain ridge, can be referred to as an obstacle gain path. It is assumed that the obstacle will introduce additional path attenuation. However, the angular distance may be reduced because of the changed path geometry from the obstacle. The possible reduction in the scatter loss may be offset by the increased loss due to diffraction over the obstacle. In some situations the common obstacle may be visible to both terminals, and the path loss might be less than the smooth earth path loss. The International Radio Consultative Committee (C.C.I.R.) has developed the following formula for diffraction loss relative to free-space [Ref. 20:p. 170]:

$$L_d = 20 \log_{10} \left[\sqrt{2\pi} \sqrt{\frac{2(d_a + d_b) \tan \theta_{et} \tan \theta_{er}}{\lambda}} \right] \quad (3-6a)$$

where d_a = transmitter to obstacle distance (m)

d_b = receiver to obstacle distance (m)

When the take-off angles are less than 10 degrees and

d_a is greater than $2d_b$ then Equation 3-6a can be approximated by:

$$L_d \doteq 20 \log_{10} \left[2\pi\theta \sqrt{\frac{d_a}{\lambda}} \right] \quad (3-6b)$$

7. Worst-Hour Loss

Seasonal annual-to-worst month path loss variations can be determined from a knowledge of the annual changes in surface refractivity of the atmosphere over the path. The C.C.I.R. recommends a loss variation of 0.2 dB (U.S.) and 0.5 dB (Europe) per unit change of refractive index.

The worst-hour median loss can be derived by assuming a log-normal distribution during the month. It was shown by Panter, [Ref. 12:p. 401], that on a log-normal distribution, the 99.9 percent point can be approximated by the value 3.1σ in decibels below the median, where σ is the standard deviation of the log-normal distribution. The worst-hour median loss can be determined as:

$$\begin{aligned} \text{Worst-Hour Median Loss} &= \text{Median Annual Path Loss} \\ &+ \text{Difference of Annual-to-Worst-Month Median Loss} \\ &+ 3.1 \sigma_{wm} \end{aligned}$$

where σ_{wm} = standard deviation of the worst-month

Figure 3-7 Annual and Winter Monthly Standard Deviation
 (After Panter, Ref. 12:p. 359)

distribution obtained from Figure 3-7.

8. Aperture-to-Medium Coupling Loss

The parabolic reflector microwave antenna gain equation, [Ref. 12:p. 103], can be expressed in decibels as:

$$G = 20\log_{10} f + 20\log_{10} D - 52.6 \text{ dB} \quad (3-7)$$

where D = aperture diameter (feet)

An illumination factor of 0.54 was assumed to derive Equation 3-7. It would appear that Equation 3-7 depicts an ever increasing power gain as the antenna aperture area increases. However the power received by an antenna does not increase linearly with an increase in antenna diameter, D . This effect is called aperture-to-medium coupling loss or loss in antenna gain [Ref. 12:p. 362].

Aperture coupling loss in troposcatter systems is caused by a non-planar wavefront due to atmospheric irregularities, and a geometric effect due to the decrease in the scattering properties with height inside the scatter volume. An incoming wavefront consists of many plane waves, each arriving at a different angle from the scatter volume. If the arrival angle range variation

is much smaller than the antenna beamwidth the wavefront will appear nearly plane. If the common volume is much wider than the receiving antenna's beamwidth a wider angle range will result, and the wavefront will appear non-planar.

Basically, coupling loss can be explained as limited antenna pickup, as compared to the effective scatter volume dimensions and the antenna 3 dB beamwidth. Figure 3-8 compares aperture coupling loss results between several authors. A unique constant curve is presented by the C.C.I.R. [Ref. 21:p. 145]. This curve is independent of the scatter angle and is written as:

$$L_C = 0.07 \exp \left[0.055 (G_T + G_R) \right] \quad (3-8)$$

where G_T, G_R = transmit, receive antenna gain (dB)

This empirical formula gives a high coupling loss and will not be used in the program. The proposed empirical curve appears as the average of several different formulas and will be used as a conservative estimate for the aperture coupling loss.

Figure 3-8 Aperture-to-Medium Coupling Loss
 (After Levin, Ref. 21)

9. Combined Free-Space/Scatter Loss

Yeh, [Ref. 22], has derived the following formula to calculate the combined free-space and scatter loss, in decibels:

$$L_s = 30 \log_{10} f + 20 \log_{10} d + 10\theta + 0.2(N_s - 310) + 57 \quad (3-9)$$

where f = operating frequency (MHz)

d = great circle path distance (miles)

θ = scatter angle (degrees)

N_s = surface refractivity

10. Waveguide/Connector Loss

The waveguide attenuation factor was derived for standard rigid waveguide. At an operating frequency of 4.5 GHz the waveguide loss will be approximately 1.25 dB per 100 feet [Ref. 18:p. 7-14]. Each waveguide connection will introduce an additional 0.06 dB per joint [Ref. 1:p. 210].

11. Absorption Loss

Rainfall, snowfall, and fog produce atmospheric absorption loss which depends on the amount of moisture and on the frequency. Figure 3-9 was used to

Figure 3-9 Estimated Atmospheric Absorption
(After Ref. 18:p. 2-43)

estimate the rainfall attenuation on a particular transmission path at four (4) rainfall rates [Ref. 18:p.2-43].

C. DESIGN PARAMETERS

1. Carrier-to-Noise Ratio

The performance of troposcatter communications circuits are determined by the minimum acceptable ratio of hourly median carrier signal to thermal noise for a type of modulated signal. This ratio, expressed in decibels, is called the carrier-to-noise ratio (CNR). The following equation is used to determine the received carrier power level:

$$P_r(\text{dBW}) = P_t(\text{dBW}) - L_T(\text{dB}) \quad (3-10)$$

where P_t = transmitter power output (dBW)

L_T = total median transmission loss (Equation 3-1)

The receiver noise threshold level is written as:

$$P_n(\text{dBW}) = -204(\text{dBW}) + NF(\text{dB}) + 10\log_{10} B_{IF} \quad (3-11)$$

where -204 dBW = thermal noise constant

NF = receiver noise figure (dB)

B = receiver IF bandwidth (Hz)

IF

Finally the carrier-to-noise ratio, [Ref. 10:p. 411],

is:

$$\text{CNR(dB)} = P_r(\text{dBW}) - P_n(\text{dBW}) \quad (3-12)$$

where CNR = carrier-to-noise ratio (dB)

P = received power level (dBW)

P_r
P = receiver thermal noise level (dBW)
n

2. Digital Radio Link Parameters

In digital systems the modem performance is usually plotted versus average bit energy, E_b , to the receiver noise spectral density, N_o . The probability of error (often called bit error rate) will be determined from the E_b/N_o ratio. The transformation of the calculated carrier-to-noise ratio (CNR) to E_b/N_o is written as [Ref. 23:p. 158]:

$$E_b/N_o = \text{CNR(dB)} + 10 \log_{10} B_w - 10 \log_{10} R \quad (3-13)$$

where B_w = transmission noise bandwidth (Hz)

R = transmission data rate (bit/sec)

3. Propability of Bit Error Calculations

Current military multichannel communications use Pulse Code Modulation/Time Division Multiplexing (PCM/TDM) techniques to transmit digital information over both frequency modulated (FM) and phase modulated (PM) troposcatter carrier systems. The quality of the multiplexed circuits is determined by the number of bit errors that occur because of the channel fading and multipath dispersion. The probability of bit errors can be predicted for different PCM carrier modulation methods. Multiphase signaling and M-ary orthogonal signaling over a Rayleigh fading channel are derived by J. G. Proakis [Ref. 14:pp. 490-499].

The bit error rate (BER) for QPSK (four-phase phase shift keying) and DPSK (differential phase shift keying) is expressed as:

$$P_b = \frac{1}{2} \left[1 - \sqrt{\frac{\mu}{2 - \mu^2}} \sum_{k=0}^{L-1} \binom{2k}{k} \left(\frac{1 - \mu^2}{4 - 2\mu^2} \right)^k \right] \quad (3-14)$$

where μ = correlation coefficient

$$\mu = \sqrt{\frac{\overline{y_c}}{1 + \overline{y_c}}} \quad (\text{for coherent PSK})$$

$$\mu = \frac{\overline{\gamma_c}}{1 + \overline{\gamma_c}} \quad (\text{for DPSK})$$

where γ_c = average received E_b/N_0 per channel

γ_b = average received E_b/N_0 per bit

$$\gamma_b = \frac{L \overline{\gamma_c}}{j}$$

where L = order of diversity

$j = 1$ (for BPSK signaling)

$j = 2$ (for QPSK signaling)

Bit error probabilities are depicted in Figure 3-10 for two-phase and four-phase DPSK signaling with $L = 1, 2$ and 4 .

Orthogonal signaling may be viewed as M -ary FSK (Frequency Shift Keying). The expression for the probability of symbol error (P_M), derived by Proakis, assuming no diversity ($L = 1$) is:

$$P_M = \sum_{m=1}^{M-1} \frac{(-1)^{m+1} \binom{M-1}{m}}{1 + m + m \overline{\gamma_c}} \quad (3-15)$$

where $M = 2$ (for BPSK signaling)

$M = 4$ (for QPSK signaling)

The equivalent bit error rate (BER) can be computed using:

$$P_b = \left(\frac{2^{k-1}}{2^k - 1} \right) P_M \quad (3-16)$$

Figure 3-10 Probability of Error (BPSK/QPSK)
(After Proakis, Ref. 14:p. 492)

where $k = \log M$
 2

The graphs of P versus E_b/N_o for $M = 2, 4$ and $L = 1, 2, 4$ are shown in Figure 3-11.

The Distortion Adaptive Receiver [DAR] is currently being used in the military troposcatter digital radio set, AN/TRC-170. Experimental modem performance results are illustrated in the BER versus E_b/N_o curves, Figure(s) 3-12 and 3-13. The results are determined for three (3) different multipath delay values.

Sunde, [Ref. 24:pp. 144-214] has derived a general expression for the maximum differential transmission delay. This equation is valid when the transmitting and receiving antenna beamwidths are different:

$$\delta = \frac{d}{2} \left[\left(\frac{\theta}{2} + \theta_{et} \right) \left(\frac{\theta}{2} + \theta_{er} \right) - \frac{\theta^2}{4} \right] \quad (3-17a)$$

where d = path distance (meters)

θ = scatter angle (mrad)

θ_{et} = transmitter take-off angle (mrad)

θ_{er} = receiver take-off angle (mrad)

The time dispersion (multipath spread) relative to the

Figure 3-11 Probability of Error (M-ary FSK)

(After Proakis, Ref. 14:p. 499)

PERFORMANCE OF DUAL PULSE DAR

Figure 3-12 DAR Performance - Dual Diversity
(After Zawislán, Ref. 4:p. 4)

PERFORMANCE OF DUAL PULSE DAR

Figure 3-13 DAR Performance - Quad Diversity
(After Zawislan, Ref. 4:p. 4)

average time delay for unequal antenna beamwidths is:

$$\Delta = \frac{\delta}{2c} = \frac{\delta}{2(3 \times 10^8 \text{ m/s})} \quad (3-17b)$$

where $c = 3 \times 10^8 \text{ m/sec}$

In the case of equal transmitting and receiving antenna beamwidths, Equation 3-17b is simplified to:

$$\Delta = \frac{3d\theta^2}{16c} \quad (3-17c)$$

For a particular order of diversity, the probability of error can be computed for the AN/TRC-170 troposcatter radiolink by evaluating a least-squares polynomial equation derived from experimental data curves.

4. Fade Margin and System Reliability

The system fade margin, in decibels, is the difference between the "practical threshold" level and the median received signal level. The propagation reliability values for the worst fading condition, Rayleigh fading, can be compared with their required fade margins in Table II [Ref 1:p. 225]. The "practical threshold", or minimum acceptable received signal level, cannot be below the FM improvement threshold

TABLE II

RAYLEIGH FADING PROPAGATION RELIABILITY

Single Hop Propagation Reliability (%)	Fade Margin (dB)
90.0	8
99.0	18
99.9	28
99.95	33
99.99	38
99.999	48

[Ref. 25:p. 71]. The fade margin can be evaluated by:

$$\text{Fade (dB)} = P_r(\text{dBm}) - N_p(\text{dBm}) \quad (3-18)$$

where N = "practical noise threshold"

$$N_p = P(\text{dBm}) + \text{FM improvement}$$

$$P_n = -174 \text{ dBm} + 10 \log \frac{B}{10 \text{ IF}} + \text{NF}$$

W. T. Barnett and A. Vigants of Bell Telephone Laboratories, [Ref 25:pp. 59-60], have developed an empirical method to determine the nondiversity annual path availability. Barnett's procedure begins by defining U_{ndp} as the nondiversity annual outage probability and r as the fade occurrence factor:

$$r = \frac{\text{actual fade probability}}{\text{Rayleigh fade probability}}$$

If F is the fade margin in decibels:

$$r = \frac{\text{actual fade probability}}{10^{-F/10}}$$

For the worst month:

$$r_m = a \times 10^{-5} \left(\frac{f}{4} \right) d^3 \quad (3-19)$$

where d = path length (statue miles)

- f = frequency (GHz)
- F = fade margin (dB)
- a = 4 (for smooth earth, over water, flat desert)
- a = 1 (for average terrain with some roughness)
- a = 0.25 (for mountainous terrain)

Considering the annual fade occurrence:

$$r_{yr} = br_m \quad (3-20)$$

- where
- b = 0.5 (for hot, humid coastal areas)
 - b = 0.25 (for normal, temperate or subarctic)
 - b = 0.125 (for very dry climate)

Finally the nondiversity annual path outage is:

$$U_{ndp} = r_{yr} 10^{-F/10} \quad (3-21)$$

The annual nondiversity availability percentage is:

$$A = 100(1 - U_{ndp}) \text{ (percent)} \quad (3-22)$$

The percentage of availability is improved with the use of frequency and space diversity. Figure 3-14 is used to graphically determine the approximate

availability improvement for various percentages of frequency separation (F.S.). Figure(s) 3-15 (Dual Diversity) and 3-16 (Quad Diversity) provide a graphical method to determine the percent of path availability (percent of level exceeded) for different diversity combining techniques.

5. Diversity Requirements

The antenna spacing, in meters, required for effective space diversity has been experimentally derived for frequencies greater than 1 GHz, in the horizontal as [Ref. 11:pp. 145-146]:

$$\Delta_h = 0.36(D^2 + 1600)^{1/2} \quad (\text{meters}) \quad (3-23a)$$

and in the vertical as:

$$\Delta_v = 0.36(D^2 + 225)^{1/2} \quad (\text{meters}) \quad (3-23b)$$

where D = parabolic antenna diameter (m)

A satisfactory frequency separation, in MHz, for frequency diversity has been derived as:

$$\Delta_f = (1.44f/d)(D^2 + 225)^{1/2} \quad (\text{MHz}) \quad (3-23c)$$

Figure 3-14 Approximate Interference Fading
Distribution versus Order of Diversity
and Frequency Separation
(After Ref. 18:p. 2-46)

Figure 3-15 Short-Term Fading (Dual Diversity)
(After Ref. 18:p. 4-11)

Figure 3-16 Short-Term Fading (Quad Diversity)

(After Ref. 18:p. 4-13)

where f = transmitter frequency (MHz)

θ = scatter angle (mrad)

d = path length (km)

6. Analog Radio Link Parameters

The analog radiolink considered will be a FM transmitter using frequency division multiplexing (FDM).

a. Receiver IF Bandwidth

For FM modulation techniques, the receiver IF bandwidth is computed as [Ref. 18:p. 8-16]:

$$BW_{IF} = 2(\Delta F_p + F_m) \quad (3-24)$$

where F_p = peak frequency deviation (Hz)

F_m = maximum modulating frequency (Hz)

The peak frequency deviation is the product of the frequency modulation index and the bandwidth of the modulating signal. The maximum modulating frequency is computed as the sum of the minimum modulating frequency, the voice channel bandwidth, and the frequency spacing between multiplexed supergroups. The calculated IF bandwidth can now be used to compute the receiver noise

threshold, Equation 3-11. The carrier-to-noise ratio is determined by Equation 3-12.

b. Expected Channel Noise

According to DCA System Performance Specifications [Ref. 18:p. 3-11], the channel noise standard for a troposcatter link is:

$$N(pWp0) = \frac{L}{2000} (16,000) \quad (3-25a)$$

and

$$N(dBa0) = 10 \log_{10} (pWp) - 6 \text{ dB} \quad (3-25b)$$

where L = path length (nautical miles)

pWp = picowatts psophometrically weighted measured at, or referred to, a zero transmission level point.

The term dBa refers to decibels of noise power above a reference noise power, with an adjustment factor to compensate for equipment weighting. The referenced noise power that dBa is referred to is -85 dBm . To obtain $dBa0$, it is required to calculate the number of dB above this reference power the signal is. For flat voice channels, the corrected reference level is -82 dBm and the expression for $dBa0$ is:

$$\text{dBaO} = 82 - \text{SNR} \quad (3-26)$$

The signal-to-noise ratio , SNR, must be calculated to compute Equation 3-26. The channel SNR may be calculated after the carrier-to-noise ratio (CNR) has been determined by Equation 3-11. The relationship between channel SNR and system CNR in a FM/FDM system is [Ref. 1:p. 272]:

$$\text{SNR} = \text{CNR} + D_{\text{im}} + \text{FM}_{\text{im}} - L_f + P_{\text{im}} \quad (3-27)$$

where FM_{im} = FM improvement factor (assumed 20 dB)
 D_{im} = diversity improvement factor (Fig. 3-17)
 P_{im} = preemphasis improvement factor (Fig. 3-18)
 $L_f = -10 + 10 \log_{10} N$ (dB)
 where N = number of voice channels

Figure 3-17 SNR Improvement from Diversity Techniques

(After Freemann, Ref. 1:p.224)

IV. HEIGHT GAIN COMPUTATION

A. GENERAL

One of the purposes of this research was to develop a tactically practical method of calculating the height gain caused by the presence of an elevated tropospheric duct. The calculation must provide a result that was within 10 dB of the PDUCT computer program prediction. Several related works were investigated for a possible approach to the problem. Military troposcatter systems have introduced several constraints to the height gain problem. These constraints include:

1. The transmitter and receiver terminals are both located outside and below the elevated duct.
2. The operating frequency range was between 4.5 GHz to 5.0 GHz.
3. The geographical area of system deployment was limited to Western Europe (i.e. West Germany).

A statistical analysis of elevated duct histograms was obtained from several radiosonde recording stations located throughout West Germany [Ref. 26]. This information is condensed in Table III. Elevated ducts that had a percentage of occurrence greater than twenty

percent (20%) over the 5 year recording period were prime candidates for further study. Eight (8) elevated ducts were selected as typical for the area. Their optimum coupling heights ranged from 951 to 1452 meters above the surface. The elevated duct intensities were all less than 6 M-units with 4 M-units being the dominant value.

TABLE III
ELEVATED DUCT HISTORICAL INFORMATION

Station Location (LAT/LONG)	Mean Optimum Coupling Height (Meters)	Mean Duct Intensity (M-Units)	Mean Duct Thickness (Meters)
Stuttgart, FRG (48-49N/09-11E)	1452	4	115
Essen, FRG (51-23N/06-58E)	1412	3	106
Hannover, FRG (52-28N/09-41E)	1376	4	109
Rheine, FRG (52-16N/07-25E)	1257	3	113
Idar-Oberstein, FRG (49-41N/07-19E)	1151	3	88
Emden, FRG (53-22N/07-13E)	1071	4	124
Goch, FRG (51-40N/06-10E)	1044	6	172
Greifswald, FRG (54-05N/13-22E)	951	4	119

(After Ortenburger, Ref. 26, Vol. 12)

Height gain values, in decibels, were computed by the PDUCT program for each of the eight selected ducts. The following common input parameters were entered into the PDUCT program for each duct. [Ref. 7]:

1. The transmitter site elevation was fixed as the reference at 5 meters above the surface.
2. The receiver site elevation was increased from 5 to 280 meters in 25 meter increments.
3. The path distance was increased from 75 to 325 kilometers in 50 meter increments.
4. The antenna polarization was set for both horizontal and vertical polarization.
5. The frequency of interest was increased from 4500 MHz to 5000 MHz in 100 MHz increments. The frequency was changed every PDUCT program run for each selected duct of interest.
6. The relative permittivity (15), conductivity (0.01 mho/m), and maximum mode attenuation (1.0 dB/km) were selected for the path characteristics.

B. MATHEMATICAL FORMULATION

The PDUCT height gain results for each duct were investigated, and the following observations were discovered. The height gain values increased exponentially as the receiver elevation approached the bottom of the elevated duct. The other significant observation was that for any fixed receiver elevation, the height gain increased linearly with increased path

distance.

Two empirical methods were considered in developing the height gain prediction model. One method was to directly store the individual height gain results for each of the elevated ducts and then to interpolate a height gain result from a database. This would have required an extensive height gain database. The chosen approach was to approximate height gain curves from the PDUCT results using a least-squares curve fitting program. A second order polynomial equation was derived for each frequency of interest at the initial 75 kilometer path length for each selected duct height.

The height gain program module consisted of eight (8) optimum coupling height decision regions which cooresponded to the selected elevated ducts. Each duct height region contained a height gain polynomial equation for each frequency of interest. For a particular operating frequency and optimum coupling height, a baseline height gain was estimated and multiplied by an incremental range correction factor. This range factor was the average differential difference in height gain between the successive 50 kilometer path increments. Figure 4-1 outlines how the height gain estimate was computed.

Figure 4-1 Height Gain Estimation Flowchart

C. RADIOSONDE DATA ANALYSIS

Elevated ducts are described by their optimum coupling height, duct intensity, and duct thickness. This information can be determined indirectly from real-time radiosonde data taken along the system's path length. The atmospheric pressure, vapor pressure, temperature and relative humidity readings are used to calculate the refractive index, N , for various altitudes using the expression, [Ref. 27:p.4]:

$$N_s = \frac{77.6}{273 + T} P + \frac{48.1 H P_w}{273 + T} \quad (4-1)$$

where P = atmospheric pressure (millibars)

T = temperature (celsius)

P_w = saturated vapor pressure (millibars)

H = relative humidity (%)

The radiosonde information can be entered into the program. The refractive index values are calculated for available altitude readings and then converted to modified refractive index values. At this point a M-profile plot can be obtained along with a radiosonde data listing. If an elevated duct does exist, the optimum coupling height, intensity, and thickness can be

determined directly from the M-profile. These duct descriptors must satisfy the respective limits established by the height gain prediction model. If the detected elevated duct exceeds the limits of the model, the height gain prediction will become inaccurate. The program user will be alerted of this condition. At this point the design engineer must decide to obtain the height gain from an alternative computation or neglect ducting effects.

V. RESULTS

A. GENERAL

For validation purposes, the TROPD Program was used to determine the design predictions for a typical tropospheric scatter communications system. Table IV outlines the proposed system specifications and assumptions. Both the terrain and radiosonde data have been assumed to accommodate the program's capabilities. The program results are illustrated in Figure(s) 5-1 through 5-4. The Radiosonde Environmental Data Listing (Figure 5-3) identifies the occurrence of a tropospheric duct by detecting a "trapped" radio ray path condition. Other refractive bending conditions identified are super-refractive (bending toward the earth's surface), normal (standard bending), and sub-refractive (upward bending). The M-Profile Plot, Figure 5-4, graphically verifies the program's computed duct parameters.

B. HEIGHT GAIN COMPARISON

Height gain prediction model results were compared with the PDUCT program computed values for identical elevated duct parameters. Height gain curves were

TABLE IV
PROPOSED EXAMPLE SYSTEM SPECIFICATIONS

Elevation:	13 meters	94 meters

Terrain Data Available: Near Obstacle Path Mode

Radio Terminal: Military (AN/TRC-170V3)

Diversity: Dual

Frequency: 4560.0 MHz

Antenna Diameter: 15 Ft. Parabolic

Waveguide Length: 25 Ft. per Antenna

Digital Trunk Data Rate: 2.048 Mb/s

Transmission Bandwidth: 3.5 MHz

Radiosonde Data Available: Surface Duct Detected

plotted for two test cases: (1) a fixed optimum coupling height and range with a varying frequency, and (2) a fixed optimum coupling height and frequency with a varying range. Figure(s) 5-5a thru 5-5c has shown that a prediction error of approximately 5 dB is possible. The error increases as the frequency approaches the adjacent frequency increment. In this case height gain values validated at 4700 MHz have been averaged into those computed for 4600 MHz to produce a shift of the prediction curve. Figure(s) 5-6a thru 5-6c illustrate the results of only changing the path distance. In this case the greatest error detected was within 3 dB of PDUCT, which supports the linearity between height gain and range.

VI. SUMMARY

A. CONCLUSIONS

An interactive, computer-aided design program for military tropospheric scatter communications systems was developed. The program provides the communications engineer with an efficient and accurate system performance algorithm that can be used in a tactical environment on a microcomputer. The following thesis objectives were accomplished:

1. Both analog and digital troposcatter radio terminals are included as design options.
2. The influence of elevated tropospheric ducting on systems installed throughout West Germany was considered. A height gain estimation model was derived using numerical results obtained from the FDUCT main-frame computer program.
3. System performance predictions can be calculated for the newly deployed digital troposcatter radio, AN/TRC-170.
4. Real-time radiosonde information can be analyzed to determine the presence of both surface and elevated tropospheric ducts.

The accuracy of the height gain model was bounded by the range of selected duct parameters. However height gain results of elevated ducts which satisfied the limits of the model were within 5 dB of the FDUCT computer

model. The model did not compute the height gain for surface-based ducts.

B. RECOMMENDATIONS

Additional research is required and should focus on the following areas.

1. The validation of the computer-derived system performance results can be conducted during standard operational testing. Real-time radiosonde data should be obtained from available tactical weather facilities and tropospheric ducting phenomena determined. Received signal strength data can be recorded and statistically analyzed.
2. The height gain model should be expanded to include unlimited duct parameters, e.g. surface-based ducts and elevated surface ducts.
3. The effects of tropospheric ducting can be studied further within the laboratory. Radiated energy, produced by laser light, can be transmitted through a fluid medium containing light-scattering particles. A common scatter volume can be formed by mirror-like apertures at the laser sources. The refractivity index of the medium could be controlled to simulate ducting conditions. The received energy could be detected and experimental results studied.

APPENDIX A

The following prediction formulas were developed by the National Bureau of Standards (NBS) for calculating the long-term median basic transmission loss, L_{bsr} , [Ref. 12:p. 389] and [Ref. 18:pp. 8-8 thru 8-14].

1. Long-term Median Basic Transmission Loss

$$L_{bsr} = 30 \log_{10} f - 20 \log_{10} D + F(\theta d) - F_o + H_o \quad (A-1)$$

where f = frequency (MHz)

d = mean sea level arc distance (km)

$F(\theta d)$ = attenuation function (dB)

F_o = scattering-efficiency term (dB)

H_o = frequency-gain function (dB)

2. Attenuation Function

For a particular symmetry factor, S , and approximate surface refractivity, N_s , the following figures are used to determine the attenuation factor, $F(\theta d)$:

For a surface refractivity:

$N_s = 250$ Refer to Figure A-1

$N_s = 301$ Refer to Figure A-2
 $N_s = 350$ Refer to Figure A-3
 $N_s = 401$ Refer to Figure A-4

3. Scattering-Efficiency Term

The following equation can be used:

$$F_o = 1.086 \left(\frac{\eta_s}{h_o} \right) (h_o - h_1 - h_{1t} - h_{1r}) \quad (A-2)$$

where h_o = height of transmitter/receiver antenna beam intersection (km)

h_1 = height from obstacle elevation baseline to the antenna beam intersection (km)

h_{1t} = transmitter obstacle elevation (m)

h_{1r} = receiver obstacle elevation (m)

4. Frequency-Gain Function

The frequency-gain function is expressed by as:

$$H_o = \frac{H_o(r_1) + H_o(r_2)}{2} + H_o \text{ (dB)} \quad (A-3)$$

and $r_1 = 41.92 \theta f h_{te}$
 $r_2 = 41.92 \theta f h_{re}$

Figure A-1 Function $F(\theta d)$ for $N = 250$
S
(After Ref. 18:p. 8-9)

 (After Ref. 18:p. 8-10)

Figure A-3 Function $F(\theta d)$ for $N = 350$
 (After Ref. 18:p. 8-11)

Figure A-4 Function $F(\theta d)$ for $N = 401$
 (After Ref. 18:p. 8-12)

$$\text{and } H_o = 6 \left[0.6 \log_{10} \eta_s \right] \log_{10} S \log_{10} q$$

where θ = scatter angle (angular distance) (mrad)

f = frequency (MHz)

h_{te} = transmitter elevation (km)

h_{re} = receiver elevation (km)

$S_o = a_o / \beta_o$ (symmetry factor)

$q = r_2 / (s)(r_1)$

$H_o(r_1)$ and $H_o(r_2)$ are graphically derived using
