ABSTRACT

Many Navy applications of *composites*, including ships' superstructures, submarine air flasks and missile rocket motor casings, require high strength and reliable materials. Composite strength reliability is dictated by individual fiber breaks at low loads (lower tail) and the accumulation of the fiber failure sites.

This study examined the effects of applying a preload to a graphite/epoxy composite tow prior to complete polymerization of the matrix. The objective was to break the (inevitable) weak fibers and minimize the effects of the associated stress concentrations, subsequently limiting the clustering of fiber failures. By eliminating the lower tail, the shape of the Weibull distribution is reduced, thereby enhancing composite reliability.

ACKNOWLEDGEMENTS

I would like to thank my mentor Professor Edward M. Wu for his guidance and dedication to this project, and express my appreciation to Mr. Jim Nagoette for his technical assistance and cooperation during the past year. And finally to my family for their support and patience , Thank-you.

I. INTRODUCTION

In the 1960s, *Composite Materials* were referred to as "Space Age Materials". Today, composite structures are common through out our society. The rapid growth of the composite materials industry has been phenomenal, perhaps only exceeded by the advancements in computer technology. The concept of composite materials is simple, in that two or more structurally compatible materials are combined to produce an end product with attributes greater than the sum of the constitutes. But as new applications for composite materials are developed so follows an increase in unanswered questions with regards to reliability, especially associated with vital national defense systems, public transportation systems and aerospace and hydrospace exploration. As engineers it is important that we do not let the state of the art exceed the state of the science. We must have answers to those difficult questions concerning composite material applicability, maintainability and reliability.

Composite reliability is the focus of attention at the Advanced Composites Laboratory at the Naval Postgraduate School, Monterey California. Here questions are being investigated regarding composite reliability as a function of service life, strength and test methodology. The primary goal of composite material research is to be able to have a better understanding of how composite materials behave over an extended service life and to further investigate the mechanics of composite strengthening. A

secondary function is the investigation into improved testing methods so that research techniques can be translated into production applications.

The primary *objective* of this study was to investigate composite reliability as a function of the strengthening mechanisms. This was accomplished by studying the affects of preloading a graphite bundle prior to complete curing of the epoxy matrix. After the matrix had cured, the graphite strand ultimate tensile strength was determined and the results were compared to a benchmark value based on previous testing.

In addition, individual fiber testing was conducted so that a mathematical model may be developed in order to determine the optimum bundle preload level. Fiber testing was also conducted in order to demonstrate that the Integrated Fiber Testing system developed at the Naval Postgraduate School (NPSIT) could be use as a viable and accurate test method. This was accomplished by conducting fiber testing using an INSTRON Model 4200 materials tester using current American Society of Testing and Materials (ASTM) procedures and comparing the results obtained using the NPSIT system. Graphite fibers having different strength properties were tested in order to show that the testing systems used could accurately ascertain any small differences in composite properties. The focus of this study was on fiber diameter and fiber tensile strength.

II. BACKGROUND

Load bearing graphite composite materials consist of high strength / high modulus graphite impregnated with a ductile reinforcing matrix. The performance characteristics of the composite material are controlled by three factors:

- Strength and modulus of the graphite fiber
- Strength and modulus of the epoxy matrix
- Effectiveness of the bond between the matrix and fiber, with regards to the mechanics of load transfer at the interface.

The overall tensile failure process of this simple system is extremely complex, however for the purpose of this study this can be simplified by assuming a two dimensional model and that failure initiation occurs within the fiber only. This failure model was first presented by B.W. Rosen (Ref.1 and 2). It consisted of parallel fibers in a homogeneous matrix, loaded in tension, assuming a uniform strain supported primarily by the fibers.

The most important concepts developed in this classical study were the fact that the fibers were considered to have statistically distributed flaws or imperfections. These flaws resulted in fiber failure at various stress levels, therefore Rosen considered each fiber as a series of links and that the individual fiber failure process was a function of the weakest link principle. Finally, that the statistical strength distribution of these flaws could be approximated by a Weibull distribution.

A. FIBER FAILURE PROCESS

Initially when a fiber *bundle* ,without epoxy, is loaded in tension, the individual fiber failures occur randomly at the site of a flaw at a load much less than failure load ($x_1 < x_f$). When this occurs the stress (σ_1) in the fiber becomes zero, and the stress in the surviving fibers increase to a new stress level equal to some value $K * \sigma_1$. The existence of some individual fiber failures may not be catastrophic in that the increase in stress is shared equally by the remaining fibers as long as $K * \sigma_1 < \sigma_f$. Then applied tension x can be increased to a new value $x_2 > x_1$ then this process is repeated until $K_i * \sigma_i \geq \sigma_f$. Excluding any effects due to twist or friction, catastrophic bundle failure occurs after each individual fiber breaks once.

When the fiber bundle is impregnated with an binder matrix the mechanical behavior of the composite *strand* is altered. The addition of the matrix creates a unique load transferring system. This provides for transverse load sharing between each individual fiber and longitudinal load sharing to another segment of the fiber. The matrix also provides the mechanism for localizing the effects of microcracks within the composite material. These two functions combined provide for the distinct mechanical performance of fiber reinforce composite materials.

The composite failure process based on Rosen's failure model, with matrix binder, predicts different results from dry bundles. When the initial load x_i is applied initial fiber failures still occur at the inevitable flaw sites, however the effects are confined to a localized region. Stress σ decreases to zero, and the shear τ in the matrix reaches a maximum value. The axial load is transmitted by this shear to only the neighboring fiber segments, (see

Figure 1). The neighboring fibers now show a *load concentration* due to the fiber break. At the broken fiber tip there exists a length of fiber which is ineffective in carrying the applied load. This is known as the *ineffective length* δ . The increase in shared stress on the immediate neighbors is substantially greater than that shared by the fibers that are a greater distance from the failure site.

Figure 1. Fiber Bundle Model

The determination of the ineffective length δ is difficult, and requires an understanding of the shear stress distribution along the interface. The ineffective length is estimated by Rosen [Ref. 1] to be:

$$\delta = 1/2 \{ (V_f^{-1/2} - 1) E_f / G_m \}^{1/2} \cosh^{-1} \{ [1 + (1 + \phi)^2] / 2[1 - \phi] \} d_f$$

V_f - Volume fraction of fiber

E_f - Modulus of fiber

G_m - Shear modulus of matrix

ϕ - Fiber efficiency or the fraction of the undistributed stress value below which the fiber is considered to be ineffective

d_f - Fiber diameter

B. COMPOSITE FAILURE

In general there are three basic modes of composite failure. The first is debonding which is failure at the fiber/matrix interface which is caused by a high interface shear stress (Figure 2a). This failure may start with a single broken fiber and propagates within the interface, along the fiber length, which in turn drastically increases the ineffective length δ . Thus increasing the likelihood of the crack propagating to another flaw site. The study of this type of failure identifies the need for improving the interface properties such as adhesion and toughness properties of the epoxy (Note: $x_i \ll x_f$). The second type of composite failure is crack propagation (Figure 2b). This occurs when an initial crack is developed at the flaw site and propagates transversely across the composite. Crack propagation is controlled by the fracture toughness of the matrix and fiber and thus minimizing the effects on

local load sharing. This failure mode may be associated with some slight debonding. (Note: $x_i \ll x_f$).

Figure 2a.

Figure 2b.

Figure 2c.

Figure 2. Composite Failure Model

Finally, if debonding and crack propagation are controlled then composite failure occurs when as load is increased, the number of statistically distributed fiber failures accumulates in the vicinity of one cross section such that when the load shared in the surviving fibers exceeds the ultimate load of the system ($x_i \geq x_f$). This mode of failure is usually a combination of debonding and crack propagation, occurring at a much higher load level, (Figure 2c).

C. LOAD SHARING

The most pronounced effects of adding a matrix binder to the fiber bundle is that of load sharing. This is best discussed using a microbundle model developed by S.L. Phoenix. [Ref. 3]. This model, (Figure 3) is made up of n fibers, each consisting of m links having a length of δ , the ineffective length. In each microbundle ($= n * \delta$) there exists a set of statistically distributed flaws. When the load x is applied the fibers will sequentially fail, in accordance with a Weibull distribution function.

$$F(x) = 1 - \exp [-(x/\beta_x)^\alpha]$$

Where α is the shape parameter and β is the scale parameter.

Because the individual fiber consists of m links, the weakest link theorem applies. Therefore, the value of β_x is a function of gage length and must be corrected for GL.

$$\beta_{2x} = \beta_{1x} (GL_1 / GL_2)^{1/\alpha}$$

When an initial fiber failure x_1 occurs in a *weakest* link the load on each immediate neighbor increases to a value $X=K_1*x$, where K_1 is the load concentration factor and $K_1>1$, (Figure 3). If another weak link exists within the region of concentrated load, then a second fiber failure will prematurely occur. This in turn creates an additional load sharing burden on the neighboring fibers $X = K_2*x$, where $K_2>K_1>1$, (Figure 3). Therefore, randomly created load concentrations may prematurely break a larger

number of fibers at a load x_1 than would otherwise normally occur, subsequently weakening the composite. J.M. Hedgepeth [Ref. 4] provided quantitative values to the load concentration factors, where $K_1 = 1.33$, $K_2 = 1.60$, $K_3 = 1.83$ and $K_4 = 2.03$. Meaning, for example, that the load in the fibers adjacent to three consecutive fiber breaks equals $1.83 \times$ applied load.

Figure 3. Load Concentrations Model

If the random fiber breaks occurring at x_i were dispersed throughout the composite the effects of load concentrations K would be minimal, however this can not be controlled. Therefore an attempt must be made to control the effects of the spatial clustering of fiber breaks and load concentrations in a local region.

A.S. Tetelman [Ref. 5] and C. Zweben [Ref. 6] provide excellent summaries of the composite failure process and the effects of load concentrations. Tetelman also discussed a few concepts for minimizing load concentrations and controlling crack propagation. These include the use of discontinuous fibers, using fibers or matrix consisting of various modulus of elasticity and the use of prestressing at elevated temperatures. In fact prestressing composite bundles at elevated temperatures was proven to be a viable solution during experimental work conducted by E.M. Wu. [Ref. 7]. G.J. Mills [Ref. 8] has also studied the effects of prestressing Boron/Epoxy prepregs by rolling.

D. COMPOSITE RELIABILITY

The reliability of a composite structure depends on a definite characterization of the weak strength distribution (the *weak* lower tail). Definitive evaluation of the lower tail requires a large sample size and consistent material production system.

Such a data base for composite material performance is usually developed from either limited fiber/bundle testing or complete system testing of a small sample size. A small data base, when combined with the existence of the statistically distributed flaws or imperfections in the graphite fiber due to manufacturing, processing or handling practices, makes the behavior of a given composite structure difficult to predict. When a multimillion dollar rocket motor casing or aircraft component consists of an enormous number of fiber *links*, performance reliability becomes dependent upon a statistical study of the strength characteristics. Because of the existence of

the fiber flaws, the strength values of the Weibull distribution are well dispersed within the lower tail. This imposes great restrictions on the allowable design limits for the composite structure. Ideally, there would exist nearly no dispersion in the test data (coefficient of variance approaches zero) and then the data would be completely reliable for a given strength level.

This study will focus on improving composite strength reliability by the use of preloading the fiber bundle prior to the curing of the epoxy resin in order to remove the weak fiber sites (lower tail of the Weibull distribution) and decrease the dispersion of the composite strength.

III. EXPERIMENTATION

The experimental work was concentrated in two areas. First, determining the diameter and strength of the individual fiber and second, determining the strength characteristics of a graphite tow subsequent to preloading.

The material tested was from a Hercules Magnamite high strength graphite, type AS-4 spools 008 and 019. The graphite bundle consisted of 3000 fibers with a nominal diameter of 7 micrometers and a denier of .005746 grams/inch.

A. FIBER TESTING

Individual fiber testing was a vital part of this study which provided the essential data required to determine the appropriate preload. First the fiber diameter was determined then the fiber failure strength. This information was used to develop a Weibull probability plot to statistically determine the number of fiber failures as a function of applied load.

To study the feasibility of using an alternative testing method, two testing methods were used during this study. The first method was the use of an Instron Material Tester (INSTRON), (Figure 4), with associated ASTM procedures to determine fiber failure load. Second, using a Integrated Testing system under development at the Naval Postgraduate School, Monterey, California. (NPSIT), (Figure 5).

Figure 4. INSTRON Testing System

Figure 5. NPSIT Testing System

The primary advantage to the NPSIT system is that the fiber diameter as well as the failure load can be readily determined on the same test stand. This minimizes the handling of the test samples and bias the statistical parameters.

The correlation between fiber test length and failure load has been well established in past studies and is not addressed here. A gage length of 5 centimeters was used for fiber testing. Strain rate or crosshead speed also has an effect on test results, however this effect was not studied. A constant speed of 10 percent of gage length per minute (in accordance with ASTM procedure) was employed.

Regardless of the testing method used, sample preparation (Appendix A.) and testing parameters were identical.

1. Fiber Diameter

Current methods for determining fiber diameter, as outlined in ASTM procedures, call for the use of the Scanning Electron Microscope (SEM). This is a time consuming and some what arduous task when testing large numbers of fibers.

Recent work at the Naval Postgraduate School, Monterey, has provided two additional methods which are more conducive to this study. The principles and procedures as developed by T. A. Bennett [Ref. 9] are based on the physical optics, that if a illuminated beam of light is directed at the fiber that a diffracted light pattern is produced which is perpendicular to the fiber (Figure 6).

Figure 6. Diffraction Pattern

The first method Bennett looked at was the use of a photoconductive cell to measure the distance between nodes (null intensity in the diffracted light pattern). The second method consists of the use of a microneye interfaced with an Apple Plus II microcomputer. Bennett [Ref. 9] and M. Storch [Ref. 10] then developed the data acquisition techniques necessary to accurately determine fiber diameter. The required test configuration is essentially the same for both methods, however, since only the photocells was used in this study, only those associated procedures will be further discussed.

The test equipment (Figure 5) consists of ; a low power (.052 mW) Helium-Neon laser, which provides the required light source of known wave length ($\lambda = 632.8 \times 10^{-9}$ meters). A focusing lens, a spatial filter and a collimating lens are enclosed as one unit and mounted on the end of the laser. This is necessary in order to produce the parallel light pattern. The fiber is mounted on the test stand which by use of micrometers allows for

longitudinal and transverse adjustments, rotation of the sample and adaptability to the load testing device. At the end of the tracks are two photocells mounted to adjustable pedestals which allow for transverse adjustments. The photocells are connected to two Fluke 8840A multimeters.

2. INSTRON Load Test

Individual fiber load testing was performed using the Instron Load Tester Model 4206 (INSTRON) inconjunction with compatible data acquisition systems. The data acquisition system to be used during this study is the Hewlett-Packard 3497A Data Acquisition/Control Unit and the Hewlett-Packard HP-85 for computer programming. Appendix B provides a detailed listing of the Interactive Data Acquisition Software (IDAS). IDAS was design to minimize operator effort and ensure accurate and reproducible test results. All IDAS procedures were written in accordance with American Society of Testing and Materials (ASTM) Standard Specifications.

After the required program is loaded enter RUN and then follow the outlined steps in Appendix B. The programs use the function keys to provide for flexible data acquisition. Options are normally provided for a CRT/printer output or with the graphics plotter.

Fiber diameter was measured prior to this test with the use of the NPSIT test system.

The IDAS software includes the following programs.

LDCALB - Load Cell Calibration: Characterization of the strength of a fiber required absolute calibration of the load transducer. This

was accomplished by calibrating the digital output of the load transducer by standard weights at six levels. This provided absolute calibration all analogue and the analogue to digit interface.

MCTST - Characterization of the stiffness of a fiber required the calibration of the system compliance. The total compliance measured (C_t) is the sum of the fiber compliance (C_f) plus the system compliance (C_s), all three are a function of applied load level P .

$$C_t(p) = C_f(p) + C_s(p)$$

The system compliance C_s is comprised of the compliance of the testing machine, of the cardboard tab and the adhesive which bonds the fiber to the tab. If the system compliance is assumed to be constant, then a single calibration constant (effective gauge length of zero) is determined as recommended by ASTM procedure D-3379-75(82), (Ref. 11). as discussed in ASTM procedure 3379-75(82), the effective gauge length can be extrapolated from measurement of the total compliance using three different gauge lengths. The short coming of this procedure is that it assumes that system compliance is independent of load level P . The latter was observed to be a gross assumption. Compliance calibration was accomplished using an actual zero gage length sample. In this case, the fiber compliance C_f term vanishes and the total compliance measured is the system compliance. Furthermore, the compliance, over the entire load range of the strength of the fiber measured was recorded and the data fitted by a second degree

polynomial. This second order polynomial was then used to calibrate the tensile strength test data, thereby compensating for the non-linear dependency on the load level.

QFIT - Quadratic Curve Fit: This program reads the saved Machine Compliance data and provides the three coefficients of a quadratic curve. These values E, F, G were then recorded for further use in the fiber test program to mathematically subtract from the total displacement the displacement associated with the system compliance.

FTST - Fiber Test: Is the primary program in this series. INPUTS, allows for the input of all key parameters necessary to determine the actual fiber ultimate strength. The test is run for 30 seconds at a speed of .1x gauge length (5 millimeters/minute on a 50 millimeter sample). The A, B, C, E and F inputs as discussed above are required to perform the necessary mathematical calculations. AQUIR, provides for the actual proof test and data acquisition. Once the sample is ready the program will adjust for the initial tension then start the timer, providing for 300 data readings during the 30 second. run. The results can be displayed on the CRT/printer using GRAF or on the HP Plotter using PLOT. SAV-DAT and RD-DAT provide for the storage and reading of test data. CAL, mathematically subtracts system compliance from the total displacement and provides the unbaised results.

LDTST - Load Test: Provides for a quick check of the load cell calibration using the original A, B and excitation voltage from the LDCALB results.

LDSTOR - Load/Store: is a data management tool for transferring files.

3. NPSIT Load Testing System

The Naval Postgraduate School Integrated Load testing system was developed as an alternative testing method which provides for the determination of fiber diameter as well as failure load with one test system.

The data acquisition and software is essentially the same as that used with the INSTRON test system. The only exception being that a short program was added to FTST so that fiber diameter and failure load are recorded on the same file for easier access.

By following the procedures in Appendix A and Appendix B, the NPSIT system can be quickly initialized and ready for fiber testing. After the FTST program is loaded, mount the fiber sample in the clamps. First measure the fiber diameter, as discussed and then enter AQUIR. The distinct difference between this test method and the INSTRON test method is that the NPSIT drive motor is manually controlled by the operator upon prompt from the HP-85 program, where as the INSTRON tester is software controlled.

All fiber data is recorded, displayed and stored in the same manner as with the INSTRON test.

B. TOW TESTING

The objective of graphite tow testing was to determine the effects on the strength characteristics as a result of applying a preload. Experimentally, AS-4-019 graphite bundles, from the same spool used in fiber testing, were tested.

1. Initial Set-up

The samples were prepared by paying the graphite out on a table and applying a 2 kilogram load. Then copper tabs (1 inch x 1.5 inch) were fasten to the bundle at a gage lengths of 10 inches using an epoxy mix as the adhesive. The 2 kilogram load removes the slack and aligns the individual fibers within the bundle. The copper tabs provide for an area for the bundle to be gripped in the Instron tester.

The Instron Universal Testing Instrument Model 4206 was used to provide the tensile load to the test samples. This system was used in conjunction with the 4200 Series Expanded Control Console with data acquisition being provided by the use of an IBM PC-AT. The Instron/IBM data acquisition on system provides for the real time graphical display of load versus displacement and the creation of a data base for additional computations and graphical outputs. The initial operator and report files are established prior to the commencement of testing to generate the desired reports and graphs.

2. Preloading Bundles

Prior to applying a preload, the Graphite bundle was impregnated with the epoxy matrix. The matrix consisted of a mixture of Dow DER-332 resin (55 percent by weight) and Texaco Jeffamine T403 (45 percent by

weight). (Note: extreme care and good work practices must be used when handling the epoxy products). After thoroughly mixing, the epoxy was placed in a vacuum chamber to remove the entrapped air. The graphite bundle was then dipped into epoxy and allowed to soak a sufficient amount of time to allow for complete impregnation. The bundle is removed from the epoxy bath and the excess epoxy is removed.

The impregnated strand was removed and placed on the oven curing rack, Figure 7, and air cured for 19 hours. The strands were then placed in the Instron grips. Preload was calculated, from the fiber statistical parameters in order to break a desired segment of the lower tail weaker fibers, for a preset displacement of 2.5 millimeters, at a rate of 5 millimeter/minute and immediately unloaded. The samples were placed in a temperature controlled oven and cured for 16 hours at 60 degree centigrade.

Figure 7. Oven Curing Rack

The final resin content of the strand was determined by weighing a few random samples and comparing to the weight of the dry bundle.

$$\%R = \frac{W_T - W_B}{W_T}$$

Where W_T is the total weight of the strand and W_B is the weight of the bundle (denier x gage length). A resin content of 55 to 60 percent is desired.

3. Load Testing

The failure load of the final product (the matrix impregnated composite strand) was determined using the Instron/IBM system described earlier. After the strand is mounted in the test grips the desired test files are inputted and the machine crosshead speed is set a 10 centimeters per minute. The test is allowed to continued until complete tensile failure of the composite strand occurs. The final output provides for the maximum load in kilograms and displacement at failure in millimeters. A graphical report may also be generated.

VI. RESULTS

A. FIBER TESTING

1. Fiber Diameter

A review of the statistical summary of the fiber diameter results (Table I), provides a clear indication that the test method used for determining fiber diameter produced consistent and accurate results. The normal probability plot, Figure 8, shows how the AS-4-008 series and the AS-4-019 series graphite diameters compared to the *merged* results.

A total of 79 samples were measured from the AS-4-008 graphite spool, with a mean diameter of 7.233 microns versus 82 fiber samples from the AS-4-019 spool with a mean diameter of 7.245 microns. The large variability of fiber diameter (as measured by the magnitude of the standard deviation) verifies that the fiber diameter is not consistent over the entire length.

Exploratory effort was expended in the adjustment of the test stand, optimizing the distance between the fiber and the projected plane (the photocell).. This was required to compensate for the narrow width of the photocell window. It was necessary to adjust the test stand so the width of the node was nearly as wide as the photocell. If the node is too wide, there exists several locations of maximum resistance readings. If the the node is too narrow, too much light saturates the photocell, thus making it impossible to locate the center of the node.

TABLE I: STATISTICAL SUMMARY OF SINGLE FIBER TESTING

008 Series Load (gmf)	N	Shape α	Scale β	Mean	Std Dev	Coef. Var.

2. Fiber Failure Load

Interpretation of fiber failure data is focused on two areas

- Comparison of test results from INSTRON and NPSIT testing to identify any differences.
- Comparison of the statistical strength for samples from two different spools.

In Table II statistical parameters from Table I are employed for comparison of the INSTRON and NPSIT test methods.(see Figures 9 and 10).

TABLE II. FIBER LOAD RESULTS

	Mean(gmf)		Std Dev	
	008	019	008	019
INSTRON	14.26	13.91	4.20	4.82
NPSIT	14.56	14.06	2.78	3.20
Difference	+2%	+1%	-15%	-15%

Comparing the first two columns of TABLE II, it is apparent that the mean strengths of the samples measured with the NPSIT are, slightly but consistently, higher for both spools tested. Comparing the last two columns, the variabilities of the measured samples in the NPSIT are, significantly and consistently, lower for both spools. These observation substantiate the hypotheses that the NPSIT, which integrates the fiber diameter measurement with the strength measurement, enables the elimination of several handling and storage steps, thereby minimizing the associated accidental damage.

Figure 9. Weibull Distribution Plot of Fiber Load

Figure 10. Weibull Distribution Plot of Fiber Load

Minimization of this damage results in a shift of the lower tail, of the Weibull plot, to the left (evident in both Figure 9 and Figure 10 for samples labeled *) and a significant reduction of variability and the standard deviation. Minimization of the handling damage cannot increase the intrinsic strength, therefore has no effect on the upper tail (again evident in Figures 9 and 10). The shift of the lower tail changes the geometric centroid, of the probability distribution function (pdf), therefore causing a slight increase of the mean. The consistency between the quantitative measurement with the qualitative expectations support the conclusion that the integrated NPSIT test is a worth while improvement.

For comparison of the statistical strength of the two spools, the strength is modeled by the two parameter Weibull distribution, Table III. The parameters, as based on Maximum Likelihood Estimation, of the respective data sets are summarized:

TABLE III. FIBER LOAD WEIBULL PARAMETERS

	Alpha α			Beta β		
	NPSIT	INSTRON	MERGE	NPSIT	INSTRON	MERGE
008	5.75	3.62	4.28	15.72	15.80	15.79
019	4.86	3.32	3.94	15.33	15.52	15.45
Diff	-18%	-9%	-8.5%	-2.5%	-1.8%	-2.2%

Again, note the significant difference between the α parameter (which is inversely associated with variability) for the two spools. This is particularly evident when handling has been reduced. On the other hand,

consistent with the above discussion, the difference between the β parameter (associated with mean strength) is slight. Physically, composite samples fabricated with the 019 spool which has a smaller α (or larger variability) will have a larger number of fiber breaks than those fabricated with the 008 spool. In accordance with the local load sharing model, the larger number of fiber breaks will increase the stochastic process of clustering of failure sites hence, leading to a higher composite scatter. Therefore, preloading spool 019 and observed accompanied change of composite variability will offer both a verification of the load sharing model and explore the practicality of improving composite reliability.

Complete tabulated results for all fiber diameter and tensile strength measurements are found in Appendix D.

B. TOW BUNDLE PRELOAD

The objective of preloading the tow bundle, prior to matrix binder impregnation was to decrease the variability of the composite strength. It was established in [Ref.1] and [Ref. 2] that composite failure occurred sequentially when weak fiber failure began at low load levels. As applied load is increased, the number of broken sites increased and formed spatially clustered failure sites leading to stress concentrations, the most severe of which causes catastrophic failure. This failure process can be observed by comparing the load deformation curve of a matrix-free tow bundle (curve B in Figure 11) and a matrix impregnated bundle, the composite (curve C).

For the tow bundle curve B, the initial slope of the load deformation curve is the sum of all the filaments in the bundle. As the deformation

Figure 11. Composite Deformation Curve

displacement is increased, the weakest fibers break and the load carrying capability of the entire bundle is lost, thus resulting in a decrease in slope such that the secant modulus is equal to the sum of modulus of the surviving fibers. This continues until only a few very strong fiber survive and the secant of the load deformation curve of the bundle approaches horizontal.

For the composite curve C, the initial slope of the load deformation curve is the same as that of the bundle curve B, since both have the same number of filaments. Within the composite, weak fibers start to fail at 0.3 percent strain as in the bundle. However, in the presence of the matrix binder, the load carried by the broken fiber is transferred to the neighboring fibers via the matrix and, instead of the entire fiber, only a portion equal to the ineffective length is lost. The ineffective length is approximately equal to 10 fiber diameters or in the case of graphite, in the order of 100um. Such a minute loss can not be detected from the resolution of the load deformation curve. As result the load-deformation curve remains apparently linear up to the point of catastrophic rupture even though numerous filament failures sites accumulated internally.

Therefore, it is desirable to develop a preload procedure to break the inevitable weak fibers, without creating stress concentrations which lead to premature undue breakage of the neighboring fibers. This is possible if the preload can be performed before the matrix can effectively transfer the load. Subsequently when the matrix becomes effective, the load around the broken site can be transferred to the neighbor without causing spatial clustering of broken fiber sites and subsequently reducing the variability of the ultimate strength.

The most obvious implementation is to perform the preload on a dry bundle prior to the introduction of the matrix binder. Exploration proved that this approach was not practical. In the absence of matrix binder, a broken filament unleashed the stored elastic energy dynamically leading to fraying and lost of alignment of the filaments, (see Figure 12). In fact this phenomenon occurred when preload was applied to a bundle wetted in a matrix but prior to polymerization. In such a case the surface tension of the uncured polymeric matrix is insufficient to contain the dynamic energy release of the breaking filaments. Therefore, the impregnated bundle was allowed to air cure prior to preloading to ensure sufficient surface tension to prevent fraying.

Figure 12. Fraying of Preloaded Strands

Based on the results from Appendix C, the preload level at a deformation of 3.0 millimeters would break 40 percent of the fibers. It can be expected that this is the effective strain level desired to verify the preload mechanism. Because of the fraying problem associated with this method, the preload level was reduced to a level below which fraying occurred. After a series of samples were tested at various strains, it was determined that 2.25 millimeters provided the best results for a range of room temperature curing times of 19 to 22 hours. At 2.25 millimeters, it can be predicted that 13 percent of the fibers were deliberately broken.

1. Procedure

The finalized preload procedure consisted of :

- Homogeneous mixing of epoxy and curing agent
- Impregnate graphite tow with epoxy in a flat pan
- Partially cure epoxy matrix at room temperature for 19 hours
- Preload samples, under displacement control to 2.25mm (.9% strain)
- Final cure samples at 60°C for 16 hours
- Tensile test samples at crosshead displacement of 10 mm/min.

Ultimate tensile test results for the preloaded and non-preloaded samples are listed in Appendix D. Table XV.

2. Interpretation

The tensile strengths associated with the preloaded sample are compared with the bench mark non-preloaded samples. The non-preloaded samples were prepared essentially by the same procedures listed above with

the exception of air curing and preloading, using an automated filament winding set-up with no manual handling. The expected quality of the non-preloaded samples is comparable to well controlled production quality. The preloaded samples were prepared individually with all manual handling. The quality was expected to be lower than a fully developed production process. One can expect that any improvement observed with the preloaded sample may be realized in a fully developed process.

The tensile strengths of both the non-preloaded and the preloaded samples exhibited statistical scatter precluding a deterministic comparison. Comparisons are made first at the non-parametric level and then at the parametric level together with consequences in structural efficiency and reliability.

a. Non-Parametric Comparison

Distribution-free properties of the two sets of data are presented for an objective comparisons. However, because of sample size (<25) is not sufficiently large, conclusions should be considered as qualitatively valid.

The histograms of tensile strength for the non-preloaded and the preload sample are presented in Figure 13. Preloading process is seen to have no influence on the central tendency of the strength data but has a preceptable affect of removing the lower *weak* tail. The reduction of the lower tail is beneficial to both the structural efficiency and the structural reliability. Several relevant distribution-free properties are listed in Table IV.

TABLE IV. COMPOSITE STRENGTH PROPERTIES

	Mean	Std Dev	Medium	Mode	Skewness
No Preload	46.942	3.07	47.220	47.776	-.27
Preload	46.418	2.12	46.420	46.424	-.003
Change	-1%	-31%	-2%	-2%	~100%

Consistent with the visual comparison, column one suggests no significant change of the mean strength between the two processes. However column five indicates that the nonpreload strength skewed to the weak tail whereas the skew is drastically reduced after preloading. This was also consistent with visual identification of lower tail shift after preloading, see Figures 13 and 14.

b. Parametric Comparison

The local load sharing model, [Ref. 3] provides the theoretical bases for the Weibull model for the non-preloaded samples. Characterization of the non-preloaded strength data by a two parameter Weibull model is therefore proper. Similar justification for the preload sample is not yet firmly established; this data can also be fitted by a two parameter Weibull model for expediency for comparison, with the understanding that the procedure is *ad hoc*. The Weibull parameters obtained through maximum likelihood estimator for the two sets of data are tabulated in Table V.

Figure 13. Histogram of Composite Failure Load Results

Figure 14. Weibull Distribution Plot of Composite Failure Load

TABLE V. COMPOSITE WEIBULL PARAMETERS

	shape	Scale
Nopreload	17.48	48.34
Preload	23.45	47.43
Change	+34%	-2%

The Weibull representations are also consistent with the non-parametric observations, namely no significant central tendency shift as reflected to almost identical β values; but a significant decrease in scatter as reflected in the increase in α . The increase in α affects structural efficiency (at a given reliability level). The magnitude of the potential improvement is illustrated in Table VI.

TABLE VI. SUMMARY OF RELIABILITY AS A FUNCTION OF APPLIED LOAD (KGS)

Reliability	Nonpreload	Preloaded	Change
1×10^{-3}	32.56	35.33	8.5 %
1×10^{-5}	25.02	29.03	16%
1×10^{-6}	21.93	26.31	20%

For composite applications where functional reliability of 1×10^{-3} is required, structural efficiency goes up by 8.5 %. For applications where national security reliability is 1×10^{-5} , structural efficiency goes up by

16%. For composite applications where man-safe reliability (1×10^{-6}) is required, structural reliability goes up by a significant 20%.

Alternately, an increase in α can be interpreted as to cause an increased reliability at a given design stress level, (defined as a fraction of the mean strength). For example, The probability of failure (F) at 80% of the mean decreases from 1.2% for the nonpreloaded composite to .32% for a preloaded composite, a delta of 75%

Finally, it was pointed out, earlier, that modeling the preloaded data by the two parameter Weibull model was *ad hoc*. In fact, the preloaded data when presented alone suggest a bimodel trend (Figure 15). Fitting a shape parameter, α to the lower tail return a value of $\alpha = 270$. This large value of α effectively provides for a structure that would be practically 100 % reliable at any load level below the transition between the modes (approximately 43 kilograms) or, a 100% increase in strength at 1×10^{-6} reliability. Thus potentially, the improvement from preloading is even greater. However, it must be understood that the number of samples tested herein is insufficient to establish a bimodel system. This latter interpretation is subject to confirmation by more extensive exploration.

Figure 15. BiModel Trend

V. CONCLUSIONS AND RECOMMENDATIONS

As a result of individual fiber testing it can be concluded that Individual fiber Test system developed at the Naval Postgraduate School, NPSIT, is a viable testing method which produces accurate and reproducible results. The NPSIT test, is a one step test system which provides for the determination of fiber diameter and ultimate failure load. This test method minimizes the handling of the sample, thus providing a truer characterization of the fiber. An additional advantage is that the test was performed in 40 percent less time as compared to using the INSTRON tester in conjunction with the Scanning Electron Microscope.

This study clearly demonstrated that preloading a composite, prior to complete polymerization, has a profound effect on the lower tail of the Weibull distribution, hence the overall reliability of the composite. In addition, the optimum preload level can be independently mathematically estimated, based on fiber tests results.

Further studies are recommended in the areas of;

- Use of the Micron Eye in determining fiber diameter.
- Alternate composite gripping methods.
- The effects of preloading as a function of strain rate, air curing time and different strains.
- Preloading composite strands at elevated temperatures.
- Statistical modeling to account for a multi-model distribution resulting from preload.

APPENDIX A. SINGLE FIBER TEST PROCEDURES

1. FIBER SAMPLE PREPARATION

The individual fibers were mounted on cardboard forms for ease of storage and handling. The samples were prepared in accordance with ASTM procedure D-3379-75 (reapproved 1982) [Ref 11.].

- Fabricated cardboard mounts. (3" X 5/8").
- Remove 10 inch strand of graphite form roll.
- Using a magnifier, carefully separate strand to expose individual fibers.
- Pick up one end of fiber with adhesive tape and cut to approximately twice the desired length.
- Lay fiber over cardboard mount and center (Figure 16).
- Affix the ends of the fiber with tape.
- Place cardboard on storage rack and label.
- Apply Duco cement at the ends of the fiber.

Figure 16. Fiber Mount

2. CALIBRATION OF FIBER DIAMETER SYSTEM

Before the fiber diameter can be determined using the diffracted laser beam associated with the Naval Postgraduate School Integrated Test, NPSIT a calibration curve must be established .

The calibration curve used to determine the fiber diameter shows the results when comparing the fiber diameter as measured using the diffracted laser beam (NPSIT) compared to the diameter recorded when using the Scanning Electron Microscope (SEM). Six test specimens were mounted on a 15 centimeter cardboard mount and then samples from each end were removed and carefully marked. These samples were then put under the Scanning Electron Microscope (SEM) and several diameter readings were recorded and averaged. The Scanning Electron Microscope results were used as a standard for determining the fiber diameter.

Figure 17 is a graphical representation of the calibration result, with the equation of the straight line being.

$$\text{Diam} = .89 * (\text{NPSIT}) + .3614 \quad (1)$$

A linear curve fit proves most useful and the results for an exponential or polynomial curve fit are essentially the same.

It should be noted that as the fiber diameter increases, the difference between the NPSIT results and the corresponding SEM results also increases. By reviewing Figure 6, this can be predicted because as the fiber diameter increases the spacing between the nodes (X) decreases, and so does the width of the associated dark areas. Therefore it becomes much more difficult (and less accurate) to find the center of the low intensity node using the photocells.

Figure 17. Diameter Calibration Curve

3. FIBER DIAMETER MEASUREMENT PROCEDURES

The fiber sample is first mounted in the test by inserting between the upper and lower clamps. Then the entire stand is adjusted longitudinally to achieve the desired distance (L) from the photocells. (note: the spread of the light pattern increases as L increases). The photocell pedestals are then adjusted to an approximate position corresponding to the predicted distance between the nodes, (ensure there is sufficient travel in the micrometers to allow for left and right movement). After the pedestals are secured in place, measure the distance between the photocells and record as C. Mount the micrometer in place on the photocell pedestals and zero the reading. Now the final distance between the photocells can be easily determined by adding C to the micrometer reading ΔC .

The final steps for determining the fiber diameter are performed with the lab lights off, therefore complete familiarization of all test equipment adjustments is mandatory. After the laser is turned on and the shutter opened, a red light (beam) will appear (avoid looking directly into the laser beam). It may be necessary to manually adjust the laser position and the transverse position of the test stand to obtain the optimum diffraction pattern at the point of interest on the fiber. Then manually adjust the height of the photocells to align the light pattern to the center of the photocells. The preliminary adjustments are now complete.

To determine the distance between the second nodes, each photocell pedestal is adjusted using the micrometers. The final adjustments are made transversely to locate the position associated with the highest resistance reading on the multimeter. Readjust both pedestal separately several times to ensure maximum accuracy. After you secure the laser power, record the digital micrometer reading as Delta C.

Calculate the fiber diameter, a , from equations (2) and (3) of [Ref 9.].

$$X = C + \Delta C, \quad (2)$$

$$a = n (\lambda) L / (X/2), \quad (3)$$

n = corresponding node (eg $n = 2$),

$L = 598.6 \text{ mm.}$ $C = 115 \text{ mm.}$

The accuracy of the fiber diameter is dependent upon the operators techniques, so five or six readings should be recorded and averaged.

4. LOAD TESTING

Fiber failure load was determined using either the Instron Universal Testing Instrument Model 4206 (INSTRON) or the NPSIT system. A Sensotec Inc. 50 gram Load Cell Model 31/1435-01 was used to sense fiber load. The Machine Compliance test, a cross head speed of .1 millimeters per minute was best and for the Fiber Test a speed of 5 millimeters per minute (.1 x gage length) was used.

INSTRON testing is a semi-automatic process when used in conjunction with the HP - 85 computer and an HP 3497A data acquisition system and the Interactive Data Acquisition software outlined in Appendix B.

NPSIT testing also used the same data acquisition system, however manual operation of the drive motor is required. The Control Technics Corp. Linear Actuator Model CTC-160 (gear head ratio 262:1) and associated Micrometer Controller Model MMC-10 provide the same functions as the Instron cross head. The Speed Enter was set at -200 on the thumb wheel to achieve 5 mm/min and the Ratio Enter was set at 40 for a total travel of 45 turns in one minute.

After load cell calibration and system compliance tests are complete, Fiber testing was conducted as follows.

- Run FTST program.
- Carefully mount sample in clamps.
- Select DIAM (NPSIT only).
- Measure Fiber Diameter (NPSIT only).
- Select INPUTS and input initialize data.

- Select ACQUIR, then carefully cut the cardboard mount near the bottom.
- Remove slack in fiber (NPSIT only)
- Hit program CONT and controller R/S simultaneously
- After fiber breaks and data acquisition stops, stop motor controller.
- Graph and store data.

With the INSTRON test system fiber diameter was determine from the NPSIT first. Also this system has automatic fiber slack removal functions.

APPENDIX B. INTERACTIVE DATA ACQUISITION SOFTWARE

The Interactive Data Acquisition Software (IDAS) was designed for use with the HP-85 microcomputer and the HP-3497A Data Acquisition System. This software consists of a set of programs used in determining the ultimate tensile strength and diameter of an individual fiber or filament. With the IDAS it is possible to create a load cell calibration curve and to obtain output in units of grams-force. A program was also created to determine the system compliance in accordance with ASTM procedures. Provisions for complete data analysis are provided through data storage, retrieval and plotting routines. The software gathers data at a rate of 600 points per minute and records and plots Load vs Displacement of the fiber sample.

The IDAS can be used with the INSTRON Model 4206 materials tester or the Naval Postgraduate School Integrated Test system (NPSIT). The programs listed are associated with the INSTRON test system. When using the NPSIT system, the program steps that provide for automatic control of the INSTRON (OUTPUT "704") must be deleted. Crosshead control and pretensioning of the fiber is accomplished manually. A program sub routine is listed in the FTST module and is used to determine fiber diameter using the NPSIT system. Functions keys are defined to provide ready access to commonly used sub routines.

Mr. Jim Nageotte served as the principle computer technician during the development of these programs.

Complete listing of the IDAS programs and a brief description follows.

The system Compliance module or "CTST" measures the compliance or displacement of the system without a fiber sample.

This program is menu driven using function keys to access the sub routines. Should execution halt, return to the menu by typing "cont 130".

The keys are defined here.

The program will continue to loop on the menu until a function key is depressed.

The "INPUTS" sub routine is required first. Input the variables and information needed along with the values of A and B obtained from "LDCALB".

The HP 3497 A records the excitation voltage applied to the load cell.

The equation that translates the load cell voltage into physical units of grams is adjusted for the present excitation voltage.

"INPUTS" is terminated by returning to the menu.

The data acquisition sub routine is title "ACQUIR". Acquir checks the time duration selected and if it finds it to be not greater than zero, prompts the operator to run "INPUTS" and returns to the menu.

The program pauses and waits for the operator to hit "cont". At that time a timer is started and data is acquired at a rate of 600 data points per minute.

Note: OUTPUT "704" provides for automatic control functions to the INSTRON tester. These functions provide for a slight tension in the fiber prior to the start of data acquisition.

The start of the timer is defined at the zero load.

D(I) is the displacement.

"DISP" terminates by returning to the menu.

The load data is read in.

The number of data points saved, the time the test ran and the speed are inputted..

A prompt and beep indicate the data has been read in.

The sub routine is terminated.

The "SAV-DAT" routine is just the counter part of the above routine. It first checks to see that there is data in the memory to be saved.

The memory space is computed and the file opened. The data is then saved. It is in the same form as that read in by "RD-DAT".

The sub routine is terminated

The excitation voltage is read and the calibration adjusted to compensate for any voltage drift.

The compliance coefficients are entered so that a matching compliance curve may be generated and then subtracted from the total deformation, yielding the true displacement of the sample.

The routine ends and returns to the menu.

The "ACQUIR" routine is the actual data acquisition routine.

The program checks to see that the inputs have been entered and provides prompts if no input data can be found.

The OUTPUT "704" codes provide for automatic control of the Instron tester. Initially the cross head is adjusted to provide for slight tension in the fiber, after which the timer will start and data collection will begin.

"LOADSTOR" is a utility program to allow for quick storage or access to data files. This is useful for the transfer of files.

"RD-C" and "SAV-C" read and save the "MCTST" files.

"RD-F" and "SAV-F" read and save the "FTST" files.

After loading a data file, you may press "END" and then examine or list the data in the command mode. Refer to the print out for variable names. When action complete, re-enter the program without losing the data by entering "cont 50".

APPENDIX C. DETERMINING BUNDLE PRELOAD

Before composite preload level can be determined a mathematical model, based on individual fiber data, must be developed to study the effects of gage length on the strength distribution. Previous studies have provided conclusive results that composite strength is a function of gage length. In order to predict the behavior of a 254 millimeter strand, the results of the fiber tests, (gage length = 50 millimeter) must be examined and equated to a sample that is 254 millimeters long.

Results from a previous study [Ref. 7], which examined the affects of proof testing Kevlar-49 at elevated temperatures will be used to verify the mathematical model and to establish an estimated preload level.

1. MATHEMATICAL CORRECTION FOR GAGE LENGTH

$$F1 = 1 - \exp[-(\sigma/\beta_1)^{\alpha_1}] \quad \text{for gage length} = l_1 \quad (4)$$

$$R1 = \exp[-(\sigma/\beta_1)^{\alpha_1}] \quad (5)$$

$$l_2/l_1 = n \quad \text{for gage length} = l_2$$

$$\begin{aligned} R_1 &= \prod R_1 R_2 \dots = (R_1)^n \\ &= [\exp[-(\sigma/\beta_1)^{\alpha_1}]]^n \\ &= \exp[-n(\sigma/\beta_1)^{\alpha_1}] = \exp[-n\sigma(\beta_1)^{-\alpha_1}] \\ &= \exp[-n(\sigma^{\alpha_1}/\beta_1^{\alpha_1})] = \exp[-n(\sigma^{\alpha_1}/\beta_2^{\alpha_2})] \end{aligned}$$

$$\sigma^{\alpha_1} = \sigma^{\alpha_2} \quad \alpha_1 = \alpha_2$$

$$n/\beta_1^{\alpha_1} = 1/\beta_2^{\alpha_2}$$

$$(\beta_1/\beta_2)^{\alpha_1} = n = l_1/l_2$$

$$(\beta_1/\beta_2) = l_2^{1/\alpha_1} / l_1^{1/\alpha_1}$$

$$(\beta_2/\beta_1) = (l_1/l_2)^{1/\alpha_1}$$

Results:

$$\beta_2 = \beta_1 (l_1/l_2)^{1/\alpha_1} \quad (6)$$

Mathematically, equation (6) provides for the beta adjustment for gage length .

2. KEVLAR - 49 MODEL

Based on original test data, Table VII., the beta for strain β_ϵ can be corrected for various gage lengths.

TABLE VII . ORIGINAL TEST DATA

Material	G.L.(mm)	α	$\beta(\text{gm})$	(gm/ ϵ)
Kevlar -49	50	6.7	38.9	1.3×10^3
Kevlar (25°C)	254	25.9	9.74×10^3	4.0×10^5
Kevlar (70°C)	254		9.50×10^3	3.0×10^5

Using the test data for a 50 mm. fiber and substituting β_ϵ for β_l in equation (6), where;

$$\beta_\epsilon = \frac{\beta_l}{E}$$

$$\beta_{\epsilon 2} = \beta_{\epsilon 1} (l_1 / l_2)^{(1/\alpha_1)}$$

Correction to gage lengths can be made, see Table VIII.

TABLE VIII. CORRECTED β_ϵ OF KEVLAR - 49 FOR VARIOUS GAGE LENGTHS δ .

Delta mm (ineffective length)	δ	.1	.5	1	10	50	254
Beta of Strain	β_ϵ	.076	.059	.054	.038	.030	.024

Using the results from a proof test of a Kevlar-49 strand (gage length = 254 mm) at 70°C the number of individual fiber breaks can be determined.

$$\beta\epsilon = \beta_L / \epsilon$$

$$\beta\epsilon = 9.50 \times 10^3 \text{ gms} / 3.0 \times 10^5 \text{ gms}/\epsilon$$

$$\beta\epsilon = 3.1 \times 10^{-2}$$

Note : This result is somewhere between $\delta = 10 \text{ mm.}$ and 50 mm. (Table VIII.) and correcting for gage length , equation (6), $\delta = 50 \text{ mm.}$.

The percent of fiber failures F as a function of a possible ineffective gage length is determined by equation (4).

$$F = 1 - \exp \{-(\beta_{\epsilon GL} / \beta_{\epsilon 70c})^{\alpha_1}\}$$

TABLE IX. PERCENT FIBER BREAKS AS A FUNCTION OF OF INEFFECTIVE GAGE LENGTH 70°C

δ	β_{ϵ}	F	#of fiber breaks (267 per bundle)
.1	.076	.0001	.03
.5	.059	.005	1
1.0	.054	.01	3
10.	.038	.1	27
50	.030	.39	104
100	.027	.63	168
254	.024	.99	267

Based on the fact that the strand was heated to 70°C it would not be unreasonable to expect that the ineffective length δ approaches 50 mm. Therefore from Table IX, 39 percent of the fibers broke.

3. GRAPHITE TESTING

The model was then examined for graphite fibers based on known test data from individual fiber testing conducted during this study. For gage length = 50 mm;

$$\beta_L = 15.5 \text{ gmf} \quad \alpha = 4.0 \quad \beta_\epsilon = 1.72 \times 10^{-2} \text{ mm/mm} \quad E = 900 \text{ gm}/\epsilon$$

Using equation (6), $\beta_L = 13.0 \text{ gmf}$, for gage length = 100 mm. Now applying this information to a dry bundle consisting of 3000 fibers 254 mm. long the number of fiber failures can be predicted as a function of displacement using equation (4), (Table X.)

$$F = 1 - \exp\{ - (\epsilon/\beta_\epsilon) \alpha \epsilon \}$$

$$\beta_{\epsilon_{50\text{mm}}} = .0145 \text{ mm/mm}$$

TABLE X. PERCENT FIBER BREAKS AS A FUNCTION OF STRAIN FOR GAGE LENGTH OF 254 MM.

ϵ	ΔL (mm)	F	No. of Fiber Failures
.001	.254	.00006	<1
.002	.508	.0009	3
.004	1.016	.015	44
.006	1.524	.07	214
.008	2.032	.21	626
.010	2.54	.46	1306
.012	3.04	.69	2083
.014	3.56	.89	2666
.016	4.06	.98	2929
.018	4.57	.99	2992
.020	5.08	.999	2999

For example, based on what is know of the successful Kevlar test at 70 °C ($\delta=50$ mm) it is desired to break 40 percent of the fibers during preloading. So now, the graphite bundle would be loaded until delta length equals 2.5 mm. (Table X).

These results can be graphical confirmed by reviewing a representative load-displacement plot (Figure 18) of a dry bundle (gage length = 254 mm.).

Figure 18 Load-Displacement Plot
