→ A closed bomb burning rate reduction code designed to operate on a microcomputer programmable hand calculator is presented. To accommodate the needs of a minimal computational environment simplifying assumptions were made in developing the theory form functions. Typically form function equations are valid only to the point of gas slivering. Evaluation of the program performed against synthetic data from a validated lumped parameter interior ballistics code (IBHYG2) indicates reasonable agreement with overall mean error of 1.5% or less. The program also computes experimental impetus of the calculated value for co-volume. Keywords: mathematical models; computer programs; computer applications; simulations

I. INTRODUCTION

The majority of information on the burning behavior of propellants used in interior ballistic gun simulations is obtained through burning samples of the propellant in a closed bomb. Analysis of the resulting pressure-time data, either in terms of burning rate information or experimental impetus, is of vital importance to the interior ballisticians and propellant formulators. Highly sophisticated computer programs have been written to perform the needed burning rate analyses.^{1 2} Results from these computations have proven to be extremely valuable in predicting propellant performance in guns. Such burning rate data, for instance, when used in two-phase-flow interior ballistic codes such as NOVA³ have permitted prediction of not only gun muzzle velocities and peak chamber pressures but pressure oscillations as well.⁴

Unfortunately, sophistication is obtained at a price. Often the length or other requirements of the burning rate reduction program limit the equipment on which it can be used. In addition, program complexity often hinders quick turn around between closed bomb firings and data reductions. Finally, the intricate nature of the program can inhibit attempts at modification or extension. This final point is especially critical in research programs where some parameters, such as grain geometry, may fall outside the "normal range" accounted for in the program.

The drawbacks mentioned above have become apparent during the past several years in our work on new propellants for advanced ballistic applications. The program under discussion was written as an answer to these needs. In addition to burning rate computations, the program also calculates the propellant experimental impetus based on maximum experimental pressure, a highly useful feature in evaluating experimental performance of new formulations relative to their predicted thermodynamic performance via BLAKE.⁵

MINICB is offered as a practical tool for propellant formulators and combustion researchers to furnish quick feedback on results of closed bomb

firings which could be used in guiding formulation efforts or combustion diagnostic work. Specifically, MINICB was developed to:

- a. be simple and easy to operate.
- b. be machine independent. In fact, MINICB will run on any computer using BASIC and on some programmable hand calculators.
- c. be easily modified, especially in terms of non-standard grain geometry.
- d. be usable with a full set of pressure-time data or a limited number of pressure-time points
- e. be sufficiently accurate so as to provide useful information.

In this report we present the formulation of the underlying equations together with the simplifying assumptions which were used. Validation of the program and suggestions for implementation are also included.

II. DERIVATION OF EQUATIONS

BURNING RATE EQUATIONS

A. MASS FRACTION BURNT

In determining burning rates a sample of propellant together with an appropriate amount of igniter is ignited in a closed chamber. As the igniter and propellant burn the pressure within the chamber is recorded. Using the

pressure-time history from the closed chamber, physical properties of the closed chamber, thermochemical properties of the igniter and propellant, and the grain geometry of the propellant, a relation between the burning rate of the propellant and pressure can be determined.

The burning rate analysis is a dynamic process in which calculations are performed stepwise along the pressure-time history of the burn. Mass and energy balance must be accounted for in the conversion of solid propellant to gaseous products. The process is not adiabatic since heat loss occurs to the walls of the chamber. The treatment of heat loss may be simplified, however, by assuming that it is a constant percentage throughout the burning cycle and that it can be accounted for by adjusting the theoretical gas temperature of the system by the ratio of the observed to theoretical maximum pressures.

Summarizing, the assumptions made in the burning rate analysis are presented below.

1. The original volume of the closed chamber is known.
2. The igniter is completely burnt before the propellant begins to burn.
3. The maximum pressure from the firing is known.
4. All thermochemical properties of the igniter and propellant are known.
5. The Noble-Able equation of state can be used to describe the state of the closed chamber.
6. The gas products of the igniter and propellant are thoroughly mixed at all times.
7. The rate of heat loss is constant throughout the burning process and can be represented as stated above.
8. The temperature of the system before heat loss can be given as a weighted average of the theoretical flame temperatures of the igniter and propellant gases.

The burning rate analysis requires equations to describe the mass of propellant burned in the chamber at any given instant in terms of measured pressure and known parameters. To derive the required equations start with the Noble-Able equation of state.

$$P(V_b - b) = NRT \quad (1)$$

Since the process is dynamic, the free volume of the bomb, V_b , will be constantly changing and is given by equation (2).

$$V_b = V - (C - C_p)/p_p - (C_{is} - C_i)/p_i \quad (2)$$

Also, the co-volume correction term is given by,

$$b = n_i C_i + n_p C_p \quad (3)$$

Now, recalling the assumption that the igniter is all burnt at the beginning of the analysis, hence, $C_i = C_{is}$, and substituting (2) and (3) into (1) gives equation (4).

$$P(V - C/p_p + C_p/p_p - C_p n_p - C_i n_i) = NRT \quad (4)$$

Assuming a well mixed combination of the gases from the igniter and propellant,

$$N = N_i + N_p \quad (5)$$

equation (4) becomes:

$$P(V - C/p_p + C_p/p_p - C_p n_p - C_i n_i) = RT(N_i + N_p) \quad (6)$$

Next using the relation, number of moles = weight/molecular weight, to modify equation (6).

$$P(V - C/p_p + C_p/p_p - C_p n_p - C_i n_i) = RT(C_p/m_p + C_i/m_i) \quad (7)$$

Now equation (7) can be solved for C_p .

$$C_p = \frac{P[V - C/p_p - C_i n_i] - (RT/m_i)C_i}{(RT/m_p) + P[n_p - 1/p_p]} \quad (8)$$

The term T in equation (8) stands for the system gas temperature. In an adiabatic system this would be a weighted average for the igniter and propellant flame temperatures with suitable provisions for differences in their respective heat capacities. Assuming equivalent heat capacities for propellant and igniter combustion products, it can be approximated as

$$T = \frac{CT_p + C_i T_i}{C + C_i} \quad (9)$$

Assuming further that the experimental shortfall of pressure is entirely due to cooling of the gaseous combustion products, the system temperature may be approximated as

$$T = \frac{CT_p + C_i T_i}{C + C_i} * \frac{P_{max}}{P_{theo}} \quad (10)$$

For systems where the amount of propellant is much greater than the amount of igniter, T may be approximated throughout as a constant defined by the all-burnt condition of equation (10). P_{theo} is computed using the Noble-Able equation of state with the igniter and propellant all burnt. This is equation (11) given below.

$$P_{theo} = \frac{RT_i C_i / m_i + RT_p C / m_p}{(V - n_i C_i - n_p C)} \quad (11)$$

One last simplification can be made to several of the equations by using the following expression for impetus of the igniter.

$$F_i = RT_i / m_i \quad (12)$$

Equation (11) can be rewritten as

$$P_{theo} = \frac{F_i C_i + RT_p C / m_p}{(V - n_i C_i - n_p C)} \quad (13)$$

and equation (8) for the mass of propellant burned at any instant becomes

$$C_p = \frac{P[V - C/p_p - C_i n_i] - (F_i T / T_i) C_i}{(RT / m_p) + P[n_p - 1/p_p]} \quad (14)$$

Having derived the equation for the mass of propellant burned at any instant in terms of measured pressure and known variables, several approaches to computing burning rate are possible. These are all predicated on our ability to further describe the mass of propellant burned in terms of geometric changes in the burning propellant grains. For example, if x represents the distance burned and A the surface area of the propellant when x is the distance burned then

$$C_p = A * x * p_p \quad (15)$$

or

$$x = C_p / A * p_p \quad (16)$$

Finally, differentiating both sides of (19) with respect to time gives an expression for the burning rate, r .

$$r = dx/dt = (dC_p/dt) / A * p_p \quad (17)$$

This is the approach which will be followed here since knowledge of the instantaneous surface area is a valuable tool in analyzing and understanding closed bomb results. Alternately, x , the distance burned, hence burning rate, could be expressed in terms of the mass fraction of propellant burned without invoking surface area at all. That technique, particularly suited to hand calculators, is covered in Appendix E.

B. SURFACE AREA

In computing the burning rate, r , in equation (17) the value for the surface area, A , must be known at each time step the calculations are being performed. For this program the surface area is calculated using the following scheme.

1. The amount of propellant burnt, C_p , is equal to the density times the volume of propellant burnt.
2. The volume of propellant burnt is determined from the initial dimensions of the propellant grain and the linear depth burnt, which is denoted by x .
3. From 1 and 2, C_p is a function of initial propellant grain dimensions, density, and depth burnt.
4. Thus, the depth burnt can be solved for in terms of initial grain geometry, amount burnt, and density.
5. The surface area at any time is a function of initial grain geometry and depth burnt at that time.

To illustrate the scheme, the formula used in MINICB for the surface area of a single perf grain will be derived. The derivation of other surface area equations can be found in Appendix A and in the text by Hunt.⁶ For the derivation let the propellant density be given by p instead of p_p .

Figure 1. shows a single perforated grain after it has burnt a linear distance, x , on all surfaces. The volume used or burnt is given in equation (18).

$$\begin{aligned}
 \text{Volume Used} = & L \cdot \pi \cdot \left[\left(\frac{D}{2} \right)^2 - \left(\frac{D - 2x}{2} \right)^2 \right] \\
 & + L \cdot \pi \cdot \left[\left(\frac{d + 2x}{2} \right)^2 - \left(\frac{d}{2} \right)^2 \right] \\
 & + 2x \cdot \pi \cdot \left[\left(\frac{D - 2x}{2} \right)^2 - \left(\frac{d + 2x}{2} \right)^2 \right] \quad (18)
 \end{aligned}$$

In equation (18), the first term represents the volume used along the outer lateral surface and the second term, the volume along the lateral perf surface. The final term is the additional volume lost from the ends not accounted for in the other two terms. Another approach to determining the volume used would be to take the original volume and subtract the volume

remaining after the grain had been burnt a depth x . The two approaches are equivalent and lead to the same equations.

Simplifying, equation (18) becomes

$$\begin{aligned} \text{Volume Used} = & L\pi[xD - x^2] + L\pi[xd + x^2] \\ & + (x\pi/2)[D^2 - d^2 - 4xD - 4xd] \end{aligned} \quad (19)$$

Figure 1. A single perf grain which has burnt a distance, x , on all surfaces.

Now the total amount of propellant burnt can be expressed in the following relation.

$$C_p = p * \text{Volume Used} \quad (20)$$

Substituting (19) into (20)

$$C_p = p * L * \pi * [xD - x^2] + L * \pi * [xd + x^2] \\ + (x * \pi / 2) * [D^2 - d^2 - 4xD - 4xd] \quad (21)$$

At this point equation (21) can be solved for x which then can be used to determine the surface area. Expanding and rearranging

$$2 * C_p / (L * p) = (-4D - 4d) * x^2 + (-d^2 + D^2 + 2LD + 2Ld) * x \quad (22)$$

This is now a quadratic equation in x and can be solved using the quadratic formula. First, rearrange equation (22).

$$(4D + 4d) * x^2 - (-d^2 + D^2 + 2LD + 2Ld) * x + 2 * C_p / (L * p) = 0 \quad (23)$$

Let AA = 4D + 4d, BB = (-d² + D² + 2LD + 2Ld), and CC = 2 * C_p / (L * p), then

$$x = \frac{BB \pm \sqrt{(-BB)^2 - 4*AA*CC}}{2*AA} \quad (24)$$

At this point it is necessary to determine which root corresponds to the correct value of x. Several observations:

1. AA and CC are both positive.
 2. BB is positive since D is large than d.
 3. The radical must be real since a solution must exist.
 4. The radical is always less than BB since $4*AA*CC$ is positive and is subtracted from BB^2 .
 5. Based upon 1 - 4, there are two positive real roots for x.
 6. Now, x should be the smaller of the roots. If x was the larger root then the smaller root would also be a valid solution. However, this would result in two possible solutions which is physically not possible.
- Thus, x must correspond to the root with the negative sign.

Therefore,

$$x = \frac{BB - \sqrt{(-BB)^2 - 4*AA*CC}}{2*AA} \quad (25)$$

Referring to Figure 1, the surface area of the grain corresponding to a depth x burnt is given in equation (26).

$$A = (L - 2x) \cdot \pi \cdot [D - 2x] + (L - 2x) \cdot \pi \cdot [d + 2x] \\ + 2 \cdot \pi \cdot [((D - 2x)/2)^2 - ((d + 2x)/2)^2] \quad (26)$$

This equation can now be used to determine the surface area of the grain for a given depth burnt.

Summarizing, the burning rate is given by equation (17)

$$r = dx/dt = (dC_p/dt)/A \cdot p_p \quad (17)$$

To determine the rate the following procedure is used.

1. From equation (14) C_p can be determined for each value of pressure in the pressure-time history.
2. The values for dC_p/dt can be determine from C_p using a numerical technique.
3. Using equation (26) or a similar one for the appropriate grain geometry the values for the instantaneous surface area can be determined for each value of C_p determined in 1.
4. Since p_p is a constant, the burning rate can now be readily calculate from equation (17).

EXPERIMENTAL IMPETUS

The traditional approach for determining experimental impetus is presented by Hunt⁶ in his text on interior ballistics. Exact details can be found in Appendix D. This method requires a series of closed bomb firings with different loading densities. In some propellant research efforts, where burning rate is of primary interest and sample amounts are limited, it is

often not practical to fire such a series. If a reasonably accurate value of the propellant co-volume can be obtained, however, then a reliable measure of experimental impetus may be obtained with a single closed bomb firing.

In propellant development efforts it is general practice to calculate theoretical thermodynamic properties for a proposed formulation based on its chemical composition and the heats of formation of its ingredients. In this way, theoretical values for impetus, co-volume, molecular weight of combustion products and the like are available for new formulations from computations using codes such as BLAKE. However, these theoretical thermodynamic values still need to be verified. Fortunately, while impetus is strongly sensitive to composition, co-volume is not. As stated by Hunt,

"..., since impetus is sensitive to slight variations in propellant composition, particularly in the moisture content, the experimental values of impetus should be more reliable than the calculated values. The co-volume, on the other hand, is not sensitive to small changes in composition and can only be derived experimentally by a difference process; the calculated values are therefore more reliable."

The co-volumes computed by BLAKE, therefore, can be assumed as reasonable for most systems, except for those having high levels of condensable combustion products (metal oxides/ nitrides/ sulfides/ sulfates and their derivatives). The experimental impetus computations described below are predicated on the assumption that BLAKE co-volumes are reasonably correct for the formulation.

In determining experimental impetus a sample of propellant together with an appropriate amount of igniter is completely burned in a closed chamber of known volume. The pressure-time history, including maximum observed pressure, is recorded. Based upon the maximum pressure, the closed chamber volume, thermochemical properties of the igniter, and co-volume of the propellant an

experimental impetus can be determined. (Data from the same experiment can also be used for burning rate computations). The method works best for fast-burning samples where heat loss is small.

In deriving the equation for computing the experimental impetus the following assumptions have been made in order to meet the objectives stated in the introduction.

1. The original volume of the closed chamber is known.
2. Both the igniter and propellant are completely burnt.
3. The maximum pressure from the firing is known.
4. All thermochemical properties of the igniter are known.
5. The co-volume of the propellant is known.
6. The Noble-Able equation of state can be used to describe the final state of the closed chamber.
7. The theoretical impetus of the igniter can be used in place of the experimental impetus of the igniter.

For a closed chamber with free volume, V_b , the Noble-Able equation of state is

$$P(V_b - b) = NRT \quad (27)$$

where P = pressure

b = co-volume correction term

N = number of moles of gas

T = system temperature

R = universal gas constant

Since all igniter and propellant is assumed to be completely burnt, the free volume of the chamber, V_b , is the volume of the empty chamber, V . Also, having all igniter and propellant burnt implies that the co-volume correction term, b , is the sum of the product of the co-volume and weight for the igniter

and propellant. That is,

$$b = n_i C_i + n_p C \quad (28)$$

Substituting into (27) yields

$$P(V - n_i C_i - n_p C) = NRT \quad (29)$$

Now the gas in the chamber is a mixture of gas products from the igniter and the propellant. Thus, $N = N_i + N_p$ which when substituted into (29) produces the following equation.

$$P(V - n_i C_i - n_p C) = RT(N_i + N_p) \quad (30)$$

Multiplying the right-hand side of (30), equation (31) is obtained.

$$P(V - n_i C_i - n_p C) = RTN_i + RTN_p \quad (31)$$

Since N = weight divided by molecular weight, N_i and N_p can be replaced to obtain

$$P(V - n_i C_i - n_p C) = RTC_i/m_i + RTC/m_p \quad (32)$$

Now impetus is given by the formula

$$F = RT/m \quad (33)$$

Thus, using the assumption that the theoretical impetus of the igniter can be used in place of the experimental impetus together with (33) the expression below is obtained.

$$P(V - n_i C_i - n_p C) = C_i F_i + C F_p \quad (34)$$

Finally, equation (34) can be solved for the experimental impetus of the propellant.

$$F_p = [P(V - n_i C_i - n_p C) - C_i F_i] / C \quad (35)$$

III. MINICB - PROGRAM

Program Flow

The flow of the program MINICB is presented below. A complete listing of the program together with a listing of variables used in it can be found in Appendix B.

Except for the five point differentiation the calculations used in MINICB were described in section II. As for the five point differentiation method it was obtained from a paper by Juhasz and Price⁷ and is given by the following formula.

$$dP_0/dt = \frac{-2*P_{-2} - P_{-1} + 0 + P_{+1} + 2*P_{+2}}{10*\Delta t} \quad (36)$$

In the formula P_{-2} , P_{-1} , P_0 , P_{+1} , and P_{+2} are five successive points in the data set and the derivative of the pressure is to be estimated at the pressure value of P_0 .

RUNNING MINICB

To run MINICB, load the program MINICB and run it from BASIC. For the most part MINICB is menu driven and will only require entering the necessary values for whatever computation is to be performed. The input values needed for each option are listed below in Tables 1 and 2 together with the units for each input value.

TABLE 1. Required Input for the Experimental Impetus

Delta Time -- Msec

Starting Time -- Msec

Pressure Data -- Psi

The pressure data, at fixed time intervals, can be entered by hand or read from a file stored on a disk. In either case, the pressure values are entered one per line with the last value being a -1 to terminate the input. The input should not contain time, this information is generated from knowing delta time and the starting time. Also, the pressure should always be increasing. If the pressure is not increasing then the program will produce negative burning rates (physically not meaningful) for those times where the pressure decreases. The negative burn rates reflect the fact that in the analysis a decrease in pressure means an increase in solid propellant, not heat loss, which is accounted for by an adjusted system temperature.

Output from MINICB is, of course, dependent upon which type of calculation is being performed. For the experimental impetus calculation the output is a one page summary of the input values together with the computed experimental impetus for the propellant given in Joules/gram and Ft.-lb./lb. The output for the burn rate analysis is in two parts. The first is a

hardcopy to the printer which consists of a summary of the input values, the theoretical maximum pressure, number of propellant grains and an optional table of burning rates at every 500 psi. The second form of output is a disk file which consists of a table containing time, pressure, dp/dt , percent burnt, burning rate, and surface area fraction. This file will also contain the table of burning rates at every 500 psi if the option was selected. Samples of the output available from MINICB are given in Appendix C.

IV. VALIDATION

Validation of MINICB requires an assessment of its performance in computing burning rates with its various form functions as well as in computing experimental impetus. The procedures followed and results obtained are given below.

Burning Rate Validation

A well-tested lump parameter interior ballistic code, IBHVG2,⁸ was used to simulate closed bomb burning by making the projectile weight so large that no projectile motion occurred. This permitted direct quantitative comparison of MINICB burning rate outputs with the burning rate inputs used to generate the pressure-time data up to the point of P_{max} . In addition, the results from MINICB were found to be in reasonably close agreement with experimental burning rate data computed by CBRED¹ (See Appendix G and Table F-3, Appendix F).

At the present time, MINICB contains five different form functions for grain geometry. These form functions are:

1. Cord burning cigarette fashion -- burning on one end only
2. Single perf burning only on the perf surface
3. Single perf grain

4. Generalized n-th perf grain -- the form function assumes all webs are equal and all perf diameters are equal. In addition, the form function only holds up to the point of slivering.
5. Single perf burning on both ends and the perf surface

All five form functions were exercised, see validation runs 1-5 below. For the general n-th perf grain a seven perf case was chosen. More details concerning the form functions can be found in Appendix A.

Propellants A, B, and C with bP^n burning rate laws and realistic thermochemicals were used for the simulations. The values of b and n as well as the propellant/igniter thermochemical data used in the various simulations are given in Tables 3 - 5.

Validation 1. The burning of propellant A, see Table 3, with a cord geometry burning cigarette fashion (i.e. on a single end surface) was simulated via IBHVG2 and reduced via MINICB. In place of showing all the output from MINICB, the results will be displayed graphically showing the percent difference between the burning rates calculated by MINICB and the actual burning rates as given by the burning rate law $r = .0826P^{.865}$ for different values of pressure, see Figure 2. Agreement between the burning rate values extracted and the initial burning rate values was close for the entire burn, with a mean error of 0.57 percent.

Figure 2. Percent difference between computed burn rates from MINICB and theoretical burning rates for a cord burning in a cigarette fashion. Validation 1.

Validation 2: Propellant A, Table 3, single perforated grain, burning only on the perforation surface. Results similar to the first case are presented below in Figure 3. In this case the mean error was -.87 percent.

Figure 3. Percent difference in burning rates between MINICB and rates computed using the burning rate law for a single perf grain burning on the perf surface only, validation 2.

Validation 3. Propellant A, single perforated geometry, burning on the ends and the perforation surface. Results similar to those above are given in Figure 4. In this case the mean error was 1.69 percent. The error, however, was increasing near the end of the burn, reaching a maximum of 4 percent at burnout.

Figure 4. Percent difference in burning rates between MINICB and rates computed using the burning rate law for a single perf grain burning on the ends and perf surface, validation 3.

Validation 4. Propellant B, Table 4, single perforated geometry burning on all surfaces. Results are again presented in terms of percent differences in Figure 5. In this case the difference between the derived and initial burning rates was reasonably constant, averaging 1.35 percent.

Figure 5. Percent difference in burning rates between MINICB and rates computed using the burning rate law for a single perf grain, validation 4.

Validation 5. Propellant C, Table 5, seven perforated grain burning on all surfaces. Results are presented in the same manner as above in Figure 6. The burning rates computed were approximately two percent high initially and 1.75 percent low at the end of the analysis which was performed to the point of grain slivering. The overall absolute mean error was 0.88 percent.

Figure 6. Percent difference in burning rates between MINICB and rates computed using the burning rate law for a seven perf grain, validation 5.

Overall, for the different form functions, the average error is less than two tenths of one percent in the best case and below 1.4 percent in the worst case. On the 5 to 95% interval of P_{max} the greatest observed error was ~3%. Due to the lower level of error in the constant area case, it seems probable that numerical errors are magnified during the surface area computations. The error levels above fall within the normal experimental round-to-round variation of closed bomb burning rates and, therefore, are not overly critical. Considering the simplifying assumptions made in developing the theory and the crude numerical methods used, the error levels appear reasonable for the intended application. MINICB was designed as a quick tool for determining burning rates from a limited number of pressure points. The simplifications introduced were necessary to permit running in a minimum environment.

Burn Rate Error vs. Number of Data Points

Since MINICB can be run using a programmable calculator or a computer with pressure information entered by hand, it was of interest to investigate what effect the number of pressure values entered would have on program performance. The data set for the end-burning cord, see verification run 1 for details, was reduced via MINICB using different numbers of pressure values. In all instances, points were selected at equal intervals and included the original first pressure value as well as the maximum pressure value. Data sets containing 253, 126, 64, 22, or 12 points were used. The results are presented in terms of percent difference and mean and standard deviation of percent difference, see Figure 7 and Table 6.

Figure 7. Percent Difference in burning rates between MINICB and theoretical burning rates for a cord burning in a cigarette fashion for data sets with different number of points where each set was taken from the same original data set.

TABLE 6. Mean and standard deviation of percent error for data sets with different number of points all of which were taken from the same original data set.

Number of Points	Mean	Standard Deviation
253	.567233	.474999
126	.504159	.325364
64	.42504	.093079
22	.274162	.074713
12	-.17125	.086029

Paradoxically, as the number of data points in the set decreased the mean percent error decreased. This is probably related to numerical roundoff errors in the calculated mass of propellant burnt for the smaller time steps. Similar examinations using the other form functions showed little or no dependence of the percent error on the number of data points utilized. Ultimately, this indicates that the method should be reasonably reliable when using a small number of manually entered pressure points to compute burn rates.

Experimental Impetus

It was not practical to validate experimental impetus calculations via test firings. It was possible, however, to verify the calculation by comparison with results from the BLAKE thermodynamic code. BLAKE computes pressure, impetus, co-volume, molecular weight, and other thermodynamic properties of propellant combustion products at various loading densities. In essence, the pressure from a BLAKE computation at a given loading density is the equivalent of the maximum pressure from an adiabatic closed bomb test. Under the circumstances, the experimental impetus computed by the proposed method should be the same as the theoretical impetus from BLAKE.

The propellant composition chosen for the evaluation was a ball propellant, X-4179, manufactured by the Olin Corporation. The composition of X-4179 is given in Figure 8. The input to BLAKE is given in Figure 9 and the output from BLAKE appears in Figure 10.

Figure 10. Results from BLAKE for X-4179

Using the BLAKE results for a loading density of 0.25 g/cc with a bomb volume of 100 cc the weight of the igniter (assumed to have identical thermochemical properties to the propellant) is selected as 1 gm and that of the propellant 24 gm. Figure 11 shows the results of MINICB using the experimental impetus option for this propellant with input values for the necessary thermochemical values taken from BLAKE.

PROPELLANT CO-VOLUME: 26.15 CU IN/LB

BOMB VOLUME: 100 CC
MAXIMUM PRESSURE: 55479 PSI

IMPETUS- 1163.414 J/G
IMPETUS- 390895 FT-LB/LB

Figure 11. Experimental Impetus results from
MINICB for X-4179

From Figure 10 the theoretical impetus for a loading density of 0.25 g/cc is 390964 Ft-lb/lb. MINICB calculates a impetus of 390895 Ft-lb/lb which represents a percent error of -0.0176%. This small difference is probably a result of round-off errors. Considering the purpose of the computations, which is to compute experimental impetus as a practical performance index, the agreement is reasonable.

V. SUMMARY

MINICB, with overall error limits of at most 1.5%, can be a particularly useful tool in the computation of burning rates or experimental impetus from

closed bomb pressure-time curves. This is especially true in situations where only a limited number of pressure-time data points are available, the propellant has an unusual grain geometry, or is a new formulation and feedback is quickly needed for the experimental program to proceed. Considering the minimal environment necessary for running MINICB and the simplicity of use, it is felt that MINICB meets the stated objects set out in the introduction.

T_i	Flame Temperature of the Igniter
x	Linear distance burnt
V	Volume of empty chamber
V_b	Free Volume in the bomb

APPENDIX A
SURFACE AREA FORMULAS

I. Cord Burning Cigarette Fashion: An example of this type of burning grain is shown in Figure A-1.

Figure A-1. A cord burning in a cigarette fashion.

For this particular grain geometry the burning is all on one end and the surface area of the burning surface remains constant and is given by equation (A-1).

$$A = (\pi/4) * D^2 \quad (A-1)$$

II. Single Perf Burning Only on Perf Surface: A diagram of the way in which the grain is burning is shown in Figure A-2.

Figure A-2. A single perf grain burning
only on the perf surface.

The equation for the volume burnt is given in equation (A-2).

$$\text{Volume Used} = L \cdot \pi \cdot \left[\left(\frac{d + 2x}{2} \right)^2 - \left(\frac{d}{2} \right)^2 \right] \quad (\text{A-2})$$

Squaring and simplifying in the brackets yields

$$\text{Volume Used} = L \cdot \pi \cdot [dx + x^2] \quad (\text{A-3})$$

Thus, multiplying by the density, which is denoted by p instead of p_p , to obtain the total propellant burnt, equation(A-4) is obtained.

$$C_p = p \cdot L \cdot \pi \cdot [dx + x^2] \quad (A-4)$$

Rearranging, the following quadratic equation in x is obtained.

$$x^2 + dx - C_p/(p \cdot \pi \cdot L) = 0 \quad (A-5)$$

Letting $B = C_p/(p \cdot \pi \cdot L)$ and using the quadratic formula to solve for x .

$$x = \frac{-d \pm \sqrt{d^2 + 4 \cdot B}}{2} \quad (A-6)$$

Since x is positive the positive root is chosen in the expression for x . Next the equation for the surface area for this grain is

$$A = L \cdot \pi \cdot [d + 2x] \quad (A-7)$$

Substituting (A-6) into (A-7) yields the final expression for the surface area

$$A = L \cdot \pi \cdot \sqrt{d^2 + 4 \cdot C_p/(L \cdot \pi \cdot p)} \quad (A-8)$$

III. Single Perf Burning on Ends and Perf Surface: A diagram of this grain is shown in Figure A-3.

Figure A-3. Single perf burning on ends
and perf surface.

Again start with an expression for the total volume used.

$$\begin{aligned} \text{Volume Used} = L * \pi * [((d + 2x)/2)^2 - (d/2)^2] \\ + 2x * \pi * [(D/2)^2 - ((d + 2x)/2)^2] \end{aligned} \quad (\text{A-9})$$

In equation (A-9) the first term represents the volume burnt from inside the perf and the second term that burnt off both ends which was not accounted for in the first term. Simplifying and multiplying by density to obtain the total propellant burnt equation (A-10) is obtained.

$$C_p = (\pi p/2) * [2Ldx + 2Lx^2 + xD^2 - xd^2 - 4dx^2 - 4x^3] \quad (A-10)$$

Rearranging to obtain an equation in terms of x,

$$x^3 + (-L/2 + d)x^2 + (-Ld/2 - D^2/4 + d^2/4)x + C_p/(2\pi p) = 0 \quad (A-11)$$

Now this is a cubic equation in x and the tendency is to assume that there is one real root and two complex roots. However, this is not the case. To see this, note that the intercept is positive and that the lead coefficient also positive. Thus, if a graph was made of this function it would tend to positive infinity as x went to positive infinity and would be positive for x equal to zero, see Figure A-4. Therefore, the graph must cross the positive x-axis twice or not at all. However, if it does not cross the positive x-axis then no solution would exist, but one must exist. Hence, equation (A-11) has three real roots, two positive and one negative.

Figure A-4. Graph of the Equation Defined
by Equation (A-11)

After analyzing solutions of cubic equations it became obvious that a numerical solution for equation (A-11) was the only feasible method for solving for x and keeping to the objective of having a simple and easy to run program. The Newton Iterative method, starting with an initial guess of 0, for finding roots has proven sufficient in computing the root.

Having obtained a value for x , the surface area is given by equation (A-12).

$$A = \pi[d + 2x] + 2\pi\left[\left(\frac{D}{2}\right)^2 - \left(\frac{d + 2x}{2}\right)^2\right] \quad (A-12)$$

IV. N-th Perf Grain: An example of this grain geometry for seven perfs is shown in Figure A-5.

Figure A-5. Seven Perf Grain

In the following derivation for the surface area the analysis is only correct up to the point of slivering and assumes that the webs are equal and that all perf diameters are the same. A equations will be derived for n perfs not just the seven shown in Figure A-5. Also, this analysis will not be valid for a single perf grain. As before, the starting point is the volume used and is given in equation (A-13) which is very similar to that for a single perf grain.

$$\begin{aligned}
\text{Volume Used} = & L \cdot \pi \cdot [(D/2)^2 - 2x/2]^2 \\
& + n \cdot L \cdot \pi \cdot [(d + 2x)/2]^2 - (d/2)^2 \\
& + 2x \cdot \pi \cdot [(D - 2x)/2]^2 - n \cdot [(d + 2x)/2]^2 \quad (A-13)
\end{aligned}$$

Multiplying by density to obtain the total amount of propellant burnt and rearranging to obtain an equation in x , equation (A-14) is obtained.

$$\begin{aligned}
(4n - 4)x^3 + (4D + 4nd - 2Ln + 2L)x^2 \\
+ (nd^2 - D^2 - 2Ldn - 2LD)x + 2C_p / (\pi \cdot p) = 0 \quad (A-14)
\end{aligned}$$

As in III. the cubic also has three real roots and a numerical method should be used to determine the value of x . Having determined x the surface area is given by equation (A-15).

$$\begin{aligned}
A = & (\pi/2) \cdot [(D - 2x)^2 - n(d + 2x)^2] \\
& + \pi \cdot (L - 2x) \cdot [n(d + 2x) + (D - 2x)] \quad (A-15)
\end{aligned}$$

APPENDIX D

TRADITIONAL MEASUREMENT OF EXPERIMENTAL IMPETUS^{6 9}

In this approach, heat loss and effects of the igniter are ignored. Problems with the igniter can be eliminated by having the igniter the same as the propellant. The following symbols will be used:

P	Pressure
V	Chamber Free Volume
F	Impetus
n	Co-volume
L	Loading Density
c	Charge Weight

Start with the Noble-Able equation of state,

$$P(V - nc) = Fc \quad (D-1)$$

Divide by c,

$$P(V/c - n) = F \quad (D-2)$$

Next divide by P to obtain

$$V/c - n = (1/P) F \quad (D-3)$$

Since loading density is the charge weight divided by volume, $L = c/V$. Substituting into equation (D-3) gives

$$1/L = F(1/P) + n$$

(D-4)

Now by performing a series of closed bomb firings with different loading densities and recording the maximum observed pressure a plot of $1/L$ versus $1/P$ can be made. The plot should be linear and the slope will be the impetus and the intercept the co-volume.

APPENDIX E

EQUATIONS FOR THE HAND CALCULATOR VERSION OF MINICB

As mentioned in the main body of the report an alternate approach to computing the burning rate is to determine the distance burnt, x , which corresponds to each pressure and then compute dx/dt directly instead of using equation (17), $r = (dC_p/dt)/(p \cdot A)$. For the hand calculator version of MINICB this approach was utilized since it requires fewer programming steps. The analysis is identical to the point of finding C_p . equation (14), for each value of pressure. Next, it is necessary to determine values for x for each value of C_p . In the analysis presented earlier, values of x were found by deriving a relation between x and C_p for the specific propellant under investigation based upon initial grain geometry and the relation

$$C_p = \text{density} * \text{Volume Used} \quad (\text{E-1})$$

Unfortunately, solving the expression resulting from equation E-1 for x was, for most grain geometries, quite complicated, often requiring a numerical scheme. The number of programming steps required for such an operation on a hand calculator was felt to be excessive and would result in a separate program for each grain geometry. Thus, it was decided to make a further simplification in the analysis for the hand calculator version so as to allow for the widest possible range of form functions. Starting with equation (E-1), divide by the original mass of propellant giving equation (E-2).

$$C_p/C = \text{density} * \text{Volume Used}/C \quad (\text{E-2})$$

Now C_p/C is the mass fraction burnt and will be denoted by M . Also, C , the total mass of propellant, is the density multiplied by the total original volume. Thus, equation (E-2) can be rewritten to produce equation (E-3).

$$M = \frac{\text{density} * \text{Volume Used}}{\text{density} * \text{Total Original Volume}} \quad (\text{E-3})$$

Canceling density and writing the volumes in terms of volume per grain equation (E-4) can be obtained.

$$M = \frac{\text{Number of Grains} * \text{Volume/grain used}}{\text{Number of Grains} * \text{Original Volume/grain}} \quad (\text{E-4})$$

therefore.

$$M * \text{Original Volume/grain} = \text{Volume/grain used} \quad (\text{E-5})$$

Now the original volume/grain is a constant based upon the original grain geometry and volume/grain used is determined by the original grain geometry and the distance burnt, x . Hence, equation (E-5) could be used to define a relation between M , the mass fraction burnt, and the depth burnt, x . Using this expression to actually calculate x would require as many programming steps as before. However, assuming increasing values of x , a reasonable assumption, a series of values for the mass fraction burnt can be computed. These values may then be fitted empirically to an equation such as

Routines for such a curve fitting are available for many calculators. The empirical equation can then be used to determine the values of x which correspond to each value of C_p in the program. This approach will reduce the computation of x to an exponentiation and multiplication. Routines for such a curve fitting are available for many calculators. Results for the seven perf grain used in validation 5, Table 5 are shown in Table E-1. Again the analysis is only valid up to the point of slivering which for a seven perf grain occurs at about 80% all burnt.

TABLE E-1. Fitting to an Equation
 $x = a*M^3 + b*M^2 + c*M + d$
 for a Seven Perf Grain

Web ~ 0.03988 inches

Distance Burnt Inches	Mass Fraction Burnt
.0025	.09195951
.005	.1883845
.0075	.2891035
.01	.3939452
.0125	.502738
.015	.6153106
.0175	.7314915
.01994	.8481996

Values for a, b, c, and d

a = 0.001758388
b = -0.006253527
c = 0.0275523105
d = 0.000022268

Goodness of Fit: $R^2 = 0.999999885$

Using the technique above for various other form functions has resulted in similar values for R^2 . Thus, it appears that using a cubic equation to relate depth burnt and mass fraction burnt is a reasonable assumption and should provide an acceptable alternative for determining the depth burnt, x , in the hand calculator version of MINICB.

APPENDIX F

HAND CALCULATOR PROGRAM

Listings for the various programs and subprograms which make up the hand calculator version of MINICB are given below for a Hewlett-Packard HP-41C calculator.* The remaining section of the Appendix presents comparisons between runs of the hand calculator version and the BASIC version of MINICB and a comparison with CBRED2.

* Hewlett-Packard and HP-41C are tradenames of the Hewlett-Packard Corporation. Use of these names does not constitute indorsement by the US Army.

To evaluate the hand calculator version of MINICB three different cases were selected. The first two involved a comparison with results from the BASIC version of MINICB. These comparison were performed to investigate the effect of expressing the depth burnt in terms of the mass fraction burnt via a cubic function. Thus, the first comparison was with the the cord burning in a cigarette fashion. This formuncion results in a perfect fit between x and M, $a=b=d=0$ and $c = \text{grain length}$, and hence there should be almost perfect agreement between the results. The only difference is the numerical accuracy between the machines. Results for this comparison are shown in Table F-1 and Figure F-1. In the second comparison, a seven perf grain was used to evaluate the effects of the curve fitting. Details of the curve fitting for this grain are given in Appendix E. Results are found in Table F-2 and Figure F-2. Finally, a comparison was made with results of CBRED2 for a 19 perf grain. The results are given in Table F-3 and Figure F-3. In viewing the results it is important to keep in mind that the hand calculator version was being performed with a very limited number of pressure-time points, 11, 24, and 13 points respectively for the comparisons.

35000	8.283	8.302	0.232
40000	9.411	9.352	-0.628
45000	10.539	10.377	-1.537
50000	11.294	11.45	.381

13 data points used

Figure F-3. Comparison of Calculator Version of MINICB with CBRED2 for a Nineteen Perf Grain

With an absolute error of 0.63% the agreement between the calculator version of MINICB and CBRED2 is excellent for this particular comparison. Similar results have been obtained for other form functions and propellants.

Based upon the result of the comparisons it is felt that the calculator version of MINICB can be used with a high degree of confidence for computing burning rates from a limited number of data points.

APPENDIX G

COMPARISON OF THE BASIC VERSION OF MINICB
WITH CBRED2

For the sake of completeness, the results of MINICB were compared for a limited number of cases with the results from BRL's standard burning rate reduction code, CBRED2, an extension of CBRED. Typical results are presented below. A common experimental pressure-time history obtained from a closed bomb firing was used as input to both programs. Thus, this comparison is relative, comparing only the performance of both programs to each other and not to a burning rate known a priori. Details of the propellant and igniter used in the closed bomb firing are given in Table G-1. Results from the code are presented in Table G-2 and graphically in Figure G-1.

TABLE G-1. Details of Propellant and Igniter used in Closed Bomb Firing

	Propellant	Igniter
Type:	JA2	FFFG
Weight(lb):	0.1528	0.002205
Density(lb/in ³):	0.0578	-----
Gamma:	1.2247	1.25
Impetus(ft-lb/lb):	363241	97500
Co-volume(in ³ /lb):	27.42	30.00
Flame Temperature(K):	3437	2000

Number of data points 101

TABLE G-2. Comparison of Burning Rate Between MINICB and CBRED2 for a 19-perf Grain

Pressure Psi	Rate Inch/s		Percent Difference
	MINICB	CBRED2	
5000	1.335	1.378	3.185
10000	2.489	2.543	2.13
15000	3.734	3.742	0.21
20000	4.833	4.875	0.87
25000	6.072	6.026	-0.75

USER EVALUATION SHEET/CHANGE OF ADDRESS

This Laboratory undertakes a continuing effort to improve the quality of the reports it publishes. Your comments/answers to the items/questions below will aid us in our efforts.

1. BRL Report Number _____ Date of Report _____

2. Date Report Received _____

3. Does this report satisfy a need? (Comment on purpose, related project, or other area of interest for which the report will be used.) _____

4. How specifically, is the report being used? (Information source, design data, procedure, source of ideas, etc.) _____

5. Has the information in this report led to any quantitative savings as far as man-hours or dollars saved, operating costs avoided or efficiencies achieved, etc? If so, please elaborate. _____

6. General Comments. What do you think should be changed to improve future reports? (Indicate changes to organization, technical content, format, etc.) _____

CURRENT ADDRESS	_____
	Name

	Organization

	Address

	City, State, Zip

7. If indicating a Change of Address or Address Correction, please provide the New or Correct Address in Block 6 above and the Old or Incorrect address below.

OLD ADDRESS	_____
	Name

	Organization

	Address

	City, State, Zip

(Remove this sheet, fold as indicated, staple or tape closed, and mail.)
