AN IN SITU INFRARED STUDY OF THE OXIDATION OF
SULFUR DIOXIDE ON PLATINUM ELECTRODES

by

Carol Korzeniewski*, William McKenna**, and Stanley Pons

Department of Chemistry, University of Utah, Salt Lake City, Utah 84112.

*Department of Chemistry, The University of Michigan, Ann Arbor, MI 48109.

**Eastman Kodak Co., Kodak Research Laboratory, B-204, Building 82
Rochester, NY 14650.

The oxidation of sulfur dioxide on metal electrodes is of interest for its application in a variety of industrial processes, particularly in operations involving degradation of automobile emissions, production of energy, and winning of sulfide ores. The oxidation of sulfur dioxide by electrochemical methods is a complex process in which intermediates and products are formed which strongly adsorb on the electrode surface. A large number of electrochemical investigations have appeared which employ voltammetric techniques to obtain mechanistic information about the process (1-6). However, the oxidation process at platinum electrodes is a strong function of electrode pretreatment at cathodic potentials; thus, the electrochemical studies are not all in agreement. *Electrochem. Soc.*

Studies using cyclic voltammetry indicate that when SO_2 is introduced into an aqueous acid solution held at potentials about +0.25 V (SCE) (near the open circuit potential) oxidation of SO_2 begins at about +0.5 V (SCE) and is rapidly poisoned by formation of surface oxide species at more anodic potentials (3,5,6). Separate mechanisms have been proposed for the oxidation on clean and oxide covered platinum surfaces at these potentials. When the potential is swept cathodic following the initial oxidation sweep, an anodic peak appears at about 0.6 V (SCE) (5,6). At potentials in the hydrogen evolution region two cathodic waves appear which have been assigned to reduction of SO_2 to form adsorbed sulfur species which alter the electrochemistry of subsequent oxidation cycles. The nature of this surface species and the effect on the oxidation process have been the target of several electrochemical investigations (3,6).

In this analysis, an in situ infrared spectroscopic study of the oxidation of sulfur dioxide on platinum electrodes is undertaken. The focus of this investigation is on the oxidation processes which occur at potentials in the double layer region and where platinum oxide is formed. Also presented are spectra collected at cathodic potentials, where the surface activating sulfur

A-1

Spec 1

species is believed to form.

The experiments were performed in a three electrode cell made from a glass syringe (JAS Instrument Systems) (7). A CaF_2 infrared transparent window was mounted on the front of the cell and the electrode-window distance was made as small as possible (about 1 μm). The working electrode was constructed from a disk of platinum (about 9 mm dia.) which was sealed in glass and polished to a mirror finish with alumina in decreasing particle sizes down to 0.05 μm . The electrode was cleaned by continuous cycling between -0.25 V and +1.2 V (SCE) until sharp hydrogen waves were obtained. Following cycling, the electrode potential was held at +0.3 V (SCE) and sulfur dioxide was released into the cell. All reported potentials are with reference to the saturated calomel electrode.

Infrared spectra were obtained using the method of subtractively normalized interfacial Fourier transform infrared spectroscopy (SNIFTIRS) (7). As the electrode processes are irreversible, a staircase potential step scheme was used to prevent elimination of spectral information by signal averaging (8). All spectra are computed from the average of 512 interferograms and normalized to a reference spectrum obtained at +0.3 V. Positive going bands are due to species present at +0.3 V and negative going bands arise from species formed at the new potential. Infrared spectra were obtained using an IBM IR/98 Series infrared spectrometer.

Solutions were prepared from analytical grade sulfuric acid (J. T. Baker) and triply distilled water. Sulfur dioxide (99.98 % Matheson) was used without further purification. The electrochemistry was controlled using a potentiostat and waveform generator (Hi-Tek Instruments).

The cyclic voltammetry of SO_2 in 1.0 M H_2SO_4 is shown in Figure 1. According to the voltammetry, on the first anodic sweep from +0.3 V, SO_2 oxidation begins at about +0.5 V and is poisoned at more anodic potentials

corresponding to the onset of platinum oxide formation. On the cathodic sweep, an anodic peak is observed which has been assigned to continuing oxidation of SO_2 in the presence of the platinum oxide (6). At potentials more negative than +0.3 V two reduction peaks are observed in the voltammetry. The cathodic waves have been assigned to reduction of SO_2 to form a surface activating sulfur species. On the second sweep, both SO_2 oxidation and platinum oxide formation are diminished, behavior most likely due to an adsorbed species formed at the negative potentials.

The SNIFTIRS spectrum for the oxidation of SO_2 on clean (in the absence of platinum oxide) platinum is shown in Figure 2. The strong band appearing at 1332 cm^{-1} and the weaker band at 1151 cm^{-1} correspond to SO_2 in solution (9). The band appearing at 1168 cm^{-1} is formed as a product of SO_2 oxidation at these potentials. The spectral region between 1400 and 2000 cm^{-1} is shown in Figure 3. The sharp structure appearing in the figure is due to absorption of atmospheric water vapor. The broad band appearing at about 1650 cm^{-1} is due to loss of liquid water at the more anodic potential. The broad band at 1800 cm^{-1} arises from a product of the oxidation.

Figure 4 shows the SNIFTIRS spectrum of SO_2 oxidation at potentials where platinum oxide formation occurs. The 1332 cm^{-1} band is still apparent and formation of the 1168 cm^{-1} species still occurs. However, a shoulder at 1321 cm^{-1} now appears in the spectrum and a new band is present at 1271 cm^{-1} . The shoulder corresponds to surface SO_2 that is bonded to the platinum surface through one oxygen atom, and the 1271 cm^{-1} band occurs at energies appropriate for S-bonded SO_2 (9). Also apparent in the spectrum is a broad shift in baseline at about 1200 cm^{-1} . The position and shape of the band is characteristic of surface bound sulfate (10). Inspection of the higher energy region of the spectrum (not shown) reveals loss of water and the broad band at

1800 cm^{-1} is apparent. A visible white film forms on the electrode surface when the electrode is held at this potential for long (> 10 min) periods of time.

Following collection of spectra at anodic potentials, the electrode potential was returned to +0.3 V and a new set of reference spectra was collected. The potential was then stepped, according to the staircase method, to reductive potentials. The spectra collected at -0.1 V and -0.15 V are shown in Figure 5. The striking feature is loss of the 1168 cm^{-1} species to regenerate solution SO_2 as evidenced by formation of the 1332 cm^{-1} band. Also, broad bands at 1085 cm^{-1} and 989 cm^{-1} appear which correspond to formation of solution sulfate (9). Figure 6 shows a higher energy region of the spectrum. Broad bands appear at 2127 cm^{-1} , 1650 cm^{-1} , and 1800 cm^{-1} . The 1650 cm^{-1} band is due to formation of liquid water and the 1800 cm^{-1} band indicates loss of the oxidation product at these cathodic potentials. The 2127 cm^{-1} band is probably attributable to formation of a reduced sulfur species, possibly the species responsible for surface activation at cathodic potentials (3,6).

By analysis of the infrared spectra it appears that SO_2 is the electroactive species when the oxidation is carried out in aqueous acid solution. Further, it is apparent that two separate mechanisms operate for oxidation at potentials in the double layer region and at more anodic potentials where platinum oxide formation occurs. The bands pointing upward at 1332 cm^{-1} and 1151 cm^{-1} in Figures 2 and 4 arise from oxidation of solution SO_2 at +0.5 V and +0.9 V. In the absence of platinum oxide, it appears that solution SO_2 is oxidized to form a species characterized by absorption bands at 1168 cm^{-1} and 1800 cm^{-1} . When the oxidation is carried out at potentials where oxide is present on the platinum surface (+0.9 V), the spectra indicate displacement of adsorbed SO_2 , possibly by reaction with platinum oxide. A likely product of the reaction is adsorbed sulfate, as evidenced by the broad shift in base line at about 1200 cm^{-1} . A band

of this type is characteristic of sulfate adsorbed on a platinum electrode (10). It is unlikely that the increase in surface sulfate concentration is due to migration of sulfate from solution, as the sulfate concentration is low in solutions of sulfuric acid. The reaction of solution SO_2 also occurs at these potentials, as the 1168 cm^{-1} and 1800 cm^{-1} bands have grown, and oxidation of solution SO_2 is evident.

The oxidation of SO_2 in aqueous acid solutions gives rise to a product characterized by absorption bands at 1168 cm^{-1} and 1800 cm^{-1} . Further, reduction of this species forms solution SO_2 and water. The exact nature of this species is in question; however, electrochemical studies have suggested dithionate as a possible oxidation product (4,5). Infrared spectra obtained from Nujol mulls of sodium dithionate show absorption bands between 2300 cm^{-1} and 2000 cm^{-1} , and another strong absorption at about 1240 cm^{-1} (11). Adsorption of the dithionate species on the platinum surface could account for the strong red shifting of the infrared bands. Reduction of the species to form SO_2 and water lends further support that an adsorbed dithionate species may be involved (see Eq. 3 below); however, the exact assignment of these bands is inconclusive at the present time and further studies are underway. Reactions of adsorbed SO_2 and oxygen at platinum surfaces have been studied under vacuum conditions (12-13). The authors report formation of a sulfur-oxygen containing compound which decomposes to SO_2 and oxygen when heated; however, no identification of the product was proposed.

Assuming that adsorbed dithionate is indeed a product of SO_2 oxidation, the following mechanism is proposed from the infrared spectra:

when the reaction occurs on clean platinum at potentials in the double layer region and

when the reaction occurs in the presence of platinum oxide. Studies suggest that SO_2 oxidation occurs through an SO_3^{2-} intermediate (6). However, this species was not observed in the infrared spectra, as evidenced by the absence of bands at 1010 cm^{-1} and 961 cm^{-1} in Figures 2 and 4 (9); nevertheless, this intermediate may be too short lived to detect under these conditions.

The spectra obtained when the electrode is held at cathodic potentials indicate that reaction of the 1168 cm^{-1} species occurs to form solution sulfate as indicated by broad bands at 1085 cm^{-1} and 989 cm^{-1} (9), and regenerate solution SO_2 and water. A possible mechanism for the decomposition of dithionate is given by

which would explain the increased concentration of solution SO_2 and appearance of solution sulfate.

In the cathodic limit a new species is formed which absorbs at 2127 cm^{-1} and is likely due to formation of an adsorbed sulfur species. Reduction of SO_2 may compete with the dithionate reaction at these potentials. This may explain the appearance of the 2127 cm^{-1} band; however, a positive assignment of this band can not be made with these limited spectral data.

In conclusion, a SNIFTIRS study of the oxidation of SO_2 on platinum electrodes confirms electrochemical studies which suggest that separate mechanisms operate when oxidation occurs on clean and oxide covered platinum surfaces. Infrared spectra of a major product of the oxidation are presented and the assignment of these bands to adsorbed dithionate is proposed. Further, the reduction of this product forms solution SO_2 and water, a process not previously observed using electrochemical methods.
