19. ABSTRACT (Continue on reverse if necessary and identify by block number) Until the application of high-performance liquid chromatography (HPLC) to phytoplankton pigment analysis, it was difficult to quantitatively measure these pigment compounds. HPLC, the state-of-the-art method for the separation and quantification of photosynthetic pigments, is detailed in this report. HPLC reduces interferences caused by overlapping absorption and fluorescence bands of various pigments. HPLC-derived pigment distributions were measured in the upper 200 meters during two NOSC-sponsored cruises on the USNS LYNCH on 1-22 August 1986 and 29 July - 18 August 1987 in the Norwegian, Barents, and Greenland Seas.

High-Performance Liquid Chromatography (HPLC) Measurements of Phytoplankton Pigment Distributions of Ocean Waters

Norwegian, Barents and Greenland Seas - 1 August - 22 August 1986
Norwegian and Greenland Seas - 29 July - 18 August 1987

Charles C. Trees

1.0 INTRODUCTION

Particulates, especially phytoplankton, significantly affect ocean optical properties by absorbing and scattering light and it is the various suite of pigments (chlorophylls, carotenoids, phycobilins) present within the phytoplankton that contribute most to the attenuation of light. In coastal areas, where dissolved organic material and inorganic particulate concentrations are high, pigments have a reduced influence on the optical properties. The general absorption by the major algal pigments and the major windows of clarity in the water spectrum are shown in Figure 1. Chlorophylls (*a*, *b* and *c*) and some carotenoids (xanthophyll and carotene) have absorption maxima between 425-450 nm and from 525-575 nm for other carotenoids (fucoxanthin and peridinin) and phycoerthrins (red and blue-green algal). Between 525-650 nm another blue-green algal pigment, phycocyanin, has a maximum absorption peak. The spectra for the chlorophyll degradation products (chlorophyllides, phaeophorbides and phaeophytins) which are not shown in Figure 1 have similar absorption maxima as their associated chlorophylls.

Until the application of high-performance liquid chromatography (HPLC) to phytoplankton pigment analysis, it was difficult to quantitatively measure these various pigment compounds. HPLC is the state of the art method for the separation and quan-

ification of photosynthetic pigments and recent investigations (Gieskes and Kray, 1983; Bidigare *et al.*, 1986; Trees *et al.*, 1986) have demonstrated that HPLC methods can be routinely used for phytoplankton pigment analysis. The use of HPLC minimizes the interferences caused by overlapping absorption and fluorescence bands of the various pigments, since the pig-

ments are physically separated on the column and individually quantified by absorption and/or fluorescence detectors (Trees *et al.*, 1985).

HPLC derived pigments distributions were measured in the upper 200

Figure 1. Relative pigment absorption of 1% solutions of water clarity (Trensen, 1983).

meters by the Visibility Laboratory during two cruises on the USNS Lynch (1-22 August 1986 and 29 July - 18 August 1987) in the Norwegian, Barents and Greenland Seas. Optical variability (see VisLab EN-015-86t and OcOp-88t-001) was determined by deploying spectral radiometers and towing a self-contained, depth-undulating oceanographic recorder (UOR). This UOR measured depth, temperature, *in vivo* fluorescence, up- and downwelling hemispherical scalar irradiance and cosine irradiance at 450, 488 and 550 nm during its undulations between 5 and 50 meters (Aiken, and Bellan, 1986). Continuous sub-surface temperature and *in vivo* fluorescence was also measured from water pumped from the shipboard sea chest (2-3 meters). During transects between stations, discrete water samples were drawn from this pumping system for HPLC analysis. In addition AVHRRK sea surface temperature data was acquired from a receiving station at the University of Dundee, Scotland, and processed into sea surface temperature (SST) imagery. Cruise tracks and station locations for the two cruises are shown in Figures 2 and 3 and summarized in Tables 1 and 2.

2.0 HPLC METHODS AND INSTRUMENTATION

Hydrocasts were performed at most of the stations using a General Oceanics rosette sampler/Neil-Brown CTD system, equipped with twelve 1.5 liter Niskin bottles. Water samples for pigment analyses were drawn from the bottles which were spaced throughout the water column based on transmissometry and fluorescence profiles. At least one bottle was tripped within the particle and phytoplankton biomass maxima. Samples were then filtered through 0.4 μ m Nuclepore polyester membrane filters and either frozen in liquid nitrogen for HPLC processing on return to the Visibility Laboratory (1986 cruise) or extracted and analyzed on board the ship (1987 cruise). The extraction solvent varied between cruises in that 90% acetone was used for August 1986 cruise; whereas, a 40:60% solution of dimethyl sulfoxide (DMSO) and 90% acetone was selected for the 1987 cruise. The advantage of the latter solvent is its enhanced pigment extraction efficiencies for cyanobacteria and green algae.

The HPLC system shown in Figure 4 consisted of a Spectra Physics Extended Range Pump (SP-8700XR) and Organizer Module-Dynamic Mixer (SP-8750) equipped with a reverse-phase Radial-PAK C₁₈ column (10 μ m particle size, Waters Associates) and 500 μ l sample loop. To facilitate the separation of the dephytylated pigments (chlorophyllide *a*, phaeophorbide *a* and chlorophyll *c*) samples were mixed prior to injection with an ion

Figure 2. Cruise track and station locations during NOSC cruise in the Norwegian, Barents and Greenland Seas (1-22 August 1986).

pairing solution of tetrabutylammonium acetate and ammonium acetate (Mantoura and Llewellyn, 1983). Pigments were separated on the column using a two solvent system [A-(80:10:10; methanol:ion-pairing solution:distilled water) and B-(100% methanol)]. Solvent A was pumped for three minutes followed by a linear gradient elution to 100% B in 9 minutes and then held at 100% B for 8 more minutes. At a flow rate of 10 ml min⁻¹ the separation of the various pigments required 20 minutes. As the various chlorophylls and carotenoids were eluted off the column their peaks were measured using absorption (Waters Associates Model 440 Single Channel Absorbance Detector equipped with a 436 nm filter assembly) and fluorescence detectors (Turner Designs Model 10 equipped with a liquid chromatography cell or Kratos FS-950 Fluoromat). A sample chromatogram using this method is shown in Figure 5. The outputs from the detectors were recorded on a Spectra Physics Two Channel Computing Integrator (SP-4270) and pigment concentrations were calculated from calibration tables (concentration per peak height or area) which were prepared from pigment standards.

3.0 DATA

The HPLC derived pigment concentrations for both cruises are listed in Appendices A, B, C and D. Nine pigment compounds were identified and quantified from the chromatograms. The continuous *in vivo* fluorescence and temperature for the August 1986 cruise is shown in Figure 6; whereas, the 1987 data from the continuous monitoring system is contained in OcOp-88t-001.

4.0 DATA ANALYSIS

Only a preliminary analysis of the HPLC derived pigment, optical and remote sensing data has been completed. A brief review of these results, focusing on vertical and horizontal bio-optical measurements across the Arctic Front during the 1986 cruise, will be given.

The circulation of the Greenland Sea is characterized by a cyclonic (counterclockwise) gyre with a strong western boundary current. Its southern extent is limited by the Jan Mayen and East Icelandic Currents; whereas, the northern flow is centered near the Mohns Ridge and merges with the West Spitsbergen Current (Figure 7). Along the Jan Mayen and East Greenland Currents two permanent fronts occur, the East Greenland Polar Front and the Arctic Front. Using nomenclature proposed by Swift (1986), these frontal systems divide the area into three hydrographic regions (the polar domain, the region west of the East Greenland Polar Front which has direct polar influence, the Atlantic domain, the region east of the

Figure 8. UOR transect of the Arctic Front (solid line) and continuous sub-surface track line (dotted plus solid lines) superimposed over an AVHRR sea surface temperature image for 4 August 1986 of the Greenland Sea.

Arctic Front which is dominated by Atlantic waters; and the Arctic domain, the transitional region between these fronts).

An AVHRR sea surface temperature image (4 August 1986) of the Greenland Sea is shown in Figure 8 and superimposed on it is the location of a 60 mile UOR transect (solid line) across the Arctic Front on 19 August, 15 days later. Sea surface temperature expressions of this front extend continuously from just south of Jan Mayen Island across the Greenland Sea to the southwestern edge of Spitsbergen (77°N 10°E). Numerous eddies, which have a general westward translation, can be observed along the front, as well as, vorticity structures further south several hundred miles. The much warmer waters of the Atlantic domain (darker area) can be observed near the bottom of the image. Using additional imagery from previous years, the Arctic Front has been found to be a permanent feature following bottom topography (Mohs and Knipovich Ridges).

UOR measurements confirm this inhomogeneity, as inferred from the satellite imagery, of the surface and sub-surface bio-optical fields over relatively short spatial scales in both Arctic and Atlantic domain waters. Such changes are shown in Figure 9 as vertical sections of temperature and chlorophyll concentrations for the 60 mile UOR transect. From the temperature profile, the Arctic Front was encountered halfway through the tow with a surface temperature change from less than 6°C to over 9°C within 10 miles. The steep thermal boundary coincided with a pigment gradient which had maximum chlorophyll concentrations above 1.8 mg m^{-3} in the upper 20 meters. This was in contrast to the sub-surface chlorophyll peak of 1.0 mg m^{-3} in the thermocline in the Arctic waters north of the front. The UOR was retrieved while chlorophyll concentrations were still elevated and therefore, the width of this surface pigment bloom could not be ascertained from the data. Using continuous *in vivo* fluorescence data from the shipboard sea chest, the width was found to be 150 miles with the magnitude of the fluorescence signal verified by discrete HPLC measured samples (Figure 10b).

With the exception of the vertical and horizontal structure of the chlorophyll

Figure 9. Vertical sections of temperature ($^{\circ}\text{C}$) and chlorophyll concentrations (mg m^{-3}) as determined by *in vivo* fluorescence during a transect across the Arctic Front (19 August 1986) of the Undulating Oceanographic Recorder (UOR).

field, the optical properties likewise spatially change. Since ocean color is determined by the backscattered irradiance which originates from depths above the 37% light level ($1/K$), the analysis of the UOR data can be restricted to the upper 20m or within the mixed layer depth. Figure 11 shows average values for temperature, chlorophyll, diffuse attenuation coefficient (K) and reflectance (R) across the Arctic Front; where the points were derived by averaging or regressing the data from 0 to 20m meters of each undulation. The frontal boundary is depicted by a sharp bio-optical gradient; such that, within in one UOR undulation (an horizontal distance of 0.8 miles) the average chlorophyll concentration doubled and $K(450)$ increased by 38%. A comparison of the average bio-optical prop-

ties on either side of the front is listed in Table 3. Both $K(450)$ and $K(550)$ increased across the front indicating a shallowing of the optical depths from 8.8 to 4.9m and from 10.6 to 8.2m, respectively. Reflectance at 450nm showed a 24.5% decrease due to the increase in absorption by the phytoplankton; whereas, $R(550)$ showed no discernible change.

Changes in the vertical structure of chlorophyll concentration across the front infer that different phytoplankton assemblages were exploiting the different physio-chemical environments of each water mass. These changes have been confirmed by both phytoplankton identification and enumeration and HPLC pigment analysis. A small number of phytoplankton samples were analyzed which showed the presence of *Thalassiosira*

Figure 10. Pigment concentrations during a 620-mile transect across the Arctic Front

delicatissima cleve; ca. $75,000 \text{ l}^{-1}$) and occasionally unquantified numbers of *Phaeocystis pouchettii* in the Arctic waters; whereas, predominantly coccolithophorids (*Emiliania huxleyi*; ca. $100,000 \text{ l}^{-1}$ and *Coccolithus pelagicus*; ca. $11,000 \text{ l}^{-1}$, together with its crystalline phase; ca. $11,000 \text{ l}^{-1}$) were found south of the front, but still within the high pigment band. These coccolithophorid concentrations, although indicative of a bloom condition, are not excessively high, since Holligan *et al.* (1983) have reported values up to two orders of magnitude higher for waters around the English Channel.

Discrete sub-surface samples from the shipboard sea chest were analyzed by HPLC methods to quantify the suite of phytoplankton pigments present. Many of these pigment compounds can be used as bio-markers (Wright and Jeffrey, 1987) for various algal groups (e.g. chlorophyll *b* for green algae; fucoxanthin for diatoms; 19'-hexanoyloxyfucoxanthin for coccolithophorids, peridinin for dinoflagellates). A 620 mile transect of subsurface temperature, chlorophyll and pigment profiles are shown in Figures

Table 3. Summary of bio-optical properties of the two different water masses as measured from the UOR.

	Arctic Domain	Atlantic Domain
Temperature ($^{\circ}\text{C}$)	5.68 ± 0.28	8.33 ± 0.17
Chlorophyll (mg m^{-3})	0.37 ± 0.12	1.52 ± 0.34
K(450) (m^{-1})	0.114 ± 0.008	0.205 ± 0.025
K(550) (m^{-1})	0.094 ± 0.009	0.122 ± 0.011
R(450)	0.049 ± 0.005	0.037 ± 0.006
R(550)	0.043 ± 0.007	0.044 ± 0.004

Figure 11. Twenty-meter averages for temperature ($^{\circ}\text{C}$), chlorophyll (mg m^{-3}), diffuse attenuation coefficient (m^{-1}) and reflectance across the Arctic Front during a UOR tow.

10a, b, and c which started around $75^{\circ} 20' \text{N}$ $3^{\circ} 45' \text{W}$ in Arctic domain waters and went through Station 18 and the Arctic Front and ended at Station 19 (Atlantic domain waters; see Figure 8, dashed and solid lines). Two samples were collected within the pigment band indicating over a five fold increase in chlorophyll *a* concentrations (Figure 10b). Fucoxanthin and hexanoyloxyfucoxanthin also increased with hexanoyloxyfucoxanthin, a coccolithophoride marker, increasing from below detection limits to up to 1500 picomoles L^{-1} (Figure 10b). South of the pigment band (500 miles and farther) hexanoyloxyfucoxanthin concentrations were still elevated relative to fucoxanthin, indicating the existence of a resident population of coccolithophorids in Atlantic domain waters.
