ABSTRACT

We present an algorithm for finding optimal three-dimensional paths above polyhedral models of terrain. Airspace is modeled as irregularly-shaped regions of homogeneous probability-of-detection, with respect to one or more fixed observers. We plan paths by first finding an optimal set of contiguous visibility regions, then an optimal piecewise-linear flight path through this envelope, using Snell's Law to find locally-optimal maneuver points. The performance of our region-finding algorithm favorably compares with an alternate approach using regular cubic regions.

I. INTRODUCTION

Path planning is an important and growing area of research in artificial intelligence. Recent research has produced an extensive and sophisticated body of knowledge. Much of this work has been restricted to the (essentially) two-dimensional path planning problem for a ground vehicle moving on ground terrain. However, many interesting and potentially useful path-planning problems involve true three-dimensional paths. Examples include aircraft flight-paths, submersible paths underwater, overhead-crane paths within large factories, tunneling plans for underground shaft mines, and routes for microwave communications links. Many of these areas have potential for application within the U. S. Navy.

Unfortunately, the three-dimensional path-planning problem is not a simple extension of the two-dimensional path-planning problem. Many physical restrictions exist which constrain the three-dimensional problem in ways which are fundamentally different from the constraints found in two-dimensional problems (it is generally not possible to stop in mid-air while flying, for instance). Certain abstractions may be made to simplify the problem. If one thinks of the two-dimensional path planning problem as finding a path through a flat, two-dimensional graph of a given precision (or granularity), then a three-dimensional path planning problem can be thought of as a search through a

three-dimensional graph, again of a given granularity. This graph is the search space.

If one considers a cube of air 1000 meters on a side as a search space, dividing it into 10 meter cubes will produce a search graph containing one million nodes. Using 25-meter cubes, 64 thousand nodes will be needed to define the search graph. Using 50-meter cubes, eight thousand nodes will be needed. This is illustrated in Figure 1.

To handle this over-abundance of search space, certain assumptions can be made concerning the type of path desired and the nature of the search graph. One method is to reduce the volume of the search space by aggressive pruning (e.g., making assumptions) as the search progresses. This thesis proposes an alternate method for reducing the size of the search space, where, by coalescing nodes sharing some common characteristic, the size of the search space is reduced before the search starts. Other characteristics (such as travel cost, altitude, cloudiness, humidity, for example) of the original nodes must then be compensated for while performing the actual search. To illustrate this approach, a subclass of the generalized three-dimensional routing problem was selected for analysis. Only two factors were used in optimization while path planning through the three-dimensional search graph: visibility (probability-of-detection), and cost (or energy expended). Visibility will be used as the grouping characteristic, and cost will be used

Figure 1. Search Graph for Simple 3-D Search in Cross-Section

as the compensating characteristic which must be compensated for as the search progresses. All path planning will be conducted over idealized, polyhedral approximations of terrain.

This thesis will thus consider three-dimensional routing problems which plan routes between two given points in space over terrain modeled as a polyhedron, optimizing the route for low probability-of-detection and cost, given a finite number of immobile observers to generate the visibility criteria. This subclass of problems includes such "real world" examples as route planning for cruise missiles from launch point to final approach on target; routing of manned attack aircraft to (and from) a mission objective; the routing of a submersible through a field of active sonar devices; and detecting "holes" in the area air defense of a high value target. Optimizing for high probability-of-detection instead of low probability-of-detection has application to another class of problems, such as routing of commercial passenger aircraft between radar sites, maintaining a Remotely Piloted Vehicle within line-of-sight (LOS) communication of one or more controllers, or ensuring that ground-based autonomous vehicles remain within LOS communication of one or more communication sites for as long as possible.

Given a piece of terrain, and an observer, as in Figure 2, the airspace can be divided into two regions: airspace

Figure 2. The Concept of Visibility Regions

that is visible to the observer, and airspace which is not. These regions can be determined by a simple construction involving the observer and the terrain. All of the air within a given visibility region will be considered as a single entity when discussing visibility of that region; any one point within the region is no more or less visible than any other point. Using this argument, then, the airspace above the observer in Figure 3 can be reduced to a very simple graph when evaluating visibility. In terms of Figure 3b and 3c, being "not visible" means being at graph node 3; being "visible" means being at graph node 1 or 2. This abstraction of the visibility of space will be a powerful tool in the three-dimensional path planning which follows. Figure 4 illustrates a more complex example.

The second aspect of the class of path planning considered here involves minimizing the energy expended to get between two points. Energy costs are a function of location and velocity. These costs depend upon the scale of the terrain, and the type of device which is expected to follow the final path. To simplify matters, a more "generic" approximation based on distance travelled was developed, using linear corrections to account for energy lost or gained while turning, diving and climbing.

Path analysis for the problems discussed above involves combining visibility information obtained from a visibility model with energy costs in an appropriate manner. An optimal

Figure 3. Construction of a Search Graph

Figure 4. A More Complex Search-Graph Construction

path, or "best path," minimizes the weighted average of the probability-of-detection and energy that must be expended. In general, this optimal path will not be the same as either the minimum energy path (ignoring visibility), or the minimum probability-of-detection path (ignoring cost).

An artificial-intelligence search method called A* search can perform the visibility-region sequence-planning within the context of the visibility and cost modelling techniques discussed above. However, the path-planning problem is not then completely solved, since A* search will produce a contiguous series of regions (volumes) with common visibility characteristics shown in Figure 5, called a volume path. An optimal piecewise linear path must still be found within the confines of the volume path produced by the A* search, such that the path is linear within each volume. Determination of the optimal piecewise-linear flight path through the volume path reduces to an optimization problem in three-dimensions. Fermat's Principle from optics can be used to solve this optimization problem.

The remaining sections of this thesis describe an implementation of the three-dimensional path planning approach discussed above. Chapter II introduces all relevant background topics, including solid geometry, A* search and Fermat's Principle. Chapter III describes the visibility-grouping and path-planning algorithms in detail, while Chapter IV describes the details of their algorithms.

Figure 5. Types of Paths

Results of the implementation will be presented in Chapter V, which shows both the visibility models and some representative flight paths over a variety of terrain features. Finally, Chapter VI discusses the strengths and weaknesses found in the algorithms and their implementations.

II. BACKGROUND

A significant amount of previous work has been done in path-planning, although very little of it has involved three-dimensional path-planning [Ref. 1]. A family of generalized search algorithms has been developed [Ref. 2] which can be applied to almost any sort of search problem when the search nodes are discrete and enumerable. These generalized search methods have been successfully applied to various two-dimensional path-planning problems [Ref. 3], [Ref. 4] and [Ref. 5], and two of these generalized search methods will be used in the three-dimensional path-planning problem presented in this thesis. Only a small body of published literature discusses three-dimensional path-planning, and that addresses rather abstract versions of the problem (for example, [Ref. 6] discusses path-planning along the surface of a solid convex volume).

A. RELATED PROBLEMS AND SOLUTIONS

1. General Predefined-Node Search Algorithms

[Ref. 2] contains a description of all generalized search algorithms. Table 9-5 from that reference is reproduced as Table 1, illustrating most of the currently used generalized search algorithms, and some of their features. All of these search functions seek to find some path (often an optimal path, but not always) between a given

TABLE 1. SEARCH METHODS

<i>Name of search strategy</i>	<i>Uses agenda?</i>	<i>Uses evaluation function?</i>	<i>Uses cost function?</i>	<i>Next state whose successors are found</i>
Depth-first search	no	no	no	A successor of the last state, else a successor of a predecessor
Breadth-first search	yes	no	no	The state on the agenda the longest
Hill-climbing (optimization)	no	yes	no	The lowest-evaluation successor of the last state
Best-first search	yes	yes	no	The state on the agenda of lowest evaluation value
Branch-and-bound	yes	no	yes	The state on the agenda of lowest total cost
A* search	yes	yes	yes	The state on the agenda of lowest sum of evaluation value and total cost

* Reprinted from Rowe, Neil C., Artificial Intelligence Through Prolog, Prentice-Hall, 1988

start point to a given goal point, through a finite search space. The search space may be a representation of physical objects, such as a graph representing terrain, or it may represent more abstract concepts, such as the set of all possible steps in fixing a car [Ref. 2]. Most searches that find optimal paths (A*, Best-first, Branch-and-bound), use some sort of metric to judge the distance to either the start point, goal point or both. These metrics are then used to decide which paths through the search space are optimal, or lowest cost. These metrics are called cost functions and evaluation functions.

A cost function is a function which produces a number representing the effort (or cost, or energy expended) to get to a given point in the search space from the start point. An evaluation function is similar to a cost function, except that it produces a number which indicates the expected cost to get to the goal from a given location in the search space. A* search uses the sum of the cost and evaluation functions to decide which paths are optimal (e.g., lowest total cost) as the search progresses through the search space towards the goal. Because of this, A* search is generally regarded as the best of the search methods, even though it is the most complicated [Ref. 2]. Other search methods can be used if optimality can be sacrificed, or if the particular problem at hand can be best solved using a less sophisticated search algorithm.

The three-dimensional path planning program uses A* search for path-planning through the visibility volumes, and the best-first search in one application where the cost function has no meaning.

2. Path Planning in Two-Dimensions

Current work in two-dimensional path planning can be divided into three major approaches; path-oriented approaches, spatial-reasoning based algorithms and blind search methods [Ref. 7]. The path-oriented approach uses a search space of all possible paths (developed by some other search method) from the start to the goal, and then selects the best path from this list using concepts from decision theory [Ref. 2]. The spatial reasoning approach reasons about how paths are affected by obstacles. An example of this is the visibility graph. Visibility graphs, or V-graphs, have a search space composed of lines of mutual visibility between edges and vertices of obstacles. Path planning is accomplished along these lines, from the start point to the goal. Blind searches generally use a form of wavefront propagation search, which subdivides the search area into small squares, and then finds paths by looking, one square at a time, in all directions, until the goal is reached. The search graph in this search consists of the squares as nodes, and the connections between squares as the edges of the graph. Most of these methods can be adapted to

the three-dimensional path-planning problem in one form or another.

3. Path Planning in Three-Dimensions

The current approaches to the three-dimensional path-planning problem center on a three-dimensional version of the two-dimensional visibility graphs or involve attempts to decompose the three-dimensional problem to a two-dimensional problem [Ref. 6]. This thesis is unique in approaching the problem by reducing the size of the search space by grouping possible graph nodes, and then applying a simple search to find an optimal path.

4. Fermat's Principle

Fermat's Principle, first proposed by Pierre de Fermat in 1657, states that light rays travelling through an optical medium will always take the path which can be traveled in the least amount of time [Ref. 8]. As light passes through several layers of different optical mediums, then, it will travel along a path with the shortest optical path length. Fermat's Principle leads to Snell's Law, which states that

$$N_1 \sin \theta_1 = N_2 \sin \theta_2 \quad (2-1)$$

where

N_1 is the index of refraction of material #1,

θ_1 is the angle of incidence, measured from the normal,

N_2 is the index of refraction of material #2, and

θ_2 is the angle of refraction, measured in a counter-clockwise sense from the normal.

Figure 6 illustrates this effect. Fermat's Principle provides a useful method of minimizing the total transit time of a path between start and goal points. Assuming that the flight path is flown at a constant speed, this minimized transit time can be multiplied by the speed (a constant) to produce a minimized distance:

$$\text{Distance} = \text{Time} * \text{Speed} \quad (2-2)$$

As a result, all Snell's Law optimizations will be discussed as optimization of distance, even though time is actually the variable optimized. Note that this is only true if the speed is a constant, and if no other costs are accounted for at the turn-point. If turn costs were to be included in the Snell's Law optimization, then Equation 2-2 will not hold.

The index of refraction used in Snell's Law can be constrained to be the probability-of-detection of a particular visibility volume, so that a path through a series of visibility volumes can be considered analogous to a light ray passing through a series of optical mediums. Minimizing the deviation from Snell's Law at each transition layer between volumes will guarantee minimization of the total path

Figure 6. Snell's Law

length because minimization of Equation 2-1 is convex [Ref. 4].

5. Visibility Models

A significant amount of prior research has been done in the area of visibility and visibility algorithms. The three-dimensional path-planning program requires an all-around visibility model. Fortunately, some aspects of standard graphics approaches to visibility can be modified for use for this model. [Ref. 10] refers to finding shadow regions of polyhedral solids by projecting planes from the observer to the edges of a shadowed object, creating a shadow polygon behind the shadowed object.

B. MATHEMATICS BACKGROUND

1. Planes

A quick overview of some basic three-dimensional mathematics is in order at this point. A plane in space is represented by an equation of the form

$$Ax+By+Cx=Ao \quad (2-3)$$

where A, B and C are the coefficients of the vector N normal to the surface of the plane.

$$N=Ai+Bj+Ck \quad (2-4)$$

and Ao is found by substituting the coordinates of any point in the plane into the left hand side of Equation 2-3 [Ref. 11]. Figure 7a illustrates this arrangement.

Plane Representation
(a)

Line Segment Representation
(b)

Figure 7. Lines and Planes

2. Lines

A line in space has a more complicated representation. Any line in space is completely defined by two vectors: a position vector leading from the origin to any point on the line, and a direction vector pointing along the direction of the line. The coordinates of any point along the line can be determined by changing the coefficient (or parameter) t in the line equation

$$P(x,y,z)=A+B+C+t*(D+E+F) \quad (2-5)$$

where A , B and C are the coefficients of the position vector, and D , E and F are the coefficients of the direction vector

$$\text{Position Vector}=Ai+Bj+Ck \quad (2-6)$$

$$\text{Direction Vector}=Di+Ej+Fk. \quad (2-7)$$

This is called the parametric form of a line in space [Ref. 11], and is illustrated in Figure 7b.

The parametric form of a line is very useful since any single point along the line may be specified by a single parameter, rather than two or three different variables. A line segment can thus be easily defined by means of two parameters, one each for the endpoint of the line segment. If the parameter at one endpoint is arbitrarily set to zero, then the entire line segment can be represented by a single parameter and some constants.

3. Volumes

Figure 8 illustrates the structure of solid polyhedra, or volumes, used in this thesis. The relationships between volumes, points, edges, facets and planes can be best illustrated by the hierarchical graph of Figure 9. These relationships form the foundation for the subsequent development of the data types to be used to represent these objects during the implementation of the path planning program. These data structures will be presented in detail in Chapter IV.

Figure 8. Volume Structure

Figure 9. Relationships Among Solid-Geometry Data Structures

III. VISIBILITY AND PATH-PLANNING ALGORITHMS

This chapter will describe the algorithms used for three-dimensional path planning. Most of this chapter will discuss visibility determination and path planning. Later sections will present algorithms in solid geometry.

As discussed in Chapter I, a fundamental concept in this work is the application of a grouping, or coalescing criteria to three-dimensional volumes in the three-dimensional path planning problem, using one or more common characteristics within large regions of airspace to simplify the search problem. The common characteristic used here will be visibility.

The three-dimensional path-planning algorithm breaks naturally into two halves: static-visibility determination and path planning. The static-visibility determination phase uses the grouping characteristic (visibility) to find visibility volumes, and then builds a search graph. Path planning performs the search through the search graph, which generates the volume path defined in Chapter I. The path-planning algorithm must then find the final optimal piecewise-linear path through the volume path.

A. VISIBILITY-REGION CONSTRUCTION

1. Terrain Model

A polyhedral model of terrain will be used for path planning to simplify the mathematics of the visibility algorithms. The terrain model used is described in [Ref. 9]. This type of terrain model produces large planar patches which are as large as possible given the terrain, not the simple triangular terrain patches found in more common polyhedral models. Figure 10a shows some sample real terrain, and Figure 10b shows the more general polyhedral model used. Figure 10b also shows the structural lines used to create a base for the terrain model. These vertical and horizontal edges simply outline the sides and bottom of the terrain to create a ground volume, which can be manipulated in the same way that any air volume can be manipulated. Creation of these lines is discussed in the following chapter.

2. Static Visibility-Determination Algorithm

The location and extent of the visibility regions is completely determined by the geometry of the terrain and the location of observers relative to that terrain. Regions of visibility (regions of non-zero probability-of-detection) are regions of points which have an unobstructed line-of-sight (LOS) from an observer. Figure 11 shows cross-sections of two different examples of such visibility regions.

(a)

(b)

Figure 10. Terrain Modeling

(a)

(b)

Figure 11. Visibility Regions

a. Determination of Visibility Regions

Non-visible regions (with respect to a single observer) are simply regions shadowed from the observer by some terrain feature. Many shadowing algorithms are available, as discussed in Chapter Two, but most are oriented towards views of terrain from particular vantage points, and generally do not involve construction of shadow volumes. Some shadowing algorithms [Ref. 10] do provide useful methods which can be extended to the full shadowing problem with great success. These methods involve constructions between an observer and significant features of the surrounding terrain. Note in Figure 11 that the limits of the visibility regions are determined by a linear construction between the observer and the points of peaks. In three dimensions (using polyhedral approximations to real terrain), these peaks would be ridge lines, and the linear construction would be a plane (see Figure 12) called the **limiting plane of visibility**).

This limiting plane of visibility is easily found, since a plane can be defined by a point (the observer) and a line (the ridge line). As a result, the visibility regions may be built using the following algorithm:

Figure 12. Construction of Visibility Volumes

```

Initial Condition:  A large volume of air above some terrain
  LOOP for Observer IN (all observers)
    LOOP for Ridge-line IN (all ridge-lines)
      CONSTRUCT Limiting Plane of Visibility using
        Observer and Ridge-line
      DIVIDE all volumes at the Limiting Plane of
        visibility
    END
  END
END

```

Algorithm 3-1. Construction of Visibility Volumes

Results of this algorithm are illustrated in a cross-sectional illustration in Figure 13a. Note that this algorithm will construct limiting planes of visibility regardless of whether the ridge line is visible from the given observer, which creates extra work. A better algorithm would consider this before building the limiting planes of visibility:

```

Initial Condition:  A large volume of air above some terrain
  LOOP for Observer IN (all observers)
    LOOP for Ridge-line IN (all ridge-lines)
      IF ridge line visible from Observer THEN
        CONSTRUCT Limiting Plane of Visibility using
          Observer and Ridge-line
        DIVIDE all volumes at the Limiting Plane of
          visibility
      END
    END
  END
END

```

Algorithm 3-2. Better Construction of Visibility Volumes

(a)

(b)

Figure 13. Results of the Visibility-Determination Algorithm

Illustrative results for this algorithm are shown in Figure 13b. This algorithm was not implemented in this thesis.

b. Visibility Criteria

After the visibility volumes are built, their visibility relative to all observers must be determined. This is best done using a simple line-of-sight (LOS) model. Since the visibility volumes define regions of uniform visibility, no point in the volume is more or less visible than any other point. For this reason, visibility can be determined from the center of the volume, which is easy to find, to an observer. If that LOS is blocked by terrain anywhere along its length, then the entire visibility volume is not visible with respect to that particular observer. See Figure 14 for an example.

Once the visibility with respect to all observers has been calculated, the probability-of-detection for all volumes may be calculated in some appropriate manner. This is a function of the individual probabilities-of-detection for all of the observers which "can see" a given visibility volume, and is discussed in detail in the following chapter and in [Ref. 2]. Volumes which are visible to no observer can be assigned a probability-of-detection of zero, or some small, non-zero baseline value.

- Volume #1 is visible from Observer #1 and not visible from Observer #2
- Volume #2 is not visible from Observer #1 and not visible from Observer #2
- Volume #3 is visible to both observers
- Volume #4 is visible to Observer #2 and not visible to Observer #1

Figure 14. Visibility Criteria

c. Additional Sub-algorithms

Several other sub-algorithms are required by the static-visibility determination algorithm; input, ridge-finding and graph-building. The input algorithm is highly dependent upon the method of representing the polyhedral terrain model, and its discussion will be delayed until Chapter IV.

(1) Ridge Finding. Implicit in the visibility volume algorithm is the ability to identify ridge lines, information not (generally) available with the input data. A ridge line is a line segment at the intersection of two facets of the terrain model such that the two facets are concave down (see Figure 15a). A complex formula is available to do this in three dimensions [Ref. 12] which is completely general. However, it is possible to take advantage of the polyhedral representation of the terrain to make a much easier algorithm.

First project the center point of one of the facets (it does not matter which) onto the plane of the other facet. If that projection is above the center point (e.g., has a higher altitude, or z value), the line is a ridge line. If any other case arises, then the line is not a ridge line. Figure 15b illustrates this essentially graphical approach. Exactly vertical cliffs are not considered here, since they are assumed not to occur in nature. This also serves to

(a)

(b)

Figure 15. Ridge-Determination Method

avoid identifying structural edges used to bound the terrain model (the top, sides and bottom) as ridge lines.

(2) Graph Building. The earlier steps in the static-visibility algorithm produce a network of adjacent visibility volumes. These volumes will be connected to their immediate neighbors by either a common facet (the usual case), or adjacent, coplanar facets (an unusual, implementation-dependent case). In either event, the connecting facet represents an edge in the search graph, and the centers of the visibility volumes represent nodes in the graph. Visibility volumes are not considered to connect at common volume vertices or volume edges. Building the search graph involves a very straight forward algorithm to find all connections between all visibility volumes:

```
LOOP for volume IN (all visibility volumes)
  LOOP for facet IN (all facets of a volume)
    FIND other volumes CONTAINING facet
    CONCLUDE THAT volume CONNECTS to
      other volumes
  END
END
```

Algorithm 3-3. Algorithm for Finding Search-Graph Edges

B. PATH PLANNING ALGORITHMS

Our path-planning is a two-step process. First an A* search algorithm is used to find the first optimal volume path from the start volume (the volume containing the start

point) to the goal volume through the search graph. Quantitative factors are included in this first step, such as probability-of-detection and turn cost. This step finds an optimal set of contiguous volumes through which the final path must move. This is the only step in the path planning process in which aerodynamic processes, such as climbs and turns, are explicitly manipulated.

The second step finds an optimal piecewise-linear path within the confines of the volume path (see Figure 5, in Chapter I). In order to reduce the complexity of the path planning process, only distance flown and probability-of-detection are optimized, using Snell's Law as an optimizing tool. For reasons to be described later in this section, maneuvers (changes in direction or in angle of climb/dive) are restricted to the boundaries between volumes, so the path produced by this step is a series of linear path segments, joined at the boundaries between volumes.

1. Volume-oriented A* Search

The classic A* method has been used in this thesis to find a "reasonable" flight path with a trade-off between minimum cost and minimum probability-of-detection. A reasonable flight path will be defined as a path in which an appropriate amount of effort has been made to avoid regions with a high probability-of-detection, while not going too far off of a minimum cost path. As an example, when driving from Los Angeles, California to Phoenix, Arizona while minimizing

cost and trying to avoid desert terrain, it can be considered reasonable to go via San Diego and Yuma (see Figure 16). It would not be reasonable to go via Barstow and Flagstaff, or via Sacramento and Denver.

As mentioned earlier, heuristics are a key tool in deciding the type of path to be found. [Ref. 2] provides an excellent discussion of the role of heuristics in path planning. Heuristics used here are:

- Remain in volumes with low probabilities-of-detection as long as possible.
- Fly low whenever possible.
- Minimize distance flown.
- Small turns are better than large turns.

These will be implemented as adjustments to the cost and evaluation functions of the A* search. Note that many of these heuristics can conflict with one another, such as the first and third ones. It is up to A* search to resolve these conflicts in a "correct" way.

A* search requires both a cost function and evaluation functions, as described in Chapter II, Section A1. since the A* search is finding a volume path through the search graph, estimators of energy use rather than exact formulas are used. These estimators account for the extra costs incurred when turning or climbing an aircraft. Energy "savings" (e.g., reduced costs over equivalent level flight) can be expected when diving.

In order to include non-energy factors in the A* search (such as probability-of-detection), they are used to arithmetically modify the results of the cost and evaluation functions to reflect the "desirability" of being in a region with a given probability-of-detection. Thus regions with a high probability-of-detection will incur a proportionally higher energy use for a given flight path than a similar region with a lower probability-of-detection. This means that no separate decision must be made to select path volumes based solely on probability-of-detection information.

a. Compensated Cost

One approach to figuring costs when using the A* search is to calculate path-segment costs based on volume-center to volume-center distances, as shown in Figure 17. Turn and altitude energy estimators can be calculated from the horizontal and vertical deviation of the current center-to-center path-segment direction from the previous center-to-center path-segment direction.

The modification to the actual cost of a path segment (volume-center to volume-center distance) for probability-of-detection can be expressed as:

$$\text{Net Cost} = (\text{Actual Cost}) * \text{PD-Modifier} \quad (3-1)$$

where "PD-Modifier" is some function of the probability-of-detection.

- Start Point at "S"
- Goal Point at "G"
- Visibility Volumes named "V1" through "V9"
- Volume center-to-center paths marked by

Figure 17. Volume Center Paths

For a flying object, certain maneuvers represent a certain fixed cost. A turn will incur such a fixed cost, which is a function of the speed of the flying object and the degree of turn. Increased turn angles will incur increased fixed turn costs, up to some maximum allowed turn angle. This can be repeated in simplified form by modifying Equation 3-1 as follows:

$$\text{Net Cost} = (\text{Actual Cost} + \text{Turn Cost}) * \text{PD-Modifier} \quad (3-2)$$

Finally, flying objects use extra energy when climbing, at a rate which is a function of the length of the climb (the Actual Cost) and the degree of the climb. They also use less energy when diving, again as a function of the length and steepness of the dive. A final change must then be made to Equation 3-1 which represents a modification for altitude changes. Note that this modifier must be a multiplicative modifier, since the energy gain/loss is a function of the length of the climb or dive.

$$\text{Net Cost} = (\text{Actual Cost} + \text{Turn}) * \text{Altitude-Modifier} * \text{PD-Modifier} \quad (3-3)$$

Equation 3-3 represents the total compensated cost for a path segment. It can be used when calculating both the cost and evaluation functions during the A* search.

b. Search Algorithm

The classic A* search algorithm, as modified for this thesis, begins with an agenda initialized to all

successors (adjacent volumes) of the volume containing the start point, and all cost and evaluation functions precalculated for those successor volumes. Then:

```
LOOP UNTIL goal-volume is on the agenda
  REMOVE the best successor from the agenda
  FIND all successor volumes to the best successor
  UPDATE path information for the successor volumes
  CALCULATE cost and evaluation functions for the
    successor volumes
  INSERT all successor volumes onto the agenda
END
```

Algorithm 3-4. Search Algorithm for Finding Volume Path

The A* evaluation function calculates the compensated cost for the distance from the center of the successor volume to the goal, ignoring obstructions, and assuming that the probability-of-detection of the successor volume applies to the entire distance to the goal. Note that this evaluation function is not the lower-bound evaluation function. The cost function is a simple summation of all compensated costs incurred up to the current volume along the current path. Adding these cost and evaluation functions gives the total cost for that successor volume

c. Optimal Piecewise-Linear Path

The optimal piecewise-linear path is the minimum-cost path, consistent with the objective of maintaining the lowest possible probability-of-detection along the path, which lies entirely within the volume path (see Figure 18).

● Start Point (a) Volume Path

(b) Piecewise-linear Path

Figure 18. Types of Paths

In order to reduce the complexity of the path planning process, this minimum cost is not modified in any way by the maneuvers along the flight path, but is simply the sum of the point-to-point distances along each path-segment of the total path. The only constraints placed on the linear path are that it must be contained entirely within the volumes comprising the volume path (since this was determined to be the optimal way to go), that maneuvers occur only at the edges of volumes, and that the distances traveled in volumes with high probabilities-of-detection be minimized.

The first two constraints can be met if all visibility volumes are convex, and all linear path line segments are "built" between facets. The convex structure of visibility volumes will ensure that any line segments connecting facets of the volume will always lie completely inside the volume [Ref. 13]. Ensuring that maneuvers occur only at volume facets is an implementation issue.

At this point, it may be useful for the reader to discard the concept of visibility volumes, and consider the construction of an optimal linear flight path as a situation in which a flight path must be found from a start point through a series of restrictive windows (see Figure 19) to the goal [Ref. 14]. The windows, in this case, are the facets which connect the volumes of the volume path. Probability-of-detection information must still reside in the spaces between the windows. These windows, or facets, will

Figure 19. Path Through a Series of "Windows"

be called **maneuver facets**, reinforcing the requirement that all maneuvers must be conducted within the plane of these facets.

Before proceeding, an initial guess at the piecewise-linear optimal path is needed. Any suitable choice will do, so a very general maneuver-facet-center to maneuver-facet-center path can be selected as the initial guess.

The third constraint, the need to minimize the distance traveled through high probability-of-detection volumes, can be handled by applying an adaption of Snell's Law. Using the probability-of-detection of a volume as the index of refraction for Snell's Law, the angles of incidence, and refraction as shown in Figure 20, Snell's Law will be:

$$(Pd1 + 1) * \sin \beta1 = (Pd2 + 1) * \sin \beta2 \quad (3-4)$$

or

$$(Pd1 + 1) * \sin \beta1 - (Pd2 + 1) * \sin \beta2 = 0 \quad (3-5)$$

or, if Snell's law is not exactly met,

$$(Pd1 + 1) * \sin \beta1 - (Pd2 + 1) * \sin \beta2 = e \quad (3-6)$$

where

Pd1 is the probability-of-detection on the incident side,

Pd2 is the probability-of-detection on the refracted side,

$\beta1$ is the incident angle,

(a)

(b)

Figure 20. Snell's Law Optimization Situations

β_2 is the refracted angle, and
e is an error item.

The index-of-refraction of Equation 2-1 is represented by one plus the probability-of-detection. This is simply to avoid having an index-of-refraction of zero when Pd_1 or Pd_2 is zero. Note that the two coefficients (Pd_1+1) and (Pd_2+1) are constant, and that β_1 and β_2 can be varied by moving the path point on the maneuver facet (see Figure 20), assuming that the other ends of the path lines remain fixed. Note also that β_1 and β_2 are actually functions of the position that the path intersects the maneuver facet, called the path point or maneuver point. As the maneuver point is moved, the values of β_1 and β_2 will change, and the value of the error in Equation 3-6 will also change. Only when Snell's Law is exactly satisfied will Equations 3-5 and 3-6 be equal. Figure 20b does not correspond to a situation found in optics, but such an arrangement does occur in path planning.

If the maneuver point is constrained to move along a line within the maneuver facet (only), then Snell's Law will guarantee that a minimum value for the error in Equation 3-6 can be found ([Ref. 3] and [Ref. 4]). If one notes that the path segments L_1 and L_2 of Figure 20 must lie in a plane, then the movement of the maneuver point can be constrained to lie in the line defined by the intersection of the plane of the maneuver facet and the plane formed by L_1

and L2. Further restricting this line to be a line segment contained within the maneuver facet will ensure that a minimum value for the error term in Equation 3-6 can be found within the maneuver facet.

Finding the optimal linear path, then, involves applying the above Snell's-Law optimization to each maneuver facet along the volume path in turn, keeping all other maneuver points fixed. A single optimization pass occurs when all maneuver points have been adjusted one. The optimization passes must then be repeated until the length of the entire linear path converges to some optimal value.

C. SUPPORT ALGORITHMS

1. Intersection of a Plane and a Volume in Space

The intersection of a plane with an arbitrary polyhedral (planar) volume in three-dimensional space depends on the shape of the volume. For the purposes of this discussion, volumes may be classified into two general types: convex and non-convex planar volumes.

a. Interception with Convex Volumes

Figure 21a shows that the interception of a convex volume will create two smaller resultant volumes. These resultant volumes are composed of whole and partial edges from the original volume plus new edges created by the intersection process itself. The newly created edges always lie in the intercepting plane, and in a plane of one of the other facets of the original volume. In general, the facets

Simple Convex Volume Intersection

(a)

Simple Non-Convex Volume Intersection

(b)

Figure 21. Volume Intersections

of the original volume will not be unaffected by the interception; several will be subdivided by the process.

There are several "degenerate" cases of interception shown in Figure 22. Note that the original volume lies entirely on one side of the intersecting plane. This observation will be useful in detecting these cases.

b. Alternative Algorithms

While several methods have been presented to intersect a plane with a volume [Ref. 10], two approaches immediately suggest themselves. The first finds the lines defined by the intersection of the plane and the planes of the facets of the volume, and then fits these "lines of intersection" onto the facets. The second approach finds the points defined by the intersection of each edge of the volume with the intersecting plane, and connects these points along the facets of the volume.

The first approach was not used due to the complexity of the fitting procedure. The second approach, the "plane-edge method," involves a simpler intersection of edges and a plane. Each edge of the original volume is intercepted with the intersecting plane in turn, possibly subdivided according to the results of the interception, and then placed in the appropriate resultant volume. Edges that lie in the plane of the interception are found or built by connecting the intersection points of the edges and the plane in an appropriate manner, and then placed in both resultant

Figure 22. Degenerate Intercept Cases

volumes. Finally the resultant volumes are checked for the degenerate conditions that indicate that a partial intercept has occurred.

(1) Intersection of a Line and a Plane. The intersection point of a generalized line and a plane in three space is derived from the equation of a plane [Ref. 11]

$$ax + by + cz = A_0 \quad (3-7)$$

and the vector-parametric representation for a edge described in Chapter II [Ref. 11]

$$r(t) = A_i + B_j + C_k + t(D_i + E_j + F_k) \quad (3-8)$$

where

$A_i + B_j + C_k$ is the equation of the position vector.

$D_i + E_j + F_k$ is the equation of the direction vector.

$t = 0$ at one end-point of the edge and

$t =$ a maximum value at the other end-point of the edge (called "t-max").

As a result, all points on the line are given by the parametric equations

$$x = A + tD \quad (3-9)$$

$$y = B + tE \quad (3-10)$$

$$z = C + tF \quad (3-11)$$

Solving these equations simultaneously yields

$$t = [A_0 - (aA + bB + cC)]/[aD + bE + cF] \quad (3-15)$$

at the intercept point, which is on the line defined in Equation 3-8.

(2) Intersection of a Edge and a Plane.

Intercepts between a edge and a plane may result in one of three situations:

- $0 \leq t \leq t\text{-max}$: This indicates that the intercept occurred within the edge. If t equals either 0 or $t\text{-max}$, then the intercept occurs at one of the endpoints, otherwise it occurs at some middle point along the edge.
- $t < 0$ or $t > t\text{-max}$: This indicates that the intercept has occurred beyond the endpoints of the edge. No intercept occurs.
- t is infinite: This occurs when the denominator of Equation 3-15 equal zero. In this case, the edge is parallel to the intersecting plane. Again, no intercept occurs.

(3) Building the Resultant Volumes. Using the assumption that two new volumes will be created upon intersection of a convex volume by a plane, the results of the line-plane intersection described above can be used to create the resultant volumes as the process occurs for each edge of the volume. In the case that no intercept occurs for a particular edge (the second and third cases above) one point of the edge must be checked for its location relative to the intersecting plane, then added to the appropriate resultant volume. For an intercept at an endpoint of an

edge, the other endpoint must be checked for its location relative to the intersecting plane, and then the unchanged edge may be placed in the appropriate resultant volume.

When the plane intersects the edge anywhere in its middle, the edge must be divided into two smaller edges. These may be placed into the resultant volumes using the procedure used for an intersection at an end point.

New edges must be built in the plane of the intercepting plane. Note that any lines or points in this plane belong in both resultant volumes. The algorithm must find the edges which connect the intercept points in this region, within the constraints of the particular construction of the original volume. These new edges demark the effect of the intersecting plane passing through the original volume, and construction of these edges involves connection of interception points in the planes of the facets of the original volume.

Now it is possible to check for the degenerate intercept conditions discussed earlier. If an intercept occurred then both of the resultant volumes must not be degenerate volumes. To be a valid volume (non-degenerate) several independent minimum conditions must be met. The resultant volumes must

- have at least four points
- have at least six edges
- have at least four facets

- meet Euler's Relation [Ref. 15],

$$V + R - E = 2 \quad (3-15)$$

where

E is the number of edges in the volume,

V is the number of vertices in the volume, and

R is the number of regions (facets) in the volume.

If either of the resultant volumes does not meet any of these degeneracy checks, then the original volume is unpartitioned by the intersection process.

c. Intersection with Non-Convex Volumes

A non-convex planar volume is one with at least one non-convex surface feature. Intersection of such a volume with a plane will produce at least two resultant volumes, but often more (see Figure 21b). It is this inability to determine exactly how many resultant volumes which will be produced, and the inability to predict their location relative to the intersecting plane, that makes interception of this type of volume difficult.

Fortunately, only one subcase of this problem arises when dealing with polyhedral terrain models. This is illustrated in Figure 23. This special situation is easily identified by adding a step to the intersection algorithm for all new edges created in the plane of the intercepting plane that tests that some non-endpoint point on the new edge (such

Figure 23. Non-Convex Intercept

as a midpoint) to see if it is included inside the original volume. If this boolean test is true, the new edge is "legitimate." If the test is false, then the new edge is outside the original volume, and must be discarded. Only one point needs to be tested for inclusion in the original volume, since the unwanted edges lie entirely outside the original volume (except for their endpoints, of course).

The non-convex interception case only occurs during an early part of the static visibility-determination phase, and then only during a clearly identifiable portion of the algorithm. This is discussed in more detail in the following chapter.

2. Facet Detection

Recall that a facet is composed of a set of planar points connected in a cycle by edges. The intersection algorithm places points and edges into the appropriate resultant volumes, but no facet information is passed from the original volume to the resultant volumes. The first of the two facet finding methods presented here needs only this information to find all of the facets of the resultant volumes; the algorithm searches through the edges of each resultant volume to find all facets. This is the search-based facet finding method. The second method presented cheats a little, and uses some information from the original volume to help find the facets of the resultant volumes after

an interception. This is the plane-based facet finding method.

a. Search-Based Facet Finding Method

This algorithm uses a best-first search to find all the facets of a volume. Recall that a best-first search is an A* search which uses only an evaluation function. This facet-determination search finds a plane in a volume defined by two edges, and then attempts to build the shortest possible coplanar closed loop of edges back to a designated endpoint of one of the lines.

The search is initialized by choosing any point as a start point, and then finding two connected edges which have the start point as an endpoint (as edges L1 and L2 of Figure 24). New edges are added to this initial set of lines if and only if:

- The new edge is connected to the end of the current edge, and
- The new edge is in the same plane as the initial two edges, and
- The opposite endpoint of the new edge is closer to the start point than any other edge which meets the criteria above. This causes the search to loop back towards the start point, creating the needed cycle of edges.

In the volume of Figure 24, for example, the search will produce a facet consisting of edges L1, L2, L4, L6, L8 and L9, all endpoints of those edges, and the plane equation of the shaded plane.

Figure 24. Facet-Determination Example

b. The Plane-Based Facet Finding Method

This method relies on the fact that all of the facet plane equations of the original volume are known, as is the plane equation of the intersecting plane. Since the resultant volumes are made from the elements of the original volume, all of the facets of the resultant volumes will have plane equations equal to those of the original volume, plus one with the plane equation of the intersecting plane. Some of the original volumes' plane equations may appear in only one resultant volume, and some will appear in both resultant volumes.

As a result, to find all of the facets of the resultant volumes, points and edges need only be partitioned into the plane equations in which they lie. Points and edges will lie in only two plane equations. Facets may then be determined relatively quickly and easily.

This method requires that the original volume and resultant volumes be convex, however, since no attempt is made to establish the connectivity of line segments in the facets created; this is assumed to be true.

c. Discussion

As can be inferred from the above description, the facet determination methods each have certain cases in which they are best used, and others in which they are best avoided. In general, the search-based method is suitable for most types of non-convex volumes, and when inputting terrain

data. The plane-based approach is best used for all types of convex volumes where some previous information is available. Both algorithms were implemented. The search-based method is used when dealing with non-convex volumes and after certain error conditions. The plane-based method is used for all convex volumes.

IV. IMPLEMENTATION

The algorithms described in the previous chapter were implemented in LISP. LISP was selected due to the availability of LISP machines and advantages in speed, numerical accuracy and sophisticated data-structure management.

A. SYSTEM SPECIFICATIONS AND REQUIREMENTS

The program was implemented on a Texas Instruments (TI) Explorer II LISP machine with 16 megabytes of memory, 60 megabytes of virtual memory, using Common LISP with the LISP Flavor System (version 6.0). The LISP code will also run on a TI Explorer I LISP machine with significant increases in execution times. The LISP code should also run on any Symbolics LISP machine with only minor changes to the flavor declarations and message passing formats, although this has not been tried.

The LISP implementation is in the seven files shown in Table 2. All primary data structures were written using the LISP Flavor System, an object-oriented programming environment. Some minor data types were implemented as property lists. The uncompiled code (interpretable) in the seven files occupies about 150,000 bytes (150K) of memory, and the compiled version occupies approximately 140K of memory.

TABLE 2. DISK FILES FOR THREE-DIMENSIONAL PATH PLANNING

<u>Filename</u>	<u>Size (text/compiled) (Kbytes)</u>	<u>Description</u>
SETUP.LISP	16/8	Main control function for most of static visibility determination phase. Includes terrain input functions.
VOLUME-FLAVORS.LISP	31/50	Defines all flavors used in the visibility determination phase, and their associated methods and support functions
COMMON-FUNCTIONS.LISP	25/15	LISP functions used by all other functions in the implementation.

TABLE 2 (CONTINUED)

<u>Filename</u>	<u>Size (text/compiled) (Kbytes)</u>	<u>Description</u>
INTERCEPT.LISP	15/9	Functions to intercept a volume and a plane.

PATH-PLANNING.LISP	29/27	Functions related to path planning.
CAMERA.LISP	15/12	Graphic display functions.

1. Terrain Input Requirements

Two alternate terrain input data formats have been implemented. The first method, accepts terrain data as a series of disjoint edges defined by endpoints. All structural lines shown in Figure 25 (and defined in Chapter III) must be included in the input data. The second input format accepts terrain data as a series of disjoint facets defined by the vertices of the facet. This input method will create the structural lines, with certain restrictions.

The first input method is designed as a simple, fast method of entering terrain data. Input is volume-oriented, and only two volumes may be entered: one ground volume and one air volume. The input format is shown in Table 3. Certain non-convex terrain features may not be entered using this format, including peaks and other embedded terrain features (see Figure 26).

The second input method is much more general than the first, and is what "real" polyhedral input terrain would be like. The method inputs only the terrain itself, builds all structural lines, and creates the air and ground volumes. Terrain may be input in multiple rectangular segments, which allows for entering the embedded terrain features of Figure 26. The only restrictions on the terrain data are that the terrain segments must be rectangular with sides parallel to the x-axis and y-axis. Table 4 provides an example of the data format for this input method.

Figure 25. Terrain Structure

TABLE 3. FIRST INPUT METHOD FORMAT

<u>Type of Data</u>	<u>Format</u>	<u>Example</u>

Figure 26. Difficult Terrain Features

TABLE 4. SECOND INPUT METHOD FORMAT

<u>Type of Data</u>	<u>Format</u>	<u>Example</u>
Point	(x y z)	(10 10 10)
Facet	((point-1) (point-2) (point-3))	((0 0 0) (10 10 10) (0 0 20))
Terrain	((facet-1) (facet-2)..(facet-n))	((0 0 0) (10 10 10) (0 0 20)) ((0 0 0) (20 20 20) (20 0 0)))

Neither input method is fault tolerant. Data is assumed to be correct, with no missing facets, points or edges. Sample terrain data for both formats is included in Appendix A.

2. Output Formats

Two outputs are produced by the implementation, text and graphical. The text output shows the state of execution, while the graphical displays show the results of computations.

Graphic displays are two-dimensional true-perspective projections of wire-frame images of various terrain, volume or path features. No shading or hidden-line algorithms are used. The simple graphics flavors used were not written as a part of this thesis [Ref. 16]. Various fixed viewpoints can be used to display objects in one display window. Multiple display windows are shown at once. Alphanumeric representations showing locations of observers, start and goal points.

Graphic displays include:

- (DISPLAY): Display all volumes.
- (DISPLAY-VOLUMES {List}): Display selected volumes.
- (DISPLAY-VISIBLE {Observer}): Display volumes visible from a given observer.
- (DISPLAY-NOT-VISIBLE {Observer}): Display volumes not visible from a given observer.
- (DISPLAY-PATH {Path}): Display a given path and all ground volumes.

- (DISPLAY-PATHS {List}): Display selected paths and all ground volumes.

Examples of most of these displays are shown in Chapter V.

B. DATA STRUCTURES

The data structures used in the three-dimensional path planning program closely mirror the basic geometric concepts presented in Chapter II. Information relative to path planning, visibility and other important parameters has also been added.

The LISP Flavor System defines templates for data structures (called flavors), which can then be created (instantiated) with unique names and components (called instantiation values). LISP flavors and instantiation values are equivalent to frames and slots as defined in [Ref. 2] and [Ref. 17]. These instantiations (or frames) can represent points, vectors, edges, facets, planes, volumes, paths or other objects. All major data structures in this implementation were written using flavors.

Volumes and paths are the basic units of manipulation in the three-dimensional path planning program, but a higher level exists. That higher level is the "universe," the collection of all observers, volumes (ground and air) relative to a particular terrain model. As the visibility determination progresses, all the changes in volumes are made

within the context of this universe flavor. The names of all paths are kept in a single global variable *LIST-OF-PATHS*.

Volumes, as discussed in Chapter II, are composed of points, edges and facets, as well as many other data items. Table 5 shows all of the instantiation values (slots) in the volume flavor. Similarly, each of the main constituent parts of a volume are themselves flavors, and have other, unique data structures, as shown in Table 6. As described in Chapter II, edges are composed of vectors. this flavor is also described in Table 6.

The remaining flavors used are for observers and agenda-items (for the A* search). Details concerning these flavors may be found in Appendix B.

C. PROGRAM STRUCTURE

The path-planning program presented here has a sequential structure which follows from the algorithms presented in Chapter III. an annotated black-box control diagram is shown in Figure 27.

1. Visibility-Model Functional Description

Functions SET-UP and SET-UP-2 implement the set of static-visibility determination algorithms described in Chapter III. Other than starting these functions by calling them, and entering some observer data between the functions, little other user intervention is required. Upon completion of the visibility determination phase, the user may use the DISPLAY or DISPLAY-VOLUMES function to verify the results.

TABLE 5. SLOTS IN THE VOLUME FLAVOR

<u>Instance</u>	<u>Variable/Slot</u>	<u>Description</u>
Visibility		A list of all observers with an unobstructed LOS to the volume.
Probability of Detection		The combined probability-of-detection for all observers in the visibility slot.
Composition		Ground or air (material in volume).
Points		A list of all the points (vertices) of the volume.
Edges		A list of the names of all the line-segments (edges) of the volume.
Facets		A list of all the facets (faces) of the volume.
Arithmetic Center		The point at the center of the volume (used for LOS and path planning calculations).
Connected to		A list of all adjacent visibility volumes.
Mixin Flavor:	Graphic (used for display of the volume).	See Appendix B.

TABLE 6. SLOTS IN OTHER FLAVORS

<u>Instance</u>	<u>Variable/Slot</u>	<u>Description</u>
x-coord		X coordinate value (a number)
y-coord		Y coordinate value (a number)
z-coord		Z coordinate value (a number)
		(a) Point Flavor
i		X coefficient of the vector
j		Y coefficient of the vector
k		Z coefficient of the vector
Start-point		Name of the vector start-point
End-point		Name of the vector end point
		(b) Vector Flavor
t-max		Parameter value at end of line-segment
Position vector		Name of the position vector
Direction vector		Name of the direction vector
Characteristics		Ridge or nil (not a ridge)
		(c) Line-segment Flavor
Edges		A list of the names of all of the line-segments of the facet.
Composition		Not used
		(d) Facet Flavor

Figure 27. Block Diagram of Program Structure

Several global variables are used to save intermediate states of the static-visibility determination process. These variables are shown in Table 7.

a. Input Terrain Data

All constants are initialized and global variables reset when function SET-UP is called. The terrain data is then read from a user-specified disk file using a user-specified input method. Figure 28a illustrates output.

b. Finding Ridges

Function SET-UP continues by calling function FIND-ALL-RIDGES, which tests all edges in the ground volume for their status as ridge lines. The test results are put in the data structure representing the edge. Figure 28b shows sample text output.

c. Making Air Volumes Convex

Function SET-UP continues by calling function MAKE-CONVEX-VOLUMES. This makes vertical planes through each ridge line, and then intersects all air volumes with this plane. This produces convex air volumes from non-convex air volumes as shown in Figure 29. This is the only time that non-convex intersection can occur, and the more restrictive intersection requirements for non-convex volumes are enabled here, as described in Chapter III, Section C1-c. Figure 28c shows sample output.

TABLE 7. GLOBAL VARIABLES

<u>Variable Name</u>	<u>Contents</u>
ORIGINAL-INPUT-VOLUMES	The names of input volumes before manipulations.
CONVEX-VOLUMES	The names of volumes after the air volumes were made convex.

d. Enter Observer Data

This is a manual user step to enter the location and effectiveness of observers to be used in the visibility model. This is done using function INIT-OBSERVER. Location is entered as an (x,y,z) coordinate, and observer effectiveness is entered as a decimal probability of detection between 0.0 (no probability of detection) and 1.0 (100% probability of detection). An observer flavor is instantiated by this function, and added to the universe instantiation.

e. Creating Visibility Volumes

A call to function SET-UP-2 will automate the rest of the static-visibility determination. This function will first call function MAKE-VISIBILITY-REGION for each observer entered by the user. This completes the visibility determination algorithm described in Chapter III. Figure 28d illustrates textual output from this function.

f. Finding Visibility

SET-UP-2 then calls function DETERMINE-VISIBILITY for each observer. This function determines the line-of-sight (LOS) from the center of each visibility volume to the observer. If the LOS is not blocked, the name of the observer is added to a list of observer names in the volume data structure. Figure 30a shows a sample output.

Function SET-UP-2 then calls function PROBABILITIES-ASSUMING-INDEPENDENCE-OR [Ref. 2], which

(c)

Figure 30. Text Output

combines the probabilities of detection for all observers which can see a given visibility volume (using the information noted earlier in the data structure of the visibility volume). Figure 30b shows a sample output.

g. Connecting Volumes

Finally, SET-UP-2 calls function CONNECT-VOLUMES. This function builds the search graph by annotating the data structure of each visibility volume with the names of the visibility volumes to which it is adjacent, using the algorithm described in Chapter III, Section A2-c. figure 30c shows a sample output.

2. Path Planning

The path-planning phase is less structured than the visibility determination phase, so no overall control function has been implemented. The user must follow a minimum sequence of actions, as shown below.

a. Entering Start and Goal Points

These points are entered using function INIT-POINT.

b. Volume Path Planning

Function A-STAR-SEARCH performs A* search for the volume path through the visibility volumes. This function will instantiate a unique name for the path created, make the initial guess at the piecewise-linear path, and place that information into the paths data structure.

An alternate function, A-STAR-SEARCH-M, finds multiple volume paths from the start point to the goal point. The paths may be compared at a later time.

c. Optimizing the Path

Finally, the user may call function OPTIMIZE-PATH which will conduct one Snell's Law optimization pass along a given volume path. This optimization function will create a new instantiation of the path flavor for the optimized path. the user may call this function repeatedly to obtain the effect of multiple optimization passes. New paths are created on each call to let the user compare paths.

D. VOLUME INTERCEPT FUNCTIONS

The functions which subdivide a volume by a plane, while not directly called by the user, form the heart of the visibility determination algorithm. MAKE-CONVEX-VOLUMES and DETERMINE-VISIBILITY are the functions which directly call the series of volume intercept functions. These user-level intercept functions develop lists of volumes to be subdivided and lists of intercepting planes. The highest level intercept function, INTERSECT-ALL-PLANES-WITH-VOLUMES conducts repeated intercepts of the volumes with the intercepting planes. The resultant volumes replace the original volume in the list of volumes to be intercepted.

The volume intercepting algorithm described in Chapter III is implemented by the lowest level intercept function INTERSECT. This function takes one volume and one plane, and

performs their intercept. Text output from this function is of the format:

```
Intercepting:  {volume-name} {A B C Ao} --- Result:
               {result-code}
```

where A, B, C and Ao are the constant coefficients of the intercepting plane. Figures 28c and 28d show examples of this output. Possible result codes are shown in Table 8.

Numeric errors can occur during the intercept function. They are the result of a rounding error associated with the use of floating point numbers in the calculation of point values and various coefficient values for vectors, edges and planes. This results in points which do not lie in planes that they should, lines that do not connect though they should, vectors that are equal being found not equal, etc. When a numeric error occurs, the intercept function will simply indicate that no intercept has occurred, a degenerate intercept condition is produced, and execution is not halted. The intercepting plane which caused the error is flagged for later use.

A method was developed to attempt to correct these numeric errors when they occur. This method adjusts the allowed imprecision of calculations, broadening the definition of equality between numbers [Ref. 18].

$$A=B \text{ if and only if } (A - B)/B < \{\text{fixed constant}\} \quad (4-1)$$

TABLE 8. INTERCEPT RESULT-CODES

<u>Code</u>	<u>Description</u>
nil (early1)	Invalid intercepting plane.
nil (early2)	Intercept along a facet of a convex volume.
nil (late 1)	Intercept at a point (only).
nil (late 2)	Not enough facets in resultant volume. Usually indicates that a numeric error occurred.
{{facet-name}}	Successful intercept, facet named is the common facet between the resultant volumes.
{{facet-name-1} {facet-name-2}...}	Successful intercept, except that, due to a numeric error, several facets are common to the resultant volumes.
Violated Euler's Relation ###	A numeric error occurred at precision ###.

The value of the fixed constant value is increased incrementally to fix a numeric error. The normal fixed constant is initially 0.25%. While correcting an error this will be increased incrementally up to a maximum of 1.0%.

If the correction method is unsuccessful in correcting the numeric error, then no further action is taken. This can have a significant impact on the validity of the visibility model, and is discussed further in Chapter VI.

V. RESULTS

Two useful metrics were developed to measure the effectiveness of the program. The number of visibility volumes built is compared to the number of visibility cubes created in a uniform-cube approach to the visibility problem to measure the effectiveness of the visibility-determination phase. The weighted average probability-of-detection for the path is compared to the maximum probability-of-detection for the path to measure the effectiveness of the path planning.

A. VISIBILITY VOLUMES

Six different airspace models were tested in the visibility-determination phase, each in three different situations, for a total of 18 test cases. Twelve of these test cases cover airspace over simple terrain models with isolated, idealized terrain features. These include various simple ridge and peak shapes. The remaining test cases represent more complex terrain. All terrain was bounded inside a 1000 by 1000 by 1000 cube (of no units).

Airspace models were tested after air volumes were made convex, after visibility processing for one observer, and after processing for two observers. The number of visibility volumes was recorded after each case. The effectiveness of the visibility model was judged against the reduction in size of the search graph, relative to a standard maximal search

graph. This standard maximal search graph is composed of 10 by 10 by 10 cubes (800,000 nodes), or 25 by 25 by 25 cubes (52,100 nodes), or 50 by 50 by 50 cubes (6,400 nodes). These assume an initial air volume from ground level at 200 units to a maximum altitude of 1000 units. The presence of terrain features represents a 25% decrease in the size of the air volume, so the final sizes of the standard maximal search graphs are 600,000, 38,400 and 4,800 nodes, respectively.

Table 9 shows the results obtained for the airspace models. Figure 31 shows one of these models (a simple ridge, called a "single ridge" in Table 9) after the air volumes have been made convex. Figure 32 illustrates the same model after processing for a single observer (the location of the observer is noted with a lozenged OBS symbol). Figure 33 and 34 show the same views with another terrain model (a complex ridge structure called a "full ridge" in Table 9) with two observers. It should be clear from Figure 34 that a graphical display of the visibility regions in even a simple problem is too confusing to be useful.

Table 9 indicates that the number of visibility volumes grows explosively as a function of the number of ridge lines and the number of observers. The graphs of Figure 35 clearly indicate a strong functional relationship between these quantities. The growth in the numbers of visibility volumes approximates an exponential curve, as a function of the number of ridge lines, as shown in Figure 35b. Such growth

TABLE 9. VISIBILITY VOLUMES BY TERRAIN TYPE

<u>Terrain Type/ Number of Ridge-lines</u>	<u>Number of Convex Volumes</u>	<u>Number of Visibility Volumes (One Observer)</u>	<u>(Two Observers)</u>
Single Ridge/1	2	4	6
Double Ridge/2	3	7	9

Figure 34. Visibility Volumes for a Full Ridge with Two Observers

(a)

(b)

Figure 35. Plots of Ridge Lines vs Visibility Volumes

Figure 31. Convex Air Volumes over a Single Ridge

is relatively innocuous with simple terrain models, but with more complex models this growth hurts the overall performance of the path-planning program. This is discussed in more detail in the following chapter.

Note the increased incidence of numeric errors (as defined in Chapter III, Section D) encountered as the number of ridges and observers increases, as shown in Table 9. These errors present potential deviations from the ideal visibility model. Volumes affected by numeric errors may not have uniform visibility for all enclosed points.

The visibility model does significantly reduce the size of the search graph from the standard maximal graph, as indicated in Table 10.

B. PATH PLANNING

Representative results for the path planning phase are shown in Table 11 and Table 12. Figures 36 through 47 illustrate some of these paths. Three views are shown for each terrain model, one for the initial, non-optimal piecewise-linear path (an initial guess, based on the volume path, and defined in Chapter III, Section B1-c), one for the optimal linear path (defined in Chapter III, Section B1-c), and one showing both paths together.

Figure 48 shows the effect of varying the location of the start point while keeping the end point fixed. This illustrates the trade-off made during path planning between

distance travelled and probability of detection. All paths displayed are non-optimal initial guesses.

Tables 11 and 12 also show the effects of the Snell's Law optimization (of Chapter III, Section B1-c) on the cost and average probability-of-detection of the paths. On average, a 10% reduction in total cost is obtained as a result of optimization, with most of that gain being realized in the first optimization step. Figures 36 through 47 also show that the optimized paths generally remain in the same planes as the initial path. This is an artifact of the optimization procedure. Lower-cost optimal paths may result if this restriction is removed.

VI. CONCLUSIONS

It is clear from the previous chapter that the visibility-volume approach presented in this thesis can be successfully applied to the three-dimensional path planning problem. Reasonable paths were produced over a variety of terrain types. Search graphs were reduced in size compared to the alternate approach proposed in Chapter V (Section A), usually by two to five orders of magnitude. The search algorithm used was an easily implemented one, and no exotic pruning criteria were necessary during the path-planning process.

A. KNOWN PROBLEMS

Several shortcomings of this approach are worth noting, however. The growth in the number of visibility volumes is exponential as the number of ridge lines increases. This slows both the static-visibility determination and the path planning. As the number of visibility volumes increases, their average size decreases, relative to the size of the original air volumes. Small visibility volumes create narrow volume paths, and this decreases the effectiveness of the optimizing function by decreasing the area available to move the maneuver points.

The presence of very small visibility volumes reduces the chances that the A* search agenda will ever contain areas of

low probability of detection. If A* search never places a low probability-of-detection volume on the search agenda, it will not be able to evaluate the effectiveness of planning a path through that volume.

Occurrences of the numeric errors discussed earlier result in volumes containing regions of non-uniform visibility, which will result in paths being planned to pass through areas of high visibility in preference to areas of low visibility. Again, the extent of this problem was not examined in this thesis, but measures recommended to correct other shortcomings will help to alleviate this problem.

No true aerodynamic effects have been included in the energy model proposed in this thesis. Such models exist, but they were intentionally left out to avoid over-complicating the problem. The energy model used here predicts energy use in the volume path-planning stage, and only minimizes distance flown and visibility during the path optimization functions. Optimization must be extended to cover aerodynamic effects (turns, climb and dive effects). Note that this will require extensions to Snell's Law to account for these non-optical effects.

Not until an optimal piecewise-linear path is found is the precise nature of the flight path known. As a result, the best overall path may be through a non-optimal volume path (e.g., the second or third solution found by the A* search). The nature of this effect should be investigated.

Non-point observers, such as a small group of radars or dispersed groups of men, are not well handled by the visibility model. Since the model is very sensitive to an increase in the number of observers (which cause a rapid rise in the number of visibility volumes, and a corresponding decrease in the size of the individual volumes within the fixed airspace), simulating a large group of observers will be impossible to handle.

No diffraction, refraction, interference or diffusion effects are implemented. These can be significant effects, especially for radar and sonar observation. Simple range models can be implemented to account for some effects, while empirically-based changes to the probability-of-detection for certain visibility volumes can account for others. Diffraction effects due to terrain could be approximated by intersecting volumes with curved visibility-boundary surfaces instead of planes. Similar approximations can be made to correct lines-of-sight for various atmospheric effects.

Finally, the program is not fast. Construction of visibility volumes can take up to 24 hours to complete for complex terrain models (for the double peak terrain of Table 9 in Chapter V, consisting of eight ridge lines and two observers). Five to ten hours is the average run time for a simple terrain model (the peak in Table 9 in Chapter V, consisting of four ridges and one observer). Search times are very short, and run from ten seconds to several minutes,

on the average; large numbers of visibility volumes will take up to 15 minutes.

B. RECOMMENDATIONS

Corrective measures not already discussed to the problems mentioned above fall into several areas: better selection criteria for planes of visibility, a method of combining visibility volumes, parallel processing for some parts of the program, and modification of the search methodology used.

Algorithm 3-2 of Chapter III for the selection and use of limiting planes of visibility was not implemented in this thesis. It alone will not prevent rapid growth in the number of visibility volumes, but will serve to slow it some. That, combined with other measures (range effects, independent processing of terrain segments, etc.) may significantly control the number of visibility volumes.

A second corrective measure, coalescing visibility volumes after their creation will help resolve the small-visibility-volume problem. This would involve adjacent volumes with the same probability-of-detection. This could create non-convex visibility volumes, however, and must be applied with caution.

Much of the visibility-determination portion of the program involves intercepts of different volumes with the same intercepting plane. These calculations are functionally independent from one another, and thus are amenable to a parallel processing. Since several hundred such

interceptions occur, significant improvements in execution times could be expected with the use of several parallel processors. Parallel processing may also help to speed up the search portion of the program.

The two-phase path-planning methodology used here should be compared with a single-phase path-planning algorithm. Finding the optimal piecewise-linear paths as the A* search progresses may result in finding a better flight path.

C. DISCUSSION

There are two advantages to the volume-oriented approach to the three-dimensional path-planning problem: the abstraction of airspace to a search graph based on large, irregular visibility volumes, and the resultant simplification of the search.

Appropriate use of the visibility volume concept ensures that A* search can effectively evaluate all possible paths from the start point to the goal without missing large areas of the search graph. As mentioned earlier, A* cannot evaluate search nodes that do not get onto the search agenda, and the use of large, irregularly shaped visibility volumes ensures that the largest possible amount of airspace is represented on the agenda by the smallest number of volumes. The effect of small vs. large versus large visibility volumes on the effectiveness of A* search should be investigated further.

Simplicity of the search function is the second significant advantage of this approach to the problem. Almost all of the work necessary to do a search is done before the search starts. No complex (and time consuming) pruning functions are implemented during the search. The only work not done before the search is the actual calculation of the cost and evaluation functions.

FILE NAME: Setup.lisp

MAIN CONTROL FUNCTIONS

This file contains several LISP functions perform overall control of the static construction phase of the code. They include the initial input control loops (for both input methods, and the control loop for the visibility region construction phase of the static construction. The initial set-up functions are first, followed by the middle phase set-up functions, large scale control functions, and finally, the actual input methods themselves.

THESIS D. H. LEWIS 20 OCT 88

ROUTINE TO INPUT A DATA STREAM AND CONSTRUCT THE VOLUME(S)

THESIS/CS4452 D.H. LEWIS 15 MAY 88

Builds the standard static flavors (Universe, above, below, and cameras), opens and reads input file, and carries the static phase through making air volumes convex.

MAIN FUNCTIONS: SET-UP (METHOD FILE)
SET-UP-2

OTHER FUNCTIONS: INITIALIZE-VOLUME
MAKE-VOLUME-WITH-FACET-DATA
DECREASSING-SORT-ON-X-P
DECREASSING-SORT-ON-Y-P
PRINT-HEADER-1

(defvar *Universe*) ; location of names for all flavors used in static
; construction
(defvar *above*) ; standard volumes used by intercept functions
(defvar *below*) ;
(defvar *input-stream*) ; system name for non-standard input file
(defvar *output-stream*) ; system name for non-standard output file
(defvar *max-altitude* '1000) ; maximum altitude in Input Method 2
(defvar *min-altitude* '0) ; minimum altitude for Input Method 2
(defvar *not-convex-volumes*) ; flag variable for Input Method 2 which tells
; which facet building function(s) to use

(defvar *original-input-volumes* 'nil) ; save various "states"
(defvar *convex-volumes* 'nil)
(defvar *final-visibility-regions* 'nil)

APPENDIX B. LISP CODE LISTING

This appendix contains the listings for all LISP code in the files shown in Table 2. File names are noted at the beginning of each file listing.

FLAVORS AND METHODS

FLAVOR: Point

METHODS: :LIST-FORMAT ; give the x,y and z values as a three-tuple
 :LIST-FORMAT-REAL ; same, in real number format
 :LIST-FORMAT-4 ; give agraphics 4-tuple "(x y z 1)"
 :PRINT ; print info on point

FLAVOR: Vector

METHODS: :LENGTH ; calculate length of vector
 :UNIT-VECTOR ; return the coeff of the unit vector
 :ENDPOINTS ; give the names of the endpoints of the vector
 :LIST-FORMAT ; give the coeffs of the vector as a 3-tuple
 :LIST-FORMAT-REAL ; same, except with real numbers
 :PRINT ; print coeff values to output file

FLAVOR: Line-segment

METHODS: :ENDPOINTS ; Return the endpoints of the line-segment
 :ENDPOINT-LIST ; Return endpoints as explicit 4-tuples
 :OTHER-END (ENDPOINT) ; Given one endpoint, return the other
 :START-POINT ; Return the start point of the line-segment
 :END-POINT ; " " end point " " "
 :LENGTH ; Find and return the length of the
 line-segment
 :BACKSUBS (T-LIST) ; Substitute the (Tx Ty Tz) list into
 the line equation
 :MID-POINT ; Find the mid point of the line-segment
 :STRATTLE-PLANE-P (PLANE) ; do the endpoints of the line-segment
 lie on opposite sides of the plane?
 :PRINT

FLAVOR: Plane

METHODS: :TEST-EQUAL (PLANE) ; Do two planes have the same coeffs?
 :LIST-COEFF ; List 4-tuple (X Y Z Ao) for plane
 :LIST-COEFF-3 ; List 3-tuple (X Y Z) for plane
 :SUBS-POINT-INTO-PLANE (POINT) ; Get Ao coeff from X,Y,Z values of point

```

: PATH PLANNING           D.H. Lewis           25 Aug 88
: -----
```

```
: Contains the flavors, methods, and functions necessary to conduct path
: planning. Divided into four main sections; Flavors, A-star
: path planning, and path optimization.
```

```
: The flavors section provides the essential path and agenda item flavors,
: and their associated method and support functions.
```

```
: The A* search section conducts an a* search of the volumes, minimizing
: cost and visibility, and creates an initial path.
```

```
: Finally, the optimization code optimizes the initial A* path according
: to snells law criteria. This section may create one or several paths
```

```
.....
: (defvar *PD-threshold* '0.0)      ; maximum desirable probability of detection
: (defvar *PD-modifier* '10.0)     ; affects effect of PD on path planning

COMMON FUNCTIONS

; This file consists of all common functions used by most of the
; files of the 3-D path planning software. Function vary from the
; very general (convenience) functions, to very detailed, special
; purpose functions (which happen to be called from two separate
; files). Functions are grouped by categories of Simple functions,
; Point functions, Vector functions, Line functions, Plane functions,
; Facet functions, Volume functions, property list functions,
; detailed (special purpose) functions, and finally, printing functions.

FUNCTIONS TO INTERCEPT A VOLUME WITH A PLANE D.H.LEWIS 27May88

These functions intercept planes with volumes and lines with planes. Multiple tests are performed to ensure proper construction of new volumes. Facets are rebuilt each time.

Main functions: INTERSECT (VOLUME PLANE)
FIND-INTERCEPT-POINT (PLANE LINE)

Other functions: GET-INTERCEPT-POINT (PLANE LINE T-INTERCEPT)
PUT-LINE-IN-CORRECT-HALF (LINE PLANE)
PUSH-ENDPOINTS (LINE VOLUME)
MAKE-NEW-DIVIDING-LINES (VOLUME OLDPOINTS NEW-POINTS)
NEW-VALID-LINE (POINT1 POINT2 VOLUME)
IN-FACET-P (POINT1 POINT2 FACET)
OUTSIDE-VOLUME (LINE VOLUME)
DENOM-IN-INTERCEPT (PLANE LINE)
GET-INTERCEPT-POINT-2 (LINE T-INTERCEPT)

(defvar *lines-in-intercept-plane* 'nil)
(defvar *large-integer* '1e4)
