Summary of the report:

Model tests with a floating breakwater in short-crested waves have been performed in scale 1:10. The breakwater is a model of a 2-pontoon CERC prototype. 2 versions are tested: fendered and stiff. Some tests in long-crested waves are also included. Wave elevation, anchor line forces, breakwater motions and hydrodynamic pressures have been measured. Simple numerical simulations of forces and motions are made. Experimental wave reduction is studied through maximum and RMS values and wave spectra. Wave transmission varies from 30% for 2s waves to 100% for 6s waves (full scale). Control of wave statistics and grouping is included. Waves in front of the model are also studied. Maximum and RMS values, auto- and cross-spectra, linear transfer functions and amplitude statistics of forces and motions are presented. The maximum force in a single sensor was 102 kN, while in a single anchor line it was larger than 150 kN. Non-linearities in motions and forces result in significantly larger extremes than predicted by linear theory. Preliminary comparisons to field measurements are made for waves and mooring forces.

1. INTRODUCTION

This report presents results from a 1:10 model scale experiment with a floating breakwater concept proposed by CERC/US Army Corps of Engineers. The experiment was carried out in the MARINTEK Ocean Basin, mainly in short-crested irregular waves. The breakwater was a model of a full-scale prototype which has been tested earlier by CERC in a 4-year test program in Puget Sound, Seattle, U.S.A. /1/. Thus a main objective of the model test was to verify the full scale results. In addition, the model test included more severe wave conditions than those observed in Puget Sound. The model tests presented in this report include measurements of wave elevation behind and in front of the breakwater, mooring line forces, breakwater motions, and hydrodynamic pressures at the front and back sides of the breakwater. A total number of 20 different test runs were made with the model, + 10 wave calibration runs. All results from the subsequent analysis are put together in separate Data Reports, one for each test run (Appendix 1-30). The most essential results for waves, forces and motions are presented in this Main Report. For the pressure measurements, we refer to the Data Reports.

All recorded data are stored on magnetic tapes at MARINTEK. Parts of each of the 20 model test runs are also recorded on video tapes, also stored at MARINTEK.

The CERC prototype, as well as the model, was made up by two rigid, rectangular boxes (pontoons). A good description of the prototype test details is found in the resulting CERC report /1/. Two different pontoon connection types were used in the present model test: fendered (no bolting) and stiff (pontoons welded together).

Additional, similar model tests with 6 pontoons were later made for the Norwegian Coastal Directorate. Results from that test are presented in a separate report /2/.

Computer simulations of the linear motions of the stiff breakwater, based on a simple numerical model, are also presented.

The work presented in the present report and in /2/ follows mainly the lines described in the Proposal /3/, except from some changes in the test

7/1136/R1/CTS/ko

program (see chapter 2.4).

The total delivery to CERC on this breakwater model test consists of this Main Report, the 30 Data Reports, and the Main Report from the 6-pontoon model test /2/.

2. TEST CONDITIONS

2.1 Test facilities

The laboratory test was performed in MARINTEK's large Ocean Basin which measures 50m x 80m. See the schematical drawing in fig. 2.1. For this test, the model scale was chosen to be 1:10. In order to simulate the average bottom depth of 18.3m in Puget Sound, the adjustable bottom was therefore set at 1.83m.

The Ocean Basin is equipped with 2 wavemaker systems (see Fig. 2.1). One of the 50m short side-walls consists of a large, horizontally double-hinged hydraulic wavemaker (wavemaker 1). In the present experiment, however, we used the multiflap wavemaker (wavemaker 2) located along one of the long sides, in order to be able to generate shortcrested as well as long-crested waves. This wavemaker consists of 144 electromechanical, individually computer controlled flaps. The generation of irregular, short-crested waves is briefly described in section 2.4.

Along the 2 sidewalls opposite to the wavemakers, rigid and impermeable beaches are installed. The beach slope is curved (zero slope at still water level).

2.2 The breakwater model and the instrumentation

The full scale prototype breakwater was made up of air-filled concrete boxes, see Fig. 2.2. and the CERC Report /1/. Since the model test included no measurements of structural dynamics of the model, it was for simplicity decided to construct the model scale breakwater pontoons with steel kernels surrounded by a stiff, impermeable foamy material ("divinycell"), see Fig. 2.3. The short ends were made of steel plates. The waves, hydrodynamics, mooring line forces and the breakwater motions are expected not to be affected by this structural difference between the prototype and the model, as long as the size, shape, weight and moments of inertia are reproduced in model scale (see Appendix A of the Proposal /3/).

Fig. 2.7 Viewing the breakwater from the short end. The mooring line connection to the pontoon can be observed.

Fig. 2.8 The fender system.

The breakwater model was tested in fendered condition (Figs. 2.4.a, 2.6, 2.7, 2.16 and 2.17) as well as in stiff condition (Fig. 2.4.b). The fenders (figs. 2.5 and 2.8) were made of a hard synthetic rubber material ("eladur"). The stiff breakwater was obtained by removing the fenders and welding the pontoons together at the short ends, which means that the total length of the breakwater was 5 cm less than for the fendered model (model scale).

A tilt test of a free floating pontoon gave a roll period equal to 1.0s, model scale. The freeboard of a free pontoon was 5 cm, while in moored condition it was 4 cm, model scale.

The mooring lines were modelled with wires and chains, as shown in Fig. 2.9 and the photographs Figs. 2.7, 2.11 - 2.14. They were modelled to simulate, as closely as possible, the prototype lines /1/ with respect to weight, size and stiffness. The stiffness was modelled with a proper spring at the bottom end of each line (see fig. 2.12, 2.13). Fig. 2.10 shows the geometry of the mooring system. A force measuring sensor was included in the chain of each line just beneath the breakwater (Fig. 2.14). Static tension force in each line was measured to be ≈ 18 N (the corresponding prototype tension was 22 kN 1). (For the central y-coupled lines, this was divided into ≈ 9 N for each of the chains between the y-coupling and the breakwater bottom).

Pressure transducers were placed on either long vertical side of the pontoons, see fig. 2.15. An optical positioning system developed at MARINTEK, OPTOPOS, was used to measure 6 motional components (x-, y-, z-position, roll, pitch, yaw) of each pontoon. (For the stiff model, only the 6 components of the whole structure were measured). See Fig. 2.18 for the definition of the coordinate system.

23 wave staffs were used to measure the wave elevation: 12 staffs in front and 11 behind the breakwater. See Fig. 2.19 for the location of the staffs. The actual design of the staffs may be observed from the photographs in Figs. 2.6, 2.16 and 2.17.

Table 2.1 shows the measuring channels used throughout the experiment. The 6 last channels, ch. 48-53, are, however, used only for the fendered model.

Table 2.1

2.3 Test program

A total number of 30 test runs were made:

10 wave calibration runs with no model (No. 101-115)

10 runs with fendered model (No. 201-215)

10 runs with stiff model (No. 351-365)

Table 2.2 explains the different tests. Test runs 107-108-109, 207-208-209, 357-358-359 were chosen to reproduce 3 CERC prototype wave records. (This reproduction is not perfectly accurate, since some of the waves of the 3 actual input spectra are somewhat shorter than recommended for the wavemaker. In addition, the 3 prototype wave records used as input waves in those 9 test runs must be expected to be disturbed by the prototype breakwater).

Registration of signals started simultaneously with the start of the wave-maker and lasted 16 minutes (model scale) (regular waves: 6 minutes). Plots of the start-up sequence (51.2s model scale) for each channel are included in the Data Reports Appendix 1-30, to serve as a tool in e.g. technical control and offset studies. In the main analysis, however, the last 13 minutes (2 minutes for regular waves) were used, in order to let the wave field have 3 minutes to build up to more or less stationary conditions. Sampling interval used is 0.050s (model scale). All signals passed through a Butterworth 4th order analog filter with cut-off at 6 Hz (model scale).

533016 FLOATING BREAKWATER MODEL TEST, 2 PONTOONS

List of all the test runs.

Wave Calibration Runs:

Run no.	Wave Condition (Full scale)
101	Jonswap spectr. $T_p=3.2s$ $H_s=0.75m$ $\gamma=3.3$ $\cos^2\theta$ dir.sp.
102	Jonswap spectr. $T_p=4.3s$ $H_s=1.00m$ $\gamma=3.3$ $\cos^2\theta$ dir.sp.
103	Jonswap spectr. $T_p=5.0s$ $H_s=1.50m$ $\gamma=3.3$ $\cos^2\theta$ dir.sp.
107	Jonswap spectr. $T_p=3.0s$ $H_s=0.93m$ $\gamma=2.0$ $\cos^2\theta$ dir.sp.
108	Jonswap spectr. $T_p=2.8s$ $H_s=0.65m$ $\gamma=2.0$ $\cos^2\theta$ dir.sp.
109	Jonswap spectr. $T_p=2.4s$ $H_s=0.65m$ $\gamma=2.7$ $\cos^2\theta$ dir.sp.
111	Jonswap spectr. $T_p=3.2s$ $H_s=0.75m$ $\gamma=3.3$ $\cos^2\theta$ dir.sp.
112	Jonswap spectr. $T_p=3.2s$ $H_s=0.75m$ $\gamma=3.3$ long-crested
113	Regular waves $T=6.3s$ $H=1.00m$
115	Regular waves $T=3.2s$ $H=0.75m$

The mean wave direction is 90 deg (perpendicular to the long sides of the breakwater) for all the test runs.

Table 2.2

2.4 Generation of irregular, short-crested waves

Basically, the simulation starts with the specification of a directional frequency spectrum $S(f, \theta)$ of the surface wave elevation $\eta(t)$. The spectrum is modelled as a monomodal JONSWAP- $\cos^{2s}\theta$ spectrum, defined by the following formulas:

$$S(f, \theta) = S(f) \cdot D(\theta) \quad (2.1)$$

$$S(f) = K_1 \cdot f^{-5} \exp -1.25(f/f_p)^2 \cdot \gamma^\beta$$

$$\beta = \exp -(f-f_p)^2 / (2\sigma^2 f_p^2) \quad (2.2)$$

$$\sigma = \begin{cases} 0.07 & f < f_p \\ 0.09 & f > f_p \end{cases}$$

$$D(\theta) = K_2 \cos^{2s}(\theta - \theta_0) \quad (2.3)$$

where γ = peak enhancement factor
 f_p = peak frequency
 θ_0 = mean wave direction
 s = directional spreading parameter
 K_1, K_2 are scaling factors

Note that this model assumes the same directional spectrum $D(\theta)$ for all frequencies.

The spectrum is specified by the 5 input parameters H_s , f_p , γ , θ_0 and s , where the last 4 are defined above, and

$$H_s = H_{m0} = 4\sqrt{m_0}$$

$$m_0 = \int_0^\infty df S(f) \quad (2.4)$$

The time series generation is then based on linear superposition of harmonic (plane) wave components with weight functions based on eq. (2.1) - eq. (2.3) and the actual frequency increments. The software for the multiflap generator combines 100 components, each with a random phase and a random direction according to the chosen directional spectrum $D(\theta)$. The frequencies chosen for the spectrum generation are non-equidistant, with a high frequency density around the spectral peak, and a lower density in the spectral tails.

2.5 Data processing

The following analysis is made:

1. Listing of simple statistics (data available immediately after each test run) - model scale.
2. Plotting of autospectra of each channel (based on FFT of blocks consisting of 2048 data points each) - full scale.
3. Plotting of the first 1024 time history points of each channel (the start-up sequence) - full scale.
4. Plotting of a block of 1250 (280 for regular waves) time history points of the following channels: Wave Staff 1, 8, 11, 13, 18, 21 + all other channels. Full scale.

The time window is chosen to include the maximum force (or wave elevation if wave calibration) recorded in the run (the same time window is used for all channels in the run).

For regular waves, additional time history plots with 280 points (for the same set of channels) are presented, showing an early stage of the wave train (after the transient, before reflection).

5. Listings of spectral and zero-up-crossing peak-to-peak parameter values for at least the following channels:
Wave staff no. 11 and 18, 3 force sensors, all motional

7/1136/R1/CTS/ko

measurements. Full scale.

All 23 wave staffs. Model scale.

6. Spectra of wave staff no. 11 and 18 are compared to theoretical JONSWAP plots, and to corresponding calibrated spectra. Wave amplitude transmission (and amplification in front) curves are plotted. Full scale.
7. Wave group spectra based on the Hilbert envelope /5/, for ch. 11 & 18 are plotted and compared to theoretical curves calculated from the measured wave spectrum. "Pinkster" formula /5,6/). Full scale.
8. Plots with zero-up-crossing wave height statistics are compared to the Rayleigh distribution (wave 11 & 18). Full scale.
9. Plots with statistics of force & motion maxima are compared to the Rayleigh distribution (3 force sensors, 6 motional components). Full scale.
10. Plots of transfer/functions between wave 11 and 3 force sensors + 3 motional components, (Wave 11 signal is taken from wave calibration - not from the actual model test run). Full scale.
11. Plots of cross spectra (coherence & phase) between wave 11 and 3 force sensors + 3 motional components (Wave 11 signal is taken from the same test run as the force & motions measurement). Full scale.

All motions measurements (Channel 42-53) are digitally filtered at 0.99 Hz (full scale) after the recording and before the main analysis. (Data in the first listings, item 1 above are however not filtered).

Complete results from the analysis described above are presented in the Data Reports - Appendix 1-30. Main results on waves, mooring line forces and motions have been selected for presentation in this Main Report. For pressure data, we refer to the data reports.

7/1136/R1/CTS/ko

3. EXPERIMENTAL RESULTS

The breakwater model experiment in the Ocean Basin resulted in a large amount of data. One of the reasons for this is the long registration period used in the irregular wave tests (≈ 1000 -1500 wave periods, of which the last ≈ 700 -1000 were used in the main analysis), which was chosen in order to give reliable statistics of the results. During the planning of the experiment, it was considered to be important to emphasize long records because moored structures like this floating breakwaters often have significant non-linear motions in the low-frequency region.

As a consequence, one had to be selective when planning the analysis and the presentation in this Main Report. We have emphasized the irregular wave tests (although some analysis is done also for the regular wave tests, see the Data Reports). It is the intention of this Main Report to point out the following essential features of the breakwater model in irregular waves:

- Wave reduction
- Wave amplification in front
- Change of wave spectrum due to model
- Wave statistics/grouping, with/without model
- Wave pattern around model
- Effect of wave short-crestedness on waves and responses
- Force and motion maximum/RMS value vs. significant wave height and peak period.
- Force and motion spectra
- Linear transfer functions
- Coherence analysis (i.e. coupling between waves-forces-motions)
- Deviations from linear (1. order) behaviour

The presentation is divided into 2 main parts:

Fendered model analysis

Stiff model analysis

which each is split up into 3 parts:

Waves

Forces

Motions

For hydrodynamic pressure data, we refer to the Data reports.

The units of all measured channels are given in Table 2.1.

3.1.2 Wave reduction/amplification around fendered breakwater model

The first plot (fig. 3.7) shows the normalized maximum wave height $H_{max,n} = H_{max}/H_{max,o}$ and normalized significant wave height $H_{mo,n} = H_{mo}/H_{mo,o}$ behind the model (wave staff 18, see fig. 2.19) as a function of the input peak wave period T_p . $H_{max,o}$ and $H_{mo,o}$ are wave height values obtained from calibration without model. Next, figs. 3.8-3.15 show plots of the distribution of $H_{max,n}$ and $H_{mo,n}$ 2m in front of (wave staffs 1 - 9), and 1m behind (wave staffs 13-21), the breakwater, for each of the 8 irregular sea states. Figs. 3.16 - 3.21 show wave spectra for wave staff 18 (1m behind) and 11 (1m in front) with and without model, compared to theoretical input values, together with resulting amplitude transmission/amplification functions. Wave height statistics, (compared to the Rayleigh distribution) and wave group spectra (compared to theoretical "Pinkster" curve /5, 6/), with and without model, are finally presented in Figs. 3.22 - 3.33. Wave group spectra are calculated as the spectra of the square Hilbert envelope of the wave elevation /5/.

3.1.3 Mooring line forces

Results are shown for force sensor no. 10, 11 and 12 (channel 33, 34 and 35), see fig. 2.10. These sensors measure tension forces in the seaside mooring lines, i.e. in front of the breakwater. By simple reasoning one realizes that these forces are likely to be larger than the leeside forces due to expected non-linear offset in the sway motion (y-position). This assumption is verified by the experiments, except from the case with very long regular waves, (6.3s period) where the forces in the opposite lines were slightly larger (see the Data Reports).

The first 3 plots (figs. 3.34 - 3.36) show the maximum force and RMS value (square root of (square mean + variance)) for each of the 3 sensors, as a function of the input (calibrated) significant wave height $H_{m0,o}$. The next 3 plots (figs. 3.37 - 3.39) show the maximum force deviation from the static force value, and the RMS deviation from the static value normalized by $H_{m0,o}$, as a function of the input peak wave period T_p . Plots of force spectra, linear transfer functions (RAO) and coherence/phase functions, for each of the 8 irregular sea states, and each of the 3 sensors, follow next (figs. 3.40 - 3.48). Wave staff 11 in front of the model is used as a reference (see section 2.5). Figs. 3.49 - 3.51 present statistics of force maxima in each test run (actually: force minima, since the force sensor gave signals with reversed sign), compared to Rayleigh curves. Finally, Figs. 3.52 - 3.54 illustrate the coupling between the 3 force sensors, and between forces and selected motions (sway-heave-roll) by coherence/phase analysis.

Note that "mean amplitude" in the statistics diagrams means "mean amplitude of the deviation from the mean force". Thus the "mean force" is the starting left point of the Rayleigh curve.

The absolute maximum force measured with this model was 102 kN full scale (test run no. 203, force sensor 9). It occurred simultaneously with 75 kN in force sensor 10. These two sensors were connected in a y-connection (see chapter 2). thus the maximum force in their common line (from the y-connection to the bottom) was more than 150 kN.

3.1.4 Motions analysis

The following presentation of results for breakwater motions is quite similar to the previous presentation of force results.

First the 3 plots in figs. 3.64 - 3.66 show the maximum and RMS values for sway (y-position), heave (z-position) and roll motion, as a function of the input significant wave height $H_{mo,0}$. Next, 3 plots showing the maximum and RMS values, normalized by $H_{mo,0}$, as a function of the input peak wave period T_p , are presented (figs. 3.67 - 3.69). See Fig. 2.18 for the definition of coordinates. Note that the presented results for heave amplitudes actually refer to minima, i.e. amplitudes in the upwards direction. Then follow 9 pages (Figs. 3.70 - 3.78) with plots of spectra, transfer functions and coherence/phase functions for sway, heave and roll; with wave staff 11 as a reference. Statistics of maxima (or in some cases: minima - see the coordinate system definition in fig. 2.18) of all 6 motions of pontoon 1 (surge-sway-heave-roll-pitch-yaw) are then presented and compared to Rayleigh curves (Figs. 3.79 - 3.84). Coupling sway-heave, sway-roll and heave-roll is finally illustrated by coherence/phase plots in Figs. 3.85 - 3.97.

3.2.2 Wave reduction/amplification around stiff breakwater model

The first plot (Fig. 3.91) shows the normalized maximum wave height $H_{max,n} = H_{max}/H_{max,o}$ and normalized significant wave height $H_{mo,n} = H_{mo}/H_{mo,o}$ behind the model (wave staff 18, see Fig. 2.19) as a function of the input peak wave period T_p . $H_{max,o}$ and $H_{mo,o}$ are wave height values obtained from calibration without model. Next, Figs. 3.92 - 3.99 show plots of the distribution of $H_{max,n}$ and $H_{mo,n}$ 2m in front of (wave staffs 1 - 9), and 1m behind (wave staffs 13-21), the breakwater, for each of the 8 irregular sea states. Figs. 3.100 - 3.105 show wave spectra for wave staff 18 (1m behind) and 11 (1m in front) with and without model compared to theoretical input values, together with resulting amplitude transmission/amplification functions. Wave height statistics (compared to the Rayleigh distribution) and wave group spectra (compared to theoretical "Pinkster" curve /5, 6/), with and without model, are finally presented in Figs. 3.106 - 3.117. Wave group spectra are calculated as the spectra of the square Hilbert envelope of the wave elevation /5/.

3.2.3 Mooring line forces

Results are shown for force sensor no. 10, 11 and 12 (channel 33, 34 and 35), see Fig. 2.10. These sensors measure tension forces in mooring lines going from the pontoons and in front of the breakwater. By simple reasoning one realizes that these forces (plus sensor no. 7, 8, 9) are likely to be larger than the forces in the lines going in the direction behind the breakwater (sensors 1-6), due to expected non-linear offset in the sway motion (y-position). This assumption is verified by the experiments, except from the case with very long regular waves (6.3s period), where the forces in the opposite lines were slightly larger (see the Data Reports).

The first 3 plots (Figs. 3.118 - 3.120) show the maximum force and RMS value (square root of (square mean + variance)) for each of the 3 sensors, as a function of the input (calibrated) significant wave height $H_{mo,0}$. The next 3 plots (Figs. 3.121 - 3.123) show the maximum force deviation from the static force value, and the RMS deviation, normalized by $H_{mo,0}$, as a function of the input peak wave period T_p . Plots of force spectra, linear transfer functions and coherence/phase functions, for each of the 3 sensors, follow next (Figs. 3.124 - 3.132). Wave staff 11 in front of the model is used as a reference (see section 2.5). Figs. 3.133 - 3.135 present statistics of force maxima in each test run (actually: force minima, since the force sensor gave signals with reversed sign), compared to Rayleigh curves. Finally, Figs. 3.136 - 3.147 illustrate the coupling between the 3 force sensors, and between forces and selected motions (sway-heave-roll) by coherence/phase analysis.

Note that "mean amplitude" in the statistics diagrams means "mean amplitude of the deviation from the mean force". Thus the "mean force" is the starting left point of the Rayleigh curve.

The absolute maximum force measured with this model was 98 kN full scale (test run no. 353, force sensor no. 7).

3.2.4 Motions analysis

The following presentation of results for breakwater motions is quite similar to the previous presentation of force results.

First the 3 plots in Figs. 3.148 - 3.150 show the maximum and RMS values for sway (y-position), heave (z-position) and roll motion, as a function of the input significant wave height $H_{m0,0}$. Next, 3 plots showing the maximum and the RMS values, normalized by $H_{m0,0}$, as a function of the input peak wave period T_p , are presented (Figs. 3.151 - 3.153). See Fig. 2.18 for definition of the coordinates. Note that the presented results for heave amplitudes actually refer to minima, i.e. amplitudes in the upwards direction. Then follow 9 pages (Figs. 3.154 - 3.162) with plots of spectra, transfer functions and coherence/phase functions for sway, heave and roll, with wave staff 11 as a reference. Statistics of maxima (or in some cases: minima - see the coordinate system definition in Fig. 2.18) of all 6 breakwater motions (surge-sway-heave-roll-pitch-yaw) are then presented and compared to Rayleigh curves (Figs. 3.163 - 3.168). Coupling sway-heave, sway-roll and heave-roll is finally illustrated by coherence/phase plots in Figs. 3.169 - 3.171.

3.3 Comparisons of model test results and field measurements: Waves and forces.

Some preliminary results of the field tests are given in /1/. The results have been further analysed by CERC, but this has not yet been reported. It should be noted that only a limited amount of the field data in /1/ can be directly compared to the model tests. This includes the rigid connection (stiff) breakwater with clump-weights installed.

Fig. 3.172, which is based on Fig. 3.91 presented earlier in this report, shows the field test results on the wave transmission coefficient C_t as a function of the peak wave period T_p (taken from table G-2 in /1/), plotted together with the model test results for the stiff breakwater. The model test values for C_t are those calculated from the significant values of the transmitted and the undisturbed wave heights. We also assume the field data C_t to be based on significant values, but instead of undisturbed wave heights the incident wave heights are used. This means that the field data values for C_t include "noise" from partially reflected waves due to the breakwater itself.

The results show that in the wave period range covered by both the model tests and the field tests, i.e. $T_p \approx 2.5s - 3.5s$, the transmission is approximately 0.4 ± 0.1 . While the model scale results show an increasing transmission with increasing wave period, this is not clearly observed in the full scale data. Field data with more long-periodic wave spectra would have made this comparison more complete.

The scatter observed between model and full scale wave transmission results are probably partly due to the fact that wave reflections have disturbed the prototype incident wave heights. Other sources of uncertainty may be the mean direction of the incoming waves (in the model test it was always 90 deg.), and reflection/diffraction from a neighbouring tire breakwater. One should also note that the wave spectrum presented in fig. G-5 /1/ shows a significant contribution in the low-frequency region. A certain amount of such low-frequency wave energy is also observed in the model test results (see fig. 3.104), but the relative contribution there is much smaller.

Fig. 3.173, which is based on Fig. 3.120 presented earlier in this report, shows the maximum peak force in one of the corner (outer) mooring lines, plotted as a function of the significant incident wave height. Only sea states with significant wave height larger than 0.5 m are included here. The "incident" wave for the model test results is undisturbed, while for the field data it is disturbed by the breakwater. The presented force data include the static pretensioning force. For the model tests this was 18 kN, while for the prototype it was 22,5 kN. We see that in spite of this difference, the total peak forces compare reasonably well.

Fig. 3.172. Wave transmission vs. peak period of incident wave - model test data compared to prototype data.

Fig. 3.173. Peak mooring line force vs. incident significant wave height - model test data compared to prototype data.

4. COMPUTER SIMULATIONS WITH A SIMPLE NUMERICAL MODEL

4.1 Brief introduction

The linear wave frequency motions of the 2 floating breakwaters (46 m and 138 m long) have been calculated by means of the two dimensional stripe-theory program WAMOF, ref /7/.

Then, the quasistatic line tensions are calculated by means of the mooring analysis program MIMOSA, ref /8/.

Note, however, that the quasistatic line tension is not representative for the total line tension in these tests. Line dynamics due to inertia forces on the clump weights, give the main contribution to the total loads in the anchor lines.

In a more comprehensive theoretical analysis, both the wave frequency and the second order response can be simulated in the time domain. Then, the dynamic line tensions, which include non-linear drag forces and inertia forces on the clump weights, can be simulated from the forced upper end motions.

4.2 System description

4.2.1 Floating breakwaters

Two floating breakwaters have been analysed:

- Floater no 1 consists of two sections, each 23 m long, with rigid connections.
- Floater no 2 consists of six sections, each 23 m long, with rigid connections.

The cross section of the breakwater is plotted in fig. 4.1. The breadth is 4.85 m and the draught is assumed to be 1.1 m.

The main data specified in the computer program WAMOF, are as follows:

	Floater no 1	Floater no 2
Length	46 m	138 m
Total mass (x)	$2.52 \cdot 10^5$ kg	$7.55 \cdot 10^5$ kg
Radius of gyration, x (x)	1.7 m	1.7 m
----- " ----- , y	13.4 m	39.8 m
----- " ----- , z	13.4 m	39.8 m

(x) Incl. clump weight contribution.

Fig. 4.1 Cross section.

4.2.2 Mooring system data

Each mooring line is divided into three segments as follows:

	Type	Diam.	Weight	Length
Upper segment:	Chain	32 mm	190 N/m	6.1 m
Mean segment:	Wire	35 mm	38.1 N/m	92.7 m
Lower segment:	Chain	32 mm	190 N/m	4.6 m

The weights specified are weights in air. The ratio of submerged weight to the weight in air, is assumed to be 0.87 and 0.81, for chain and wire, respectively.

In addition, a clump weight of 8.9 kN, (submerged) is located approx. 11.9 m from the upper end of the mooring lines.

The average modulus of elasticity is assumed to be $7.0 \cdot 10^{10}$ N/m² for the whole mooring line.

The pretension in each mooring line, with zero external force, is assumed to be 18 kN.

4.2.3 Mooring system

Two different systems are considered:

The first system, floater no 1, has 10 mooring lines, equally distributed along the floater sides. The distance between two neighbour lines is 11.5 m.

The second system, floater no 2, has 26 mooring lines, 13 to each side, and a distance of 11.5 m between each line.

In order to improve the availability of the breakwaters, the mooring lines are crossing each other below the floaters. See Fig 4.2.

Fig. 4.2 The mooring system (system no. 1).

4.2.4 Wave conditions

The following wave conditions have been analysed:

Run no	Floater no	Hs (m)	Tp (s)	γ	Spreading function	
301	1	0.75	3.2	3.3	$\cos^8$	
302	1	1.0	4.3	3.3	$\cos^8$

512	2	0.75	3.2	3.3	long crest	
513	2	1.0	6.3		" "	regular waves
515	2	0.75	3.2		" "	" "

Table 4.1 Wave conditions

All irregular wave conditions are modelled by JONSWAP type spectra.

4.3 Results

4.3.1 Wave frequency response

A linear frequency domain response analysis is performed. This means that all statistics are described by the response spectrum, only.

The response spectrum, $S_r(\omega) = H(\omega)^2 \cdot S_w(\omega)$, where

- ω is the wave frequency, (rad/s).
- $H(\omega)$ is the linear motion transfer function
- $S_w(\omega)$ is the actual wave spectrum

$H(\omega)$ is calculated by means of the two dimensional stripe theory program WAMOF, ref /7/. Geometry and mass data are specified as input to WAMOF. The average mooring stiffness, obtained from fig. 4.3, is also given as input.

The calculated motion transfer functions in six degrees of freedom are plotted in section 4.3.3, both for floater no 1 and no 2. The transfer functions are referred to the centre of gravity.

The following resonance periods are calculated:

	Floater no 1	Floater no 2
Surge	-	-
Sway	23.3 s	24.9 s
Heave	3.8 s	3.8 s
Roll	2.8 s	2.8 s
Pitch	3.8 s	3.8 s
Yaw	17.0 s	22.6 s

Results

Results from the wave frequency motion analysis are given in table 4.1 and 4.2.

The following statistical parameters are calculated from the response spectra, $S(\omega)$:

Est. max : Estimated maximum amplitude in 2 hours (full scale)

Sign. : Significant value

Tz : Zero crossing period

B. width : Band width parameter

The following notations are used for the response components in the centre of gravity:

X11 - Translation in x-direction (surge)

X22 - Translation in y-direction (sway)

X33 - Translation in z-direction (heave)

X44 - Rotation about x-axis (roll)

X55 - Rotation about y-axis (pitch)

X66 - Rotation about z-axis (yaw)

Terminal point no 1, see fig. 4.2, is considered both for floater no 1 and no 2.

Table 4.3. Wave frequency motion in c.o.g. and terminal point.
Case 2

The low frequency response, (LF) due to the slowly varying wave drift forces are not calculated in this scope of work.

In order to account for these effects, in calculation of the mooring line tension, the LF-motions should be obtained from the model tests. However, this has not been performed within this work.

In a more comprehensive analysis, both the low frequency and the wave frequency response components, and the corresponding instantaneous line tension can be simulated by means of the time domain simulation program MOSSI, ref /9/.

4.3.2 Mooring analysis

The quasistatic mooring analysis is performed by means of the computer program MIMOSA, ref /8/.

Input to MIMOSA is line data, (see chapter 4.2.2), and static environmental forces or displacements.

The total restoring force, and the tension in the heaviest loaded anchor line are plotted in fig. 4.3 versus the horizontal displacement in the terminal point.

Then the line profile is plotted in fig. 4.4, with a top tension of 18 kN.

RESTORING FORCE AND MAXIMUM LINE TENSION -----

Fig. 4.3 Force displacement characteristic.

The maximum quasistatic line tension in each wave condition is estimated by combining the estimated maximum wave frequency horizontal displacement in the terminal point (from Table 4.2), by the dotted curve in Fig. 4.3. The results are given in Table 4.4.

It should be stressed that the calculated line tensions do neither include dynamic effects in the mooring lines and the clump weights, nor the low frequency motions of the breakwater.

5. DISCUSSION AND CONCLUSIONS

The results show clearly that the wave periods chosen for the experiment cover exactly the critical range of the tested breakwater. The shortest waves (peak period irregular waves 2.4s fullscale) are very efficiently reduced by the breakwater, with relatively small mooring line forces (max ≈ 30 kN in a single line) and motions. The largest waves (peak period irregular waves 5.0s full scale, regular wave period 6.3s) are more or less unaffected by the breakwater and may cause critically large forces (max ≈ 100 -200 kN in a single line) and motions. Thus the experiment serves well as a test of the performance of such a breakwater, in addition to being used as a verification of prototype results.

As indicated through this observation, it is also clear that the wave period is one of the most critical parameters in a floating breakwater problem, for a given breakwater geometry. This is reasonable, since the mechanisms governing the hydrodynamical problem depends particularly on the breakwater size (width) relative to the wavelength, and on the roll motion resonance period.

Other important parameters of the problem are the significant wave height, the shortcrestedness of the waves, and the type of connection (coupling) between the pontoons (in the present case: fendered or stiff). In addition, the breakwater is certainly sensitive to the mean wave direction θ_m , although that dependence has not been tested in the model experiment where θ_m is 90° to the breakwater long axis in all the test runs.

The wave reduction analysis shows that the breakwater is reasonably efficient for sea states with peak periods 4s or shorter (full scale). For short-crested waves, the range of the breakwater extends to somewhat longer waves (more reflection for non-perpendicular wave contributions). The stiff model is slightly more efficient than the fendered one. One should also note that a significant part of the transmitted wave energy lies in the frequency range higher than the new wave frequencies (non-linear energy transport - water running across the breakwater.)

The analysis of the waves in front of the model shows that the breakwater works as a reasonably good reflector. This causes local and temporary

standing wave situations in front, with rough sea and fairly high wave crests due to Stoke's non-linearities. Other mechanisms contributing to the wave reduction are mainly wave dissipation and wave absorption (excitation of roll motion near resonance).

Wave height statistics and wave grouping are seen to follow the theoretical predictions fairly well, regardless of the model present or not. Long-crested waves are seen, however, to be slightly more grouped than shortcrested.

The mooring line force analysis shows that in shortcrested waves, the maximum force of a test run is generally larger for the fendered model than for the stiff model. This is mainly due to the y-shaped coupling of central mooring lines, connecting pontoon 1 and 2 (see section 2.2). The chains coupled together in the y-couplings restore the relative motions between the 2 pontoons. Restoring forces of that kind are often very abrupt and non-linear. Thus the y-coupling is perhaps a weak point of the fendered breakwater. However, for the sea states with longest waves ($\approx 5s$), the max. forces are more governed by the common motion of the pontoons, as in the case with the stiff breakwater.

The force spectra show significant non-linear components, both in the low-frequency and the high-frequency regions. The higher harmonics are partly due to nonlinear characteristics of the mooring lines at large displacement values (for moderate displacements the characteristics of the lines are expected to be close to linear - see chapter 4). The dynamics of the clump-weights probably also contribute in the higher-frequency range, as well as in the wave frequency region. For the fendered model, additional significant high-frequency non-linearities occur in the restoring force of the y-coupled chains, as a result of relative pontoon motions (see above). The low-frequency non-linearities arise from slow-drift motions of the breakwater. These motions turned out to be fairly large (see the discussion of motions analysis below).

Short-crestedness of the waves affect the fendered and stiff model differently. Results from tests in sea states having similar scalar spectra (with peak period around roll resonance) but different directional spectra (long-crested, $\cos^8\theta$ and $\cos^2\theta$) show that in the fendered model

case, the force maximum is generally larger in short-crested than in long-crested waves. This is due to more irregular pontoon motions, in particular the larger relative motion between the pontoons. With the stiff model, however, there is a moderate decrease in force maxima due to short-crestedness.

In the linear (1. order) frequency range, the force transfer functions shows a significant peak around 3s (full scale), which is close to the roll resonance of a free floating pontoon.

The results for the force statistics confirm the non-linearities observed from the spectral plots. Predictions based on Rayleigh curves generally underestimate the extreme values.

From the analysis, and in particular by means of the coherence-phase analysis, it may be concluded that the mooring forces are to a large extent governed by the following effects:

- low-frequency sway motion
- roll motion
- pitch motion
- Yaw motion (stiff model)
- inertia forces and dynamical behaviour of clump weights
- relative motion between pontoons

The influence from the clump-weights on the forces is perhaps most easily seen in the coherence/phase-plots between force 11 and sway. Here the relative phase shifts from 180 deg. for low-frequency oscillations, to 0 deg. for wave-frequency oscillations. Thus for sway oscillations in the 2 - 5s range, the maximum forces occur when the model is closest to the wavemaker. This must be due to the clump-weights (inertia forces).

The importance of effects other than those obtained from regular waves and linear theory is very well demonstrated through the tests in long, regular waves (see the Data Reports), $H = 1.0\text{m}$ $T = 6.3\text{s}$. The maximum forces measured there were 22-24 kN full scale, (Static force = 18 kN), while tests in irregular waves with $T_p = 4 - 5\text{s}$, $H_s = 1 - 1.5\text{m}$, gave force maxima larger than 100 kN.

Spectral analysis of motions show that horizontal components (surge, sway and to a certain extent, yaw) are more or less dominated by non-linear slowdrift oscillations, with the linear components observed as smaller, "distorting" effects. This slow-drift motion arises from slow drift excitation forces combined with the damping properties of the moored system. The statistical analysis strongly confirm the picture of non-linear motions. It is observed that it is clearly unsatisfactory to fit the statistics with Rayleigh distributions, which may predict extreme values to be less than half of the measured values. The shape of the statistical distribution observed for the sway motion amplitude is, with a few exceptions, fairly close to a negative exponential function (χ^2 -distribution with 2 degrees of freedom), for which the standard deviation is equal to the mean deviation from the mean value.

In the spectral and statistical plots of vertical motional components (heave, roll and pitch) a more linear behaviour is observed. Transfer functions show that for the short-crested sea states, the roll motion has a resonance around 3.0s, which is in agreement with the resonance observed for a free floating pontoon (chapter 2). For the long-crested sea state, there is no obvious resonance peak for the roll motion, although the transfer function agrees reasonably with the short-crested cases. We also note that the statistics of the roll motion in some cases deviate somewhat from linear (Rayleigh) predictions: extreme values may be significantly lower than obtained from linear theory. It may seem that the roll motion is slightly locked to a certain amplitude range.

The results show that short-crestedness reduce the sway, heave and roll motions, and increase the surge, pitch and, to a certain degree, the yaw motions. (Theoretically, both surge, pitch and yaw should be zero in long-crested sea perpendicular to the breakwater. The experiment shows, however, some motion for these components).

The coherence/phase plots between motional components show a significant coupling between sway, heave and roll, except between sway and roll for short and very short-crested waves. In the linear (wave-frequency) region, the sway-heave dependence gradually shifts from the surface-slope-determined 90° phase delay for long waves, to a 180° delay for

shorter waves (i.e. wave periods shorter than the roll resonance). Sway and roll are $\approx 150^\circ$ out of phase for long waves, while the delay reduces to $\approx 60^\circ$ - 90° for short waves. Heave and roll seem to be more or less locked to each other, with a relative phase $\approx -135^\circ$ for all wave periods, i.e. max. roll occurs always shortly before the breakwater is on a wave top. The wave short-crestedness does not seem to have any significant influence on these motional couplings, except from a moderately increasing decoupling with increasing short-crestedness, particularly for sway/roll. Phases are more or less unaffected.

Note that for small horizontal motions, especially sway and yaw, there is present a noticeable white noise arising from the optical measuring system. Motions less than 1 cm (model scale) are difficult to resolve with the actual model location in the Ocean Basin. Change of location, e.g., could increase resolution but the location was chosen to give optimal conditions for generation of short-crested waves. This noise was the reason for filtering at 3 Hz (model scale), but still the presented sway and yaw spectra and transfer functions for the smallest waves should be interpreted with care. Coherence/phase information between motional components should be ignored in frequency ranges where there is very little motional energy.

The model test experiments also included hydrodynamic pressure measurements, although they have not been presented in this Main Report. The data are, however, presented in the Data Reports. /

This report also includes a minor task with numerical simulations of the stiff breakwater motions. Significant simplifications are made in the numerical model, such as the ignorance of the clumpweight dynamics and of the slow-drift motions. The resulting transfer functions agree moderately well with the measured ones for sway, heave and roll, when one takes into account the simplifications made. Absolute values in sway and heave transfer functions show moderate ($\sim 50\%$) discrepancies. The numerically calculated roll resonance is 2.8s while the measured one is around 3.3s. The numerical peak is much sharper than the measured. For the sway motion, a peak in the numerically computed transfer function is observed at 20 - 25 s, which agrees with the measured non-linear slow-drift resonance.

Accurate computer simulations with the actual breakwater should include the above mentioned ignored effects, since they are considered to be quite essential to the problem.

Preliminary comparisons between the model tests and field data show fairly good agreement for wave transmission and peak mooring line forces, although some scatter is observed. However, only a limited part of the filed data are included in this comparison, because most of the filed data were obtained without clump-weights installed, while the whole series of model tests was carried out with clump-weights.
