By

David M. Eagle
William H. Patten
Robert J. Mulholland

ACKNOWLEDGMENTS

The author would like to thank his advisor, Dr. Davis M. Egle, for his guidance, support, and encouragement while at the University of Oklahoma. Also, the author would like to express his appreciation to his committee members, Dr. Robert J. Mulholland and William N. Patten for their expert advice.

The United States Air Force and the Air Force Institute of Technology is acknowledged for providing the opportunity and financial support for the author to study at the University of Oklahoma.

I dedicate this thesis to my wife Karen. It was her encouragement, strength, and love that has made this effort worthwhile.

ω_r	resonant frequency

DEVELOPMENT OF COMPUTER SOFTWARE
FOR THE ANALYSIS AND DESIGN OF
MODERN CONTROL SYSTEMS

CHAPTER 1

PRELIMINARIES

1.1 Introduction to the Control Systems Software Package

The classical techniques of graphical analysis and design of modern control systems involve the generation of sketches by hand. In all but the most simple systems this can be a tedious and difficult process. The purpose of this research was to develop computer software that automates this task. The software programs developed include the Root Locus, Bode Plot and all necessary support routines needed to fully automate the development of these graphs. This software is called collectively the *Control Systems Software Package (CSSP)*.

1.2 Computer System Requirements for CSSP

The CSSP programs are written for use on IBM and compatible personal computers with a graphics card and monitor installed. On machines with an Enhanced Graphics Adaptor (EGA), or higher resolution monitors, the graphs are produced in color. Computers with a Color Graphics Adaptor

(CGA) are limited to black and white plots due to the low resolution of the monitor when plotting in color.

A printer capable of supporting a graphics screen dump is required if a printout is necessary, but the printer isn't specifically needed to operate the program. A numeric coprocessor (8087, 80287 or 80387) is not required, but is highly recommended. This coprocessor increases computational speed considerably. All hardware specific settings are totally automatic and are invisible to the user.

1.3 The C Computer Language

All of CSSP's source code is written in the C language and is included for future study and possible refinement. Since the C language is very portable and is not tied to any particular hardware or operating system, very little effort would be required to rewrite this software to operate on other types computer systems. This is true for all but the video specific functions, such as the windowing routines.

The CSSP source code, provided in the Appendix, was written for and compiled with the Microsoft C Compiler version 5.0. The windowing software used to develop the screens and input windows was "The Window BOSS" Revision : 08.15.88 written by Phil Mongelluzzo of Star Guidance Consulting, Inc.. All the necessary source code and libraries needed to reproduce CSSP are provided on a 5 1/4 inch diskette, which is available at the Aerospace and Mechanical Engineering office, University of Oklahoma.

This source code is provided for educational purposes only, and is not to be used in any type of commercial application without the prior

written permission of the author. Copyright (c) 1988-1989 by Carl F. Adams, all rights reserved.

1.4 Thesis Overview

The remainder of the thesis is devoted to the discussion of the classical techniques of analysis and design using the Root Locus and Bode plots. Along with these techniques will be a discussion of the equivalent computer-aided techniques used in the CSSP program. The following is a short description of the remaining chapters.

Chapter 2: The Root Locus Method. This chapter discusses the Root Locus method of describing the transient response of a control system by determining the location of the roots of the characteristic equation as the open-loop gain is varied from zero to infinity. This chapter also introduces a set of ten rules used to help in the plotting of root locus by hand.

Chapter 3: Computer-Aided Root Locus Plotting. This chapter introduces the two most common methods of computer-aided root locus plotting. They are the numerical polynomial-factoring and angle testing methods. It talks about why the polynomial-factoring method is the simplest algorithm to program, but the price of simplicity is a longer computer run time. It also explains why the angle testing method is the harder of the two methods to program, but is usually the more efficient method for computer run time.

Chapter 4: Root Locus Program. This chapter discusses the root locus program used in the CSSP. It uses the angle testing method for plotting.

Chapter 5: Bode Plots. This chapter serves as an introduction to Bode Plots. This is a graphical technique that plots a control system's gain amplitude and phase angle response curves against the input frequency.

Chapter 6: Computer-Aided Bode Plots. This chapter describes the Bode plot algorithm used in the CSSP.

Chapter 7: Summary. This is the thesis summary.

CHAPTER 2

THE ROOT LOCUS METHOD

2.1 Introduction to the Root Locus Method

The root locus method is a powerful graphical tool used in the analysis and design of linear control systems. This method determines the location of the roots of the characteristic equation as the open-loop gain is varied from zero to infinity. By knowing the locations of these roots it is possible to not only know if a system is stable but also the degree of its stability. This method is another way of describing the transient response of the system. If a system is unstable or has undesirable response characteristics the root locus method provides possible qualitative ways to improve it.

2.2 The Root Locus Method

Consider the simple single-input single-output, closed-loop system shown in Figure 2.1.

Figure 2-1 Simple closed-loop control system

The transfer function of this system is

$$T(s) = \frac{C(s)}{R(s)} = \frac{KG(s)}{1 + KG(s)H(s)} \quad (2.1)$$

and the characteristic equation of this system is obtained by setting the denominator equal to zero. Thus the general form of the characteristic equation is given by

$$1 + KG(s)H(s) = 0 \quad \text{or} \quad KG(s)H(s) = -1 \quad (2.2)$$

or, in polar form,

$$KG(s)H(s) = 1 \angle 180^\circ \quad (2.3)$$

where K is the gain of the system. The characteristic equation contains all the information about a system's frequency response, time response, and stability. In other words, any value of s that causes the open-loop transfer function G(s)H(s) to have a gain of unity and a phase shift of 180° , and by definition a point on the root locus, will be a pole of the closed-loop system. This is a very useful fact in that evaluation of the usually simpler open-loop transfer function tells how the poles of the closed-loop system behave. Therefore, by evaluating G(s)H(s) in the complex s domain and finding the values of s that make equation (2.3) true will determine how the closed-loop poles are influenced by changes in any of the system parameters.

To determine if a given value of s is a point on the root locus for some value of K between zero and $+\infty$, it is only necessary to determine whether or not the angle of $KZ(s)/P(s) = KG(s)H(s)$ is an odd multiple of 180° and the magnitude must be equal to unity. This is known as the angle criterion and the magnitude criterion respectively and are shown in

equations (2.4) and (2.5a).

$$\begin{aligned}\sum \phi_1 &= \sum (\text{angles of the zeros}) - \sum (\text{angles of the poles}) \\ &= (2k+1)180^\circ, \quad k=1,2,\dots\end{aligned}\quad (2.4)$$

$$\frac{K \frac{s-z_1}{s-p_1} \frac{s-z_2}{s-p_2} \dots}{s-p_1 \dots s-p_2 \dots} = 1 \quad (2.5a)$$

which gives

$$K = \frac{\text{product of the pole distances}}{\text{product of the zero distances}} = \frac{P(s)}{Z(s)} \quad (2.5b)$$

2.3 Rules for Plotting a Root Locus

To help in the plotting of root loci a set of conventional rules have been developed. These rules have been thoroughly discussed in [1]. Here, a brief description of these rules is presented and applied to two systems with the following open-loop functions,

example 1:
$$\frac{K}{s(s+5)(s+7)}$$

example 2:
$$\frac{K(s+6)}{s(s+4)(s^2+4s+8)}$$

Root locus plots of the above open-loop functions are shown in Figures 2.2 and 2.3.

Figure 2.2 Root locus plot, example 1

Figure 2.3 Root locus plot, example 2

RULE 1: *There is a single-valued branch of the root locus for each of the characteristic equation roots and the total number of branches is equal to the number of open-loop poles.*

Example 1: There are no zeros and three poles, therefore; there is a total of three locus branches.

Example 2: There is one zero and four poles, therefore; there is a total of four locus branches.

RULE 2: *Each branch of the root locus starts at a pole, where $K=0$, and ends at a zero, where $K = +\infty$. If the number of poles exceeds the number of zeros, there will be zeros at infinity equal in number to the excess. Excess zeros similarly mean poles at infinity.*

Example 1: There are three more poles than zeros, which means all three of the branches go to infinity.

Example 2: There are three more poles than zeros, which means three of the four branches go to infinity.

RULE 3: *Along the real axis the locus includes all points to the left of an odd number of real poles and zeros: no distinction is made between poles and zeros, and complex poles and zeros are neglected.*

Example 1: There will be points on the real axis from $0 > \sigma > -5$ and from $-7 > \sigma > -\infty$.

Example 2: There will be points on the real axis from $0 > \sigma > -4$ and from $-6 > \sigma > -\infty$.

RULE 4: *If the number of poles n_p exceeds the number of zeros n_z , then as K approaches infinity, $(n_p - n_z)$ branches will become asymptotic to straight lines intersecting the real axis at angles given by*

$$\theta_k = \frac{(2k + 1)180^\circ}{(n_p - n_z)}, \quad k = 0, 1, 2, \dots \quad (2.6)$$

If n_z exceeds n_p , then as K approaches zero, $(n_z - n_p)$ branches behave as above.

Example 1:
$$\theta_k = \frac{(2k + 1)180^\circ}{(3 - 0)} = (2k + 1)60^\circ, \quad k = 0, 1, 2$$

Example 2:
$$\theta_k = \frac{(2k + 1)180^\circ}{(4 - 1)} = (2k + 1)60^\circ, \quad k = 0, 1, 2$$

In both examples there will be three asymptotes, one for each infinite zero, intersecting the real axis at angles of 60° , 180° and 300° .

RULE 5: The asymptotes of Rule 4 will intersect the real axis at a point, called the center of gravity, given by

$$cg = \frac{\sum \text{poles} - \sum \text{zeros}}{(n_p - n_z)} \quad (2.8)$$

Example 1:
$$cg = \frac{-0 - 5 - 7}{(3 - 0)} = -4$$

Example 2:
$$cg = \frac{-0 - 4 - 2 + 2j - 2 - 2j + 6}{(4 - 1)} = \frac{-2}{3}$$

RULE 6a: A breakaway or arrival point s_b on a real axis can be found from the equality

(2.9)

$$\frac{-1}{s_b + p_1} + \frac{1}{s_b + z_1} + \dots \pm \frac{2(s_b - \alpha)}{(s_b - \alpha)^2 + \omega^2}$$

$$= \frac{-1}{s_b + p_r} + \frac{1}{s_b + z_r} + \dots \pm \frac{2(s_b - \alpha)}{(s_b - \alpha)^2 + \omega^2}$$

where the terms on the left side of the equation come from the poles $-p_i$ and zeros $-z_i$ to the left of the breakaway point; the terms on the right-hand side come from the poles $-p_r$ and zeros $-z_r$ to the right. Positive signs are associated with the zeros and negative signs with the poles.

RULE 6b: A breakaway point occurs when K is at a relative maximum; an arrival point occurs when K is at a relative minimum.

The breakaway point can be found by solving the characteristic equation (2.2) for K and then taking the derivative with respect to s and setting it equal to zero. Then solve for the resulting roots.

Example 1: The roots of (2.2) are $s=-6.1$, -1.9 . Since the point $s=-6.1$ is not on the root locus, see Rule 3, the breakaway point must occur at $s=-1.9$.

Example 2: The two non-complex roots of (2.2) are -3.1 , and -7.3 . The breakaway point is approximately -3.1 and the breakin point approximately -7.3 .

RULE 7: Branches of the root locus are symmetrical with respect to the real axis since all complex roots appear in conjugate pairs.

This implies all root locus points that lie above the real axis will have matching mirrored points below the axis.

RULE 8: Two branches of a root locus breakaway from or arrive at the real axis at angles of $\pm 90^\circ$.

For three or more branches use Rule 9 below to calculate the departure or arrival angles.

Example 1: The breakaway point at $s=-1.9$ breaks from the real axis at $\pm 90^\circ$.

Example 2: The breakaway point at $s=-3.1$ and the breakin point at $s=-7.3$ break from the real axis at $\pm 90^\circ$.

RULE 9: *The angle criterion can be used to find the angle of departure from a complex pole and the angle of arrival to a complex zero by selecting a trial point so close to the complex pole or zero that the angles from the other poles and zeros are unaffected.*

Example 1: There are no complex poles or zeros for this example; therefore, this rule is not applicable.

Example 2: Figure 2-4 and equation 2-10 illustrate how the departure angle of -63.4° , for the pole at the point $(-2+2j)$, is derived.

$$-\alpha_4 - \alpha_1 - \alpha_2 - \alpha_3 + \alpha_4 = 180^\circ \quad (2.10)$$

RULE 10: *If $n_p - n_z \geq 2$, then the sum of the roots of the characteristic equation is constant and equal to the sum of the poles.*

This rule is limited in use, but might prove to be useful under certain circumstances. It isn't needed for examples 1 or 2. Refer to [1] for an example using this rule.

Figure 2.3: Departure Angle

CHAPTER 3

COMPUTER-AIDED ROOT LOCUS PLOTTING

3.1 Introduction to Computer-Aided Root Locus Plotting

Using the ten rules explained in Chapter 2 it is possible to construct root locus plots with a reasonable amount of accuracy; however, since this method involves hand construction and the use of a calculator, it can become confusing and tedious. To improve accuracy and to make better use of a system designer's time, a computer-aided approach to root locus plotting was developed. This chapter introduces the development of the numerical polynomial-factoring and angle testing methods used in computer-aided root locus plotting. This chapter also explains why angle testing, which is used in the root locus program discussed in chapter 4, is usually the optimum method to use for all but the simplest systems.

3.2 Numerical Polynomial Factoring

One method of computer-aided root locus plotting is to repeatedly factor the equation

$$1 + G(s)H(s) = 0 \quad (3.1)$$

as K is varied in step increments from zero to infinity. Figure 3.1 shows a simplified programming flow chart for a program using the numerical polynomial-factoring method.

Figure 3-1 Polynomial-Factoring Flow Chart

A root of equation (3.1) is any value of $s=x+jy$ that makes

$$D(s) = 1+KG(s)H(s) = 0 \quad (3.2)$$

true for any fixed value of K . This will only be true if and only if both the real and imaginary parts of $D(s)$ are equal to zero.

That is

$$\begin{cases} \text{Re}[D(s=x+jy)] = 0 \\ \text{Im}[D(s=x+jy)] = 0 \end{cases} \quad (3.3)$$

or alternatively if

$$|D(x+jy)| = 0 \quad (3.4)$$

The programing needed to solve (3.3) or (3.4) is simple, but using this method to locate the polynomial roots is a time consuming approach. This is a two-dimensional problem in x and y and repeatedly factoring this type of polynomial can be a lengthy process. This method is especially inefficient when the gain factor, K , becomes very large. It's for this reason that the angle testing method was developed.

3.3 Method of Angle Testing

Points $s=x+jy$ on a root locus are those for which the angle

$$\angle GH(s=x+jy) = 180^\circ \quad (3.5)$$

or

$$\text{Im}[D(s=x+jy)] = 0 \quad (3.6)$$

The angle testing method involves using (3.5) to find a locus departure angle starting from one of the open-loop poles. Finding the open-loop poles and zeros requires only one pass of the polynomial root finding routine, when $K = 0$, instead of the multiple passes of the polynomial-factoring method.

The departure angle is used as the starting point for a process that iterates the angle of $G(s)H(s)$ until the next point is sufficiently close to satisfy (3.6) to within some given tolerance. This means that the two-dimensional problem of x and y is reduced to a one-dimensional angle

problem. This process continues along one locus until the plot limits are exceeded. Then, starting at a new open-loop pole, the whole process is started over until all loci are complete.

The program development needed to solve (3.5) and (3.6) is much more involved than that of the polynomial factoring method; however, the savings in computation time between the two methods can more than make up for this difference. This is true for all but the simplest problems. Figure 3.2 shows a simplified programming flow chart for a program using the angle testing method.

Figure 3-2 Angle Criterion Flow Chart

CHAPTER 4

ROOT LOCUS PROGRAM

4.1 Introduction to Root Locus Program

This chapter discusses the root locus plotting program which was developed to aid the control system designer in the design and analysis of control systems. The algorithm described in this chapter follows the work of J.A. Borrie [2]. Borrie's work was based on the original work done by P. Atkinson, and V.S. Dalvi [5]. This program uses the angle testing method as explained in chapter 3. This computer program is written in the C language and all source code is provided in Appendix A.

4.2 Algorithm Development

To start, it is helpful to write the system open-loop transfer function in the form

$$G(s) = G(\sigma - j\omega) \quad (4.1)$$

$$= \frac{K \prod_{i=1}^M [(\sigma - \sigma_{zi}) - j(\omega - \omega_{zi})]}{\prod_{k=1}^N [(\sigma - \sigma_{pk}) - j(\omega - \omega_{pk})]} \quad (4.2)$$

where

- K = closed-loop gain
- M = number of complex zeros
- N = number of complex poles
- $(\sigma_{zi} + j\omega_{zi})$ = complex zeros
- $(\sigma_{pk} + j\omega_{pk})$ = complex poles

Equation (4.2) can be written in the form

$$G(\sigma - j\omega) = \frac{K \prod_{i=1}^M [(\sigma - \sigma_{zi}) - j(\omega - \omega_{zi})] \prod_{k=1}^N [(\sigma - \sigma_{pk}) - j(\omega - \omega_{pk})]}{\prod_{k=1}^N [(\sigma - \sigma_{pk})^2 + (\omega - \omega_{pk})^2]} \quad (4.3)$$

Simplify (4.3) by writing it in the form

$$G(\sigma - j\omega) = K[X + jY] \quad (4.4)$$

Where X is the real part and Y is the complex part of (4.3). To evaluate (4.4), start with the first pole $(\sigma_{p1} + j\omega_{p1})$,

$$X_1 + jY_1 = \frac{(\sigma - \sigma_{p1}) - j(\omega - \omega_{p1})}{(\sigma - \sigma_{p1})^2 + (\omega - \omega_{p1})^2} \quad (4.5)$$

Finish evaluating the remaining poles using the recursive formulas

$$X_k = \frac{(\sigma - \sigma_{pk})X_{k-1} + (\omega - \omega_{pk})Y_{k-1}}{(\sigma - \sigma_{pk})^2 + (\omega - \omega_{pk})^2} \quad (4.6)$$

$$Y_k = \frac{(\sigma - \sigma_{pk})Y_{k-1} - (\omega - \omega_{pk})X_{k-1}}{(\sigma - \sigma_{pk})^2 + (\omega - \omega_{pk})^2} \quad (4.7)$$

$$k = 2, 3, \dots, N$$

Evaluate the zeros of (4.4) using the formulas

$$X_{i+N} = (\sigma - \sigma_{zi})X_{i+N-1} - (\omega - \omega_{zi})Y_{i+N-1} \quad (4.8)$$

$$Y_{i+N} = (\sigma - \sigma_{zi})Y_{i+N-1} + (\omega - \omega_{zi})X_{i+N-1} \quad (4.9)$$

$$i = 1, 2, \dots, M$$

This gives

$$G(s) = K[X_{M+N} + jY_{M+N}] \quad (4.10)$$

Notice that equations (4.6) and (4.7) fail when the point $(\sigma + j\omega)$ is near a pole. This is overcome by having the program check for, and avoid

evaluating, $G(s)$ at these points.

Figure 4.1 shows a computer flow chart of the root locus algorithm. In the interests of simplicity, some of the less significant steps are not shown. For further details see Appendix C.

BLOCK 1 Input the zeros and poles of the transfer function.

BLOCK 2 Display the poles and zeros. The pole locations are marked with an x and the zeros are marked with a circle.

BLOCK 3 Set the loop counter, locus, to 1 and establish the allowable locus deviation to 0.00001. The error value was established through a trial and error process and is a compromise between locus accuracy and computation time.

BLOCK 4 Check the loop counter for being less than or equal to the total number of system loci.

BLOCK 5 As explained in Chapter 2, each locus starts at a pole and ends at either a zero or asymptotically at infinity. Use the angle criterion to calculate the departure angle at the start of the present pole. The angle criterion is best demonstrated by example. Consider a system with the following transfer function

$$G(s) = \frac{(s+z_1)}{(s+p_1)(s+p_2)(s+p_3)(s+p_4)} \quad (4.11)$$

As shown in Chapter 2, the angle criterion is given by

$$\begin{aligned} \sum \alpha_i &= \sum (\text{angles of the zeros}) - \sum (\text{angles of the poles}) \\ &= (2k+1)\pi \end{aligned} \quad (4.12)$$

Figure 4.1 Root Locus Flow Chart

where

$$k = \pm 1, \pm 2, \pm 3, \dots \quad (4.13)$$

is chosen so that

$$-\pi \leq \alpha_d \leq +\pi \quad (4.14)$$

where the angles of zeros and poles are shown in Figure 4.2. This gives

$$\alpha_d = \alpha_3 - \alpha_1 - \alpha_2 - \alpha_4 - (2k+1)\pi \quad (4.15)$$

BLOCK 6 To find the point S_q near the locus, take an incremental step, with a length of Δs , from the pole S_p in the direction of α_d . This can be seen in figure 4.3. Δs is computed to be approximately two percent of the largest open-loop pole or zero coordinate.

$$S_q = S_p + \Delta s(\cos \alpha_d + j \sin \alpha_d) \quad (4.16)$$

Figure 4.2 Angle criterion construction

Figure 4-3 Incremental step S_0

BLOCK 7 In order for a point $s = \sigma \pm j\omega$ to be on a root locus it must satisfy the equation

$$1 + KG(s) = 0 \quad (4.17)$$

or using (4.10)

$$1 + K(X - jY) = 0 \quad (4.18)$$

or

$$Y = 0 \quad (4.19)$$

$$X = -\frac{1}{K} \quad (4.20)$$

The approach to using equations (4.19) and (4.20) is to find values of $s = \sigma \pm j\omega$ that satisfy (4.19) and use these in (4.20) to calculate the corresponding value of K . Since it is unreasonable to calculate values that will make (4.19) exactly equal to zero, a small error value can be established to minimize Y .

$$|Y| \leq \text{error} \quad (4.21)$$

BLOCK 8 If the point S_0 is far enough away from the root locus that (4.21) is not true, a search at right angles to the line (S_0-S_r) is done to find a point S_R sufficiently close to satisfy (4.21). This is shown in figure 4.4.

$$S_R = S_0 - L_r (-\sin\alpha_d - j\cos\alpha_d) \quad (4.22)$$

In order to find the value for L_r , $G(s)=K[X+jY]$ is evaluated at two points along the line (S_R-S_0) . The two points are determined by using (4.22) with two different values for L . They are

$$L_1 = \Delta s 10^{-4}$$

$$L_2 = 2\Delta s 10^{-4}$$

These two trial points are applied to equations (4.5) to (4.9) and the resulting values $Y(L_1)$ and $Y(L_2)$ are interpolated together using (4.23) to minimize Y .

$$L_3 = L_1 - \frac{L_1 - L_2}{Y(L_1) - Y(L_2)} Y(L_1) \quad (4.23)$$

Figure 4.4 Right angle search

This process is repeated until $Y(L_r)$ satisfies (4.21) and at which point S_r is assumed to be found.

With the point S_r found it is possible to use equation (4.20) to find the corresponding gain, K . Furthermore, if the slope of the locus at S_r can be determined, the sequence can be repeated until the whole locus is found.

The slope at S_r can be found from:

$$m = \frac{d\omega}{d\sigma} = \frac{\sum_{k=1}^N \frac{\omega - \omega_{pk}}{r_{pk}^2} - \sum_{i=1}^M \frac{\omega - \omega_{zi}}{r_{zi}^2}}{\sum_{k=1}^N \frac{\sigma - \sigma_{pk}}{r_{pk}^2} - \sum_{i=1}^M \frac{\sigma - \sigma_{zi}}{r_{zi}^2}} \quad (2.24)$$

where

$$r_{pk}^2 = (\sigma - \sigma_{pk})^2 + (\omega - \omega_{pk})^2$$

and

$$r_{zi}^2 = (\sigma - \sigma_{zi})^2 + (\omega - \omega_{zi})^2$$

Using the two points S_r and S_s , a new point $S_T = \sigma_T + j\omega_T$ can be calculated using the (usually correct) assumption that the slope of the curve is constant over a small interval on the locus.

$$\sigma_T = \sigma_s + \frac{1-m^2}{1+m^2}(\sigma_R - \sigma_P) + \frac{2m}{1+m^2}(\omega_R - \omega_P) \quad (2.25)$$

$$\omega_T = \omega_s + \frac{2m}{1+m^2}(\sigma_R - \sigma_P) + \frac{1-m^2}{1+m^2}(\omega_R - \omega_P) \quad (2.26)$$

Equations (2.25) and (2.26) are not used for values of $m < 0.01$ and $m > 100$, when horizontal and vertical slopes are assumed respectively.

BLOCKS 9, 10 Breakpoints in the locus are treated in this algorithm as the intersection of two loci, and if the wrong path is followed after such an intersection, the calculated value of K decreases, instead of

increasing. If a search step produces such a decrease, it is regarded as unsuccessful and a new step is taken at right angles to the unsuccessful one. Since breakpoints almost always occur at right angles, this strategy is usually successful.

BLOCK 11 A locus terminates either at a zero or at infinity on an asymptote. Infinity is assumed when any of the calculated coordinates exceeds the screen coordinates. An arrow is placed at the point of exit, pointing in the direction of the exit slope, to indicate infinity.

BLOCK 12 The locus is displayed as a set of data points joined together by straight line segments. Line segments lying on the left-hand plane, in the stable region, are displayed in green, while segments lying on the right-hand plane, in the unstable region, are displayed in red.

CHAPTER 5

BODE PLOTS

5.1 Introduction to Bode Plots

This chapter serves as an introduction to Bode plots which are used in the analysis and design of control systems. This is a graphical technique that plots a control system's gain amplitude and phase angle response curves against the input frequency. It is customary to plot the gain in decibels and the phase angle in degrees against the common logarithm of the input frequency. This is the form first introduced by H.W. Bode. This discussion is not intended to serve as a complete guide to Bode plots, but rather an overview to help the reader to better understand the computer techniques discussed in the following chapter. For further details refer to reference [3].

5.2 Bode Plots

Consider the open-loop transfer function of a single-input single-output system expressed in complex frequency domain,

$$G(s)|_{s=j\omega} = G(j\omega) = A(\omega) + jB(\omega) = |G(j\omega)| \angle G(j\omega) \quad (5.1)$$

where $G(j\omega)$ is a complex variable, while $A(\omega)$ and $B(\omega)$ are real variables. To convert $G(j\omega)$ to polar form, that is in magnitude and phase form, the

following equations are used:

$$|G(j\omega)| = (A^2(\omega) + B^2(\omega))^{1/2} \quad (5.2)$$

$$\phi(\omega) = \angle G(j\omega) = \tan^{-1}(B(\omega)/A(\omega)) \quad (5.3)$$

A Bode plot of this system consists of the gain and phase curves, defined as $20 \log|G(j\omega)|$ and $\phi(\omega)$ respectively, versus the angular input frequency ω .

Example: Consider a system with the following transfer function

$$G(s) = 1/(1 + \tau s) \quad (5.4)$$

Gain: The logarithmic gain is

$$\begin{aligned} 20 \log|G| &= 20 \log(1/(1 + (\omega\tau)^2)^{1/2}) \\ &= -10 \log(1 + (\omega\tau)^2) \end{aligned} \quad (5.5)$$

In order to plot the gain versus input frequency, use the following forms for different ranges of the frequency. For $\omega \ll 1/\tau$, is approximated by

$$20 \log|G| = -10 \log(1) = 0 \text{ db}, \quad \omega \ll 1/\tau \quad (5.6)$$

For high frequencies, $\omega \gg 1/\tau$, the gain (5.5) becomes

$$20 \log|G| = -20 \log(\omega\tau), \quad \omega \gg 1/\tau \quad (5.7)$$

while at $\omega = 1/\tau$, the form is

$$20 \log|G| = -10 \log(2) = -3.01 \text{ db} \quad (5.8)$$

It is clear from (5.6) that the gain is a constant 0 db for low

frequencies, then it drops to -3.01 db at the corner or break frequency $\omega_c = 1/\tau$ and finally for high frequencies, the plot drops linearly at a slope of -20 db/decade, that is at a frequency range $\omega_1 \leq \omega \leq \omega_2$ such that $\omega_2 = 10\omega_1$. Therefore, because of this linearity, it is very convenient to plot the phase $20 \log|G|$ versus $\log \omega$. This Bode magnitude plot is shown in figure 5.1.

Phase: The phase angle for (5.4) is given by

$$\phi(\omega) = -\tan^{-1}\omega\tau \quad (5.9)$$

which has the following asymptotic and exact behaviors for a wide range of frequencies.

$$\phi(\omega) \rightarrow 0^\circ, \omega \ll 1/\tau \quad (5.10)$$

$$\phi(\omega) = -45^\circ, \omega = 1/\tau \quad (5.11)$$

$$\phi(\omega) \rightarrow -90^\circ, \omega \gg 1/\tau \quad (5.12)$$

The phase plot is shown in figure 5.2.

Figure 5.1 Bode magnitude plot

Figure 5.2 Bode phase plot

For rational transfer functions, it is only necessary to be able to plot gain and phase curves of the following types of terms:

- 1) Constant gain K .
- 2) Poles and zeros at the origin of the complex plane.
- 3) Real axis poles and zeros.
- 4) Complex conjugate pairs of poles and zeros.

A rational function can be factored into terms of above types, and the individual gain and phase curves plotted. The complete gain curve is the sum of the individual component gain curves, and the complete phase curve is the sum of the individual phase curves. A discussion of the four types of transfer function terms follows.

1. *Constant Gain K .* The logarithmic gain is $20 \log K$ while the angle is 0° . The magnitude plots are horizontal lines. This is shown in figure 5.3.

2. *Poles or Zeros at the origin of the complex plane $(j\omega)^{\pm 1}$.* A pole or zero at the origin have a logarithmic gain as

$$20 \log |(j\omega)^{\pm 1}| = \pm 20 \log \omega \text{ db} \quad (5.13)$$

which is a straight line on a semi-log paper with slope of $\pm 20 \text{ db/decade}$ and a horizontal crossing at $\omega = 1$. The phase angle for this term is $\phi(\omega) = \pm 90^\circ$. Examples of poles and zeros at the origin can be seen in figures 5.4 and 5.5.

Figure 5.3 Bode plot with constant gain $K=10$

Figure 5.4 Bode plot with one and two poles at the origin

Figure 5.5 Bode plot with one and two zeros at the origin

3. *Poles or Zeros on Real Axis* $(1+j\omega/\omega_1)^{\pm 1}$. These terms have log-magnitude,

$$20 \log |(1+j\omega/\omega_1)^{\pm 1}| = \pm 10 \log(1+\omega/\omega_1)^2 \quad (5.14)$$

The asymptotic behavior of this plot begins at $\pm 10 \log(\omega/\omega_1)^2 = \pm 20 \log(\omega/\omega_1)$ or a straight line with a ± 20 db/decade slope. The two asymptotic lines (i.e. 0 db and ± 20 db/dec.) cross each other at the point $\omega = \omega_1$ or at the corner frequency (see Fig. 5.1). However, the actual value of the logarithmic gain at $\omega = \omega_1$ is $\pm 10 \log(2) = \pm 3$ db as demonstrated with (5.4) example. The phase angle $\phi(\omega) = \pm \tan^{-1}(\omega/\omega_1)$ which begins at 0° for low frequencies ($\omega \ll \omega_1$), reaches $\phi(\omega_1) = \pm \tan^{-1}(1) = \pm 45^\circ$ and approaches $\phi(\omega) = \pm \tan^{-1}(\infty) = \pm 90^\circ$, (See Fig. 5.2). Examples can be seen in figures 5.6 and 5.7.

Figure 5.6 Bode plot with poles on the real axis

Figure 5.7 Bode plot with zeros on the real axis

4. *Complex Conjugate Poles or Zeros.* $[1+2\xi(j\omega/\omega_2)+(j\omega/\omega_2)^2]^{*1}$. Let the ratio ω/ω_2 be represented by quantity ν and evaluate the logarithmic gain as,

$$\pm 20 \log |G(j\omega)| = \pm 10 \log ((1-\nu^2)^2 + 4\xi^2\nu^2) \quad (5.15)$$

while the phase angle is

$$\phi(\omega, \xi) = \tan^{-1}(2\xi\nu/(1-\nu^2)) \quad (5.16)$$

Once again the asymptotic behaviors of the above plots will be investigated. When $\nu \ll 1$, the magnitude is,

$$\pm 10 \log(1) = 0 \text{ db} \quad (5.17)$$

and the phase angle approaches 0° . On the other end of the frequency scale, i.e. for $\nu \gg 1$, the magnitude is

$$\pm 10 \log(\nu^4) = \pm 40 \log(\nu) \quad (5.18)$$

which results in a straight line with a slope of ± 40 db/decade. The phase angle $\phi(\omega)$ approaches 0° asymptotically as $\nu \ll 1$ and reaches $\pm 180^\circ$ as $\nu \gg 1$.

The frequency ω_r at which the maximum magnitude occurs is called the *resonant frequency*. Note that as the damping ratio ξ approaches zero, the resonant frequency ω_r approaches the corner frequency ω_c . The resonant frequency is obtained by taking the derivative of the magnitude of (5.15) with respect to ν and setting it equal to zero. The resulting equation is

$$\nu^2 - 1 + 2\xi^2 = 0 \quad (5.19)$$

or

$$\omega_r = (1 - 2\xi^2)^{1/2}, \quad \xi < 0.707 \quad (5.20)$$

The maximum value of the magnitude itself is

$$M_r = |G(\omega_r)| = (2\xi(1 - \xi^2))^{-1}, \quad \xi < 0.707 \quad (5.21)$$

Figure 5.8 Bode plot with a complex pole

CHAPTER 6

COMPUTER-AIDED BODE PLOTS

6.1 Introduction to Computer-Aided Bode Plots

This chapter describes the Bode plot algorithm as shown in the computer flow chart in Figure 6.1. In the interest of simplicity, some of the less significant steps are not shown. For more detail, refer to the program listing in Appendix D.

6.2 Bode Program Description

BLOCK 1 Input the open-loop transfer function information, the number of poles and zeros and their corresponding complex roots.

BLOCK 2 Input the open-loop transfer function gain K and the lower and upper plotting frequency range values, $\omega_{\text{gal}} \leq \omega \leq \omega_{\text{gau}}$. If the lower frequency value ω_{gal} is not a power of 10, i.e. not 0.001, 0.01..., then it's converted to the next lower power of 10. Likewise, the upper frequency is converted to the next higher power of ten. As an example, if the frequency range values were input as $\omega_{\text{gal}}=0.05$ and $\omega_{\text{gau}}=300$, then their corresponding converted values would be $\text{initial}=0.001$ and $\text{final}=1000$. This conversion is done in order that the abscissa on the output plot has a starting and ending points with powers of 10.

Figure 6.1 Bode plot flow chart

BLOCK 3 Compute the number of frequency iterations. This is a function of the frequency range and the number of available horizontal output screen pixels. This insures that the minimum number of iterations are used that will produce the most accurate plot with the least amount of computer run time. Next, set the frequency loop counter, j , equal to zero.

BLOCK 4 For each iteration of the frequency loop a new frequency value, ω , must be computed. ω is given by Equation 6.1

$$\omega = \omega_{\text{gal}} + j\Delta\omega \quad (6.1)$$

where $\Delta\omega$ is the frequency step size.

Also, for each loop pass through the frequency loop, the running totals of the magnitude and phase and the pole loop counter, i , are set equal to zero.

BLOCK 5 For each iteration of the frequency loop, each of the M factored poles are evaluated to adjust the magnitude and phase running totals. Block 5 controls the poles loop and sends the program flow to the zero loop once each of the poles are evaluated.

As described in chapter 5, the transfer function can be factored into four types of terms, they are

- 1) Constant gain K .
- 2) Poles and zeros at the origin of the complex plane.
- 3) Real axis poles and zeros.
- 4) Complex poles and zeros.

BLOCK 6 Checks for poles at the origin and if true sends the flow to block 7.

BLOCK 7 Pole at the origin. Adjusts the magnitude and phase according to the following equations.

$$\text{magnitude} = \text{magnitude} - 20 \log_{10}(\omega) \quad (6.2)$$

$$\text{phase} = \text{phase} - \pi/2 \quad (6.3)$$

BLOCK 8 Checks for real axis poles and if true sends flow to block 9.

BLOCK 9 Real axis pole. Adjusts the magnitude and phase according to the following equations.

$$\text{magnitude} = \text{magnitude} - 20 \log_{10}(1 + \omega/\omega_p) \quad (6.4)$$

$$\text{phase} = \text{phase} - \tan^{-1}(\omega/\omega_p) \quad (6.5)$$

BLOCK 10 Complex pole. If blocks 6 and 8 are both false the flow comes to block 10 and the magnitude and phase are adjusted as follows.

$$\begin{aligned} \text{magnitude} = \text{magnitude} - \\ 20 \log_{10}((1 - (\omega/\omega_p)^2)^2 + 4\xi^2(\omega/\omega_p)^2)^{1/2} \end{aligned} \quad (6.6)$$

$$\text{phase} = \text{phase} - \tan^{-1}(2\xi(\omega/\omega_p)/(1 - (\omega/\omega_p)^2)) \quad (6.7)$$

Once all of the poles are evaluated, the loop counter i is set equal to 1 and the flow goes to the zero loop control block 11.

BLOCK 11 For each iteration of the frequency loop each of the N factored zeros are evaluated to adjust the magnitude and phase running totals. Block 11 controls the zero loop and sends the program flow to the constant K block once each of the zeros are evaluated.

BLOCK 12 Checks for zeros at the origin and if true sends the flow to block 13.

BLOCK 13 Zero at the origin. Adjusts the magnitude and phase according to the following equations.

$$\text{magnitude} = \text{magnitude} + 20 \log_{10}(\omega) \quad (6.8)$$

$$\text{phase} = \text{phase} + \pi/2 \quad (6.9)$$

BLOCK 14 Checks for real axis zeros and if true sends flow to block 15.

BLOCK 15 Real axis zero. Adjusts the magnitude and phase according to the following equations.

$$\text{magnitude} = \text{magnitude} + 20 \log_{10}(1 + \omega/\omega_p) \quad (6.10)$$

$$\text{phase} = \text{phase} + \tan^{-1}(\omega/\omega_p) \quad (6.11)$$

BLOCK 16 Complex zero. If blocks 12 and 14 are both false the flow comes to block 16 and the magnitude and phase are adjusted as follows.

$$\begin{aligned} \text{magnitude} = \text{magnitude} + \\ 20 \log_{10}((1 - (\omega/\omega_p)^2)^2 + 4\xi^2(\omega/\omega_p)^2)^{1/2} \end{aligned} \quad (6.12)$$

$$\text{phase} = \text{phase} + \tan^{-1}(2\xi(\omega/\omega_p)/(1-(\omega/\omega_p)^2)) \quad (6.13)$$

Once all of the poles are evaluated, the flow goes to the constant control block 17.

BLOCK 17 Once all of the poles and zeros of the transfer function are evaluated the magnitude is adjusted for the constant gain term K. Only the magnitude is adjusted since the phase change for a constant is zero.

$$\text{magnitude} = \text{magnitude} + 20 \log_{10}(K) \quad (6.14)$$

BLOCK 18 The current frequency, magnitude and phase data is stored once all of the terms of the transfer function are evaluated.

BLOCK 19 This block controls the frequency iteration loop and sends flow to the output block once the transfer function is evaluated for each of the step frequencies. If not finished, the iteration loop counter is increase by one and the loop continues.

BLOCK 20 Flow is sent here once all of the data points that describe the magnitude and phase curves are computed. Both curves are plotted together sharing the same frequency abscissa. The left-hand vertical scale represents the magnitude as measured in decibels and is shown in magenta. The right-hand vertical scale measures the phase angle in degrees and is shown in green. The magnitude curve is plotted with a solid magenta curve and the phase is plotted as a dotted green curve. The above color information only applies to plots run on a machine with an IBM compatible Enhanced Graphics Adapter (EGA). Plots run on a machine with an IBM

compatible Color Graphics Adapter (CGA) are only shown in black and white due to the low resolution of the CGA when plotting in color. The magnitude is plotted with a solid white curve while the phase is plotted with a dotted white curve.

Hard copy prints of the plots are provided by way of the print screen function. If a printout is desired, press the P key and the output is automatically sent to the printer. A example output screen is shown in figure 6.2.

Figure 6.2 Example Bode plot

CHAPTER 7

SUMMARY

7.1 Thesis Summary

With the wide spread availability of the personal computers to the control systems engineer, it would only make sense to supplement the time-honored techniques of using root locus and bode plots in the analysis and design of control systems with one that involves computer-aided support. Using the computer to do the mundane task of generating the graphs allows the designer to spend more time analyzing the system. This could also allow a student in a controls course the opportunity to learn more of the theory behind control systems analysis instead of spending all their time learning the tedious process of generating the graphs by hand. It was the purpose of this thesis to develop computer algorithms to automate this task in a easy to use format. This software is called the *Control Systems Software Package* (CSSP).
