Abstract

PERRY, DALE R. Forecasting the Tornadoic Intensities of Thunderstorms by Multivariate Techniques. (Under the direction of Charles E. Anderson.)

An investigation on the feasibility of statistically characterizing tornadic and non-tornadic thunderstorms after cells develop is the basis of this research. Nine tornado outbreak cases during the years 1984 through 1988 were studied. The intensity of each tornado-producing thunderstorm cell was obtained from Storm Data for the particular outbreak case studied. Satellite as well as radiosonde data were used to determine the meteorological parameters describing thunderstorm behavior.

One of these parameters was the downstream mass flux of an anvil outflow plume (called UMAX) and the other was the rightward deviation angle of the anvil from the storm-relative flow (called MDA). These parameters were used in a two-dimensional kinematic anvil plume model implemented on an interactive computer data system which simulated the actual anvil plume as seen in satellite imagery.

To gain an aspect of the pre-storm environment, proximity soundings were used to compute low-level vertical wind shear and potential buoyant energy (PBE) for each outbreak case. These two parameters were used to further refine the relationship between UMAX and MDA to the storm environment. A modified Fujita scale rating system was employed to characterize each outbreak cell as a weighted mean called F_w and a weighted mean square called F_w^2 . F_w was a better indicator of tornadic intensity than F_w^2 .

UMAX and MDA were used as predictors in a bivariate regression model (two-variables) to predict the tornadic intensity of a given observed cell. Linear regression yielded promising results in correlating the data, and described a "rising-ridge" surface that related UMAX and MDA to both E_v . Attempts to relate PBE and shear to F_v yielded mixed results, and only accounted for a small fraction of the error variance in the data.

When all nine outbreaks were combined into one group of data, the coefficient of determination fell drastically, implying that these rising-ridge surfaces did not conform to each other when treated as a group. Non-dimensionalizing the combined data by outbreak breakpoint number (the UMAX and MDA value that separates tornadic from non-tornadic cells) gave slightly better results.

To increase the amount of variance accounted for in the regression model, PBE and vertical wind shear were added as two additional predictors in a quadvariate (four-variable) model. Linear regression gave improved coefficients of determination in each of the nine cases, suggesting the use of variables characterizing the pre-storm environment improves the prediction of the behavior of thunderstorms.

However when the nine outbreaks were combined and then regressed with all four variables, only a slight improvement in the variance ensued. Non-dimensionalization of the data improved the coefficient of determination slightly.

An effort to stratify the entire data set, based on each outbreak's breakpoint value, was attempted. The distance of each case's breakpoint value from the origin was determined. This measure gave a basis of grouping outbreak cases based on this stratification scheme.

Bivariate and quadvariate regression was run on the resulting four groups of stratified data. Linear regression analysis of these individual groups gave coefficients of determination in the range of 0.58 to 0.76 when UMAX and MDA were used in the bivariate model, and in the range of 0.66 to 0.80 when PBE and shear were added to make a quadvariate linear regression analysis.

Quadratic regression analysis gave coefficients of determination in the range of 0.78 to 0.86 for the bivariate model, and in the 0.91 to 0.95 range for the quadvariate model. However, it is questionable whether the quadratic results can be used in the stratified scheme due to the possibility of over-fitting the model to the data.

Future research should be done to relate the stratified groups of data to other meteorological phenomena. These unknown parameters may explain the unique triggering mechanisms that occur from case to case. If this is successful, then one may be able to implement an operational forecast to predict a thunderstorm cell's tornadic potential.

Acknowledgements

I would like to express my sincere appreciation to the individuals who contributed time and effort in the completion of this thesis. I'd like to thank Professor Charles E. Anderson for his guidance, patience and editorial comments that made this thesis readable. I wish to also thank Professor John F. Monahan for putting up with my many last minute visits that made the statistics in this research presentable. Also I'd like to thank Professor Allen J. Riordan for being on my committee.

I owe thanks to Kevin J. Schrab for the use of his UMAX and MDA data as well as for his helpful suggestions. In this respect, a big thanks goes to Erik Rasmussen, a fellow OU alumnus and storm chaser, who provided me a working copy of his PBE program.

However, I wouldn't have been able to do this without the loving support and encouragement of my wife, Lorraine, and my son, Geoffrey. They were there when I needed them, and were understanding when I couldn't be there for all the little things. I also have to thank my parents, Bob and Jean, who were very supportive of me to further my education and gave me the opportunity to do so. In this regard, I also thank my sister, Marcia, and my brothers, Lee and Keith, who were there when I needed them.

I'd also like to thank Joe and Nancy Miller, who were very supportive in the work I was doing at NC State. I owe a special thank you to the U.S. Air Force for allowing me the opportunity to attend graduate school. And finally to those I haven't mentioned, especially to my fellow Air Force comrades, who made my stay at NC State enjoyable and memorable.

This research was supported under NASA Contract NAS8-36547 and NOAA Contract 50-WCNE-8-06058.

1. INTRODUCTION

1.1 Tornado Outbreak Classification

The tornado is defined as a violently rotating column of air, pendant from a cumulonimbus cloud, and nearly always observable as a funnel cloud or tuba - (a cloud column or inverted cloud cone, pendant from a cloud base) (Glossary of Meteorology, 1959). The fact that tornadoes are a rare, violent and destructive atmospheric phenomena responsible for about 100 deaths and \$200 million property damage annually (Davies-Jones, 1982) understandably elicits much concern beyond the meteorological community. This is compounded with a typical damage area 2 km long and 50 m wide (extreme cases have damage path lengths exceeding 150 km and widths of 3 km). The majority of tornadoes are deemed weak and short-lived, although 3.2% of the total tornado occurrences have resulted in deaths of one or more persons (Galway, 1983).

Climatological studies have shown that the majority of the tornado deaths which occur in severe weather watch areas are caused by outbreaks of six or more tornadoes (Galway, 1975). In fact, Galway (1975) found that outbreaks of ten or more tornadoes accounted for 73% of the tornado deaths during the period 1952 through 1973. A question arises as to how an outbreak should be defined, since a tornado "outbreak" can mean many things to many people. This is particularly true in some states where tornado occurrences are very rare.

Pautz (1969) and Galway (1975) refined the concept of a tornado outbreak by introducing three outbreak categories: small (6-10 tornadoes), moderate (11-20 tornadoes) and large (greater than 20 tornadoes). For this research an outbreak is taken to be five or more

tornadoes in a given synoptic situation to insure an adequate amount of thunderstorm cells will be examined.

Galway (1977) spatially defines three general types of outbreaks as local, progressive and line. A local outbreak was defined as an outbreak confined to a roughly circular envelope of approximately 10,000 mi^2 . Local outbreaks also tend to be the shortest in duration among the three types. This type of outbreak would most likely be caused by one or several cells. A progressive outbreak was defined as an outbreak that advances from west to east with time. Being somewhat long in length (the distance between the first and last tornado report is normally greater than 350 nautical miles) it has the longest life span of the three outbreak types. This outbreak type is more typically the result of a small number of cells. Lastly, a line outbreak was defined as one limited in eastward movement normally oriented along a north-south axis. Tornadoes that occurred in a line outbreak tend to be widely spaced in location but closely spaced in time. This type of outbreak is one in which a significantly larger number of cells would be involved. For purposes of this research these classifications are important in determining how many cells to pick for an outbreak case.

1.2 Tornadic Thunderstorms Characterized By Satellite Data

Previous work by Anderson (1979) investigated the use of geosynchronous satellite imagery to identify tornadic thunderstorms. Anderson examined the characteristics of storm tops and their related cirrus outflow patterns in five tornado outbreaks. His research yielded three characteristics of thunderstorm anvil behavior when viewed from the satellite prospective: a cirrus plume was strongly

displaced to the right of the ambient wind, in some cases up to 90 degrees; the cirrus outflow had anticyclonic rotation; and the outflow plume contained spiral bands extending clockwise from the center of the storm.

Further studies by Schrab (1988) and Anderson and Schrab (1988) centered on the possibility of identifying potential tornadic thunderstorms using characteristic signatures produced by the anvil emerging from a thunderstorm cell. These signatures were obtained by inputting parameters into a two-dimensional fluid simulation model implemented on the McIDAS (Man-computer Interactive Data Access System), a remote interactive computer terminal linked to the University of Wisconsin, Madison. These characteristic signatures were called UMAX and MDA. The parameter UMAX was defined as the maximum flux of radial outflow of anvil material defining a simulated cloud anvil plume. It has been shown that mass flux is directly related to tornadic intensity (Colquhoun and Shepherd, 1985). The other parameter, MDA (measured deviation angle), was defined as the clockwise deviation of the centerline of the anvil from the storm-relative ambient wind at the outflow level. Anderson (1979) suggested a connection between anvil outflow patterns and tornadic thunderstorms, which MDA tries to describe.

The anvil model simulates how an anvil outflow plume appears after time. The model does this by injecting an assemblage of particles into a two-dimensional fluid flow defined by a constant ambient wind plus a combination of Rankine vortex with or without compensation of vorticity farther out (Schrab, 1988). Thus the computed particle outline

simulates the thunderstorm anvil envelope defined by UMAX and MDA. Schrab used this model in conjunction with available upper air data and a loop of three consecutive satellite pictures taken in a Lagrangian format at 1 km resolution in the visible and 4 km resolution in the IR. McIDAS allowed the user to isolate the representative temperature level of the anvil during this loop sequence, enabling the ambient wind at the anvil level to be determined. Care was also taken to avoid thunderstorm cold tops (overshooting the tropopause) and anvil edges, as these are not representative of the actual anvil plume being measured. By looping through the satellite images and overlaying the anvil envelopes, an assessment was made as to how well the simulated anvil matched the actual anvil plume. If the simulated envelope was too small then an increase in UMAX was needed. If too large, then a decrease in UMAX was input into the model. Also examined was the simulated anvil plume deviations, or measured deviation angle (MDA), from the storm relative flow. If the simulated anvil envelope was too far right of the actual anvil then a decrease in the clockwise tangential circulation parameter was input into the model. If too far left, then an increase in the parameter was needed. Thus, the speed of growth of the simulated anvil plume was controlled in order to match the observed satellite imagery.

1.2.1 Bivariate Regression of UMAX and MDA

A bivariate statistical model was chosen to relate UMAX and MDA as predictors to the response variable of tornadic intensity. This model is given by the following equations:

$$\hat{y} = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \varepsilon \quad (1.1)$$

and,

$$\hat{y} = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_{11} x_1^2 + \beta_{22} x_2^2 + \beta_{12} x_1 x_2 + \varepsilon \quad (1.2)$$

where $\hat{y}$ is the response variable for tornadic intensity and x_1 and x_2 are the predictor variables. Equation 1.1 is the linear model with three terms, and equation 1.2 is the quadratic model with six terms. Table 1.1 shows the individual outbreak results from this analysis.

Table 1.1. Percent of variation (coefficient of determination or R^2) in tornadic intensity (F_w^2) that can be explained by the predictor variables UMAX and MDA for linear and quadratic bivariate regression.

Case		Linear R^2	Quadratic R^2

TX-LA	(87319)	0.7490	0.8958
NC-VA	(88333)	0.8254	0.9525

From the linear analysis, UMAX and MDA had a coefficient of determination of over 69% in predicting tornadic intensities of thunderstorms. Quadratic regression analysis of UMAX and MDA had an R^2 value of over 88% in predicting tornadic intensity. However, quadratic regression analysis cannot be applied to individual outbreak cases. This was due to the relatively small number of data observations per

outbreak set, causing the quadratic model to "overfit" the data. This overfit gives a coefficient of determination higher than it actually would have under an ideal distribution. Using this bivariate model, a dataset would need approximately 40 observations to overcome this overfit problem.

Looking at the linear results of table 1.1 suggests for a particular outbreak investigated, there appeared to be a strong connection of thunderstorm anvil characteristics to the associated tornadic intensities. In fact, a "rising-ridge" (Box and Draper, 1987) statistical surface resulted relating UMAX and MDA to tornadic intensity. This surface showed that as one ascends the ridge higher values of tornadic intensities can also be expected, and defined a breakpoint value separating tornadic from non-tornadic occurrences.

When the data were grouped into one data set, the coefficient of determination fell to just over 55%. This showed that when all nine cases were combined into one data set, the strong correlation between the predictors and the response variable was not present. This result suggests that other influences may be present to characterize cells as tornadic or non-tornadic. Even attempts to non-dimensionalize the data based on individual outbreak breakpoint values showed little improvement in the correlations. Non-dimensionalizing was done by dividing each outbreak's cell UMAX and MDA by its representative breakpoint value. For example, if a given outbreak had a breakpoint value for UMAX as 16 and MDA as 20, then all the cell's UMAX values were non-dimensionalized by dividing by 16. Likewise all the cell's MDA values were divided by 20. When applied to the other outbreaks, this gave an

overall breakpoint value of 1 and 1. In the linear analysis scheme, the R^2 value increased to 57%, an increase of only to 2%.

1.3 Tornadoic Thunderstorms Characterized by Raob Data

Previous studies have related severe local storm development to vertical wind shear and available buoyant potential energy of the environment in which the storm develops through the use of proximity soundings and/or by numerical simulation. Work by Blechman (1979) showed that as the low-level vertical wind shear increased so did the vorticity. Vertical wind shear in the low-levels (0-4km) has also been suggested to be connected to the development of tornadoic storms (Rasmussen and Wilhelmson, 1983). Further, a combination of this low-level shear in combination with low-level buoyancy has been shown to have an effect on vorticity production (Weisman and Klemp, 1982; Rasmussen and Wilhelmson, 1983). Both studies characterized tornado producing storms as having large values of shear and large amounts of buoyant energy. An attempt to relate the two as an operational index (Leftwich and Wu, 1987) yielded mixed results when trying to relate this type of index to indicate violent tornado potential.

In addition to UMAX and MDA, potential buoyant energy (PBE) and low-level vertical wind shear were added to the bivariate model to make a quadvariate model (four variable). This showed some promise when related to the tornadoic intensity of individual thunderstorm cells. This is due to the fact that tornadoic thunderstorms form in environments characterized by large potential instability and large vertical wind shear. The latter can be computed fairly easily with available sounding data.

1.4 Research Goals/Objectives.

The basic goal of this research was to eliminate the two-step process that Schrab (1988) and Anderson and Schrab (1988) described in relating UMAX and MDA in a bivariate regression model to predict tornadic intensities of thunderstorms. That is, thunderstorm anvil behavior parameterized by UMAX and MDA showed a relationship on a plotted surface that distinguished tornadic from non-tornadic cells. We had hoped that the addition of the vertical wind shear in the low-levels (0-4 km) and PBE to the bivariate model, to create a four variable polynomial regression scheme, would be sufficient to predict the tornadic intensity of a given observed thunderstorm cell, regardless of its outbreak family.

Consequently, one objective of this research was to arrive at an improved prediction of the expected intensity of a given cell whose UMAX and MDA are predetermined by measurement using satellite data and by measuring the pre-storm environment (PBE and wind shear) computed from available proximity upper air soundings. This was done by the use of a quadvariate (four variable) regression model. When the model was applied to the nine outbreak cases, a fine-tuning only of the analysis results occurred due to the addition of PBE and shear to the model.

This led to the other objective of this research, that is, to combine the data in such a way as to improve the coefficient of determination. This was done by stratifying the lumped data set into different groups based upon how each individual outbreak's surface fell into two-dimensional space. By computing the distance of each outbreak's breakpoint value from the origin helped achieve this

objective. This was done with the hope that the regression analysis results would improve, and thereby describe some commonality present in the individual outbreak data.

If the stratification scheme were successful, then we could move on to some sort of forecast in predicting the small fraction of tornadoes that turn out to be the killer tornadoes. Furthermore, an operational forecast conceivably could be implemented in which these parameters are automatically computed using real-time satellite and raob data in order to provide a more refined and accurate forecast of tornado occurrence in a tornado outbreak situation.

2. METHODOLOGY OF NINE TORNADIC OUTBREAK CASE STUDIES

2.1 Outbreak Situations Studied

This research studied nine tornado outbreak cases as listed in table 2.1. All cases involved tornadic outbreaks of five or more

Table 2.1. List of Tornado Outbreaks Used in This Research.

Outbreak Region	Date	No. Tornadoes/ No. Cells/ No. Torn. Cells	No. Killed/ No. Injured	Damage Path (in miles)
OK	26 Apr 84	7/16/3	0/5	106.0

Totals		127/137/40	109/1682	

tornadoes with areal coverage encompassing more than one state. Appendix 6.1 gives a complete listing of individual cell distribution and statistics per outbreak.

The Oklahoma outbreak of 26 April 1984 (figure 2.1) included cells in central Oklahoma into southeastern Kansas, and also central Iowa and South Dakota causing 5 injuries along damage tracks totaling 106 miles associated with 7 tornadoes. Sixteen cells were included in the population with three being tornadic.

The Wisconsin and Illinois outbreak of 27 April 1984 (figure 2.1) was associated with 7 tornadoes which killed 3 and injured 38, with two tornadoes reaching F4 in strength. This outbreak gave 16 cells to the population study, 5 of which were tornadic.

The Iowa outbreak of 7 June 1984 (figure 2.2) produced 42 tornadoes encompassing extreme northeastern Kansas to southern Minnesota and central Wisconsin. Many of the tornadoes occurred in two clusters, one reaching from northeast Iowa into south-central Minnesota and north-central Wisconsin and the second extending from northeast Kansas and southeast Nebraska through northwest Missouri into south-central Iowa and then into south-central Wisconsin. The resulting deaths from these tornadoes were 13, with 319 injuries covering 584 miles of damage paths. In keeping with the limited scope of this research, only 34 tornadoes from the outbreak were used which contributed 4 deaths and 117 injuries to the dataset.

The 10 May 1985 Nebraska outbreak (figure 2.3) encompassed north-central Kansas to south-central Nebraska. This outbreak spawned 8 tornadoes along 158 miles of damage paths and resulted in only 4 injuries. One cell alone produced two F4 tornadoes in northern Kansas. This outbreak consisted of 13 observed cells, 4 of which were tornadic.

The Ohio, Pennsylvania, New York outbreak of 31 May 1985 (figure 2.4) produced the most devastating outbreak of tornadoes since the superoutbreak of 3-4 April 1974. Two separate outbreak areas were involved: one between Lake Ontario and Georgian Bay in Canada and the other centered in northwestern Pennsylvania stretching into eastern Ohio and southwestern New York. Of the 41 tornadoes produced, 28 were in the U.S. with 535 miles of damage paths and 13 were in Canada. These tornadoes caused 76 deaths and 905 injuries, and well over \$100 million in property damage in the U.S. alone. This outbreak contributed 23 cells, 9 of which were tornadic, to the study

Figure 2.2. Tornado tracks and their associated cells for the IA outbreak. Letters indicate the cell of the tornado's origin (after Storm Data).

Figure 2.3. Tornado tracks and their associated cells for the NE outbreak. Letters indicate the cell of the tornado's origin (after Storm Data).

UNITED STATES-CANADA TORNADO OUTBREAK of MAY 31, 1985

Figure 2.4. Tornado tracks and their associated cells for the OH-PA-NY outbreak. Letters indicate the cell of the tornado's origin (after Storm Data).

population.

During the afternoon of 28 July 1986, a group of thunderstorms formed in central South Dakota and moved southwest into a mesoscale convective complex (MCC) which moved subsequently across Iowa that evening. Fourteen tornadoes were produced over 78 miles of damage paths, one being F4 in intensity, with only one injury. This outbreak contributed 12 cells to the study population, 3 of which were tornadic.

The 18 September 1986 Kansas outbreak, stretching from northeastern Colorado into northern Kansas and south-central Nebraska, produced five tornadoes. Only seven people were injured along 43 miles of damage paths. This outbreak contributed 16 cells to the study population, of which only 4 were tornadic.

The Texas and Louisiana outbreak of 15 November 1987 (figure 2.5) occurred in eastern Texas and moved to extreme northwestern Louisiana, producing 17 tornadoes that killed 11 persons and injured 287.

The North Carolina and Virginia outbreak of 28 November 1988 (figure 2.6) covered two areas: one from Raleigh in central North Carolina to south-central Virginia, while the other occurred along the coastal areas of North Carolina. There were 7 tornadoes produced with 4 deaths and 157 injuries along 125 miles of damage paths. This outbreak contributed 13 cells to the study population, 3 of which were tornadic.

2.2 Classification of Tornadic Outbreak Intensities

In order to achieve the goals and objectives set out by this research, a tornadic strength scale (Schrab, 1988) was utilized to classify each thunderstorm cell examined. Storm Data was used to match

NORTH CAROLINA-VIRGINIA TORNADOES on November 27, 1988

Preliminary mapping as of 12/02/88 based on aerial survey, 11/29 to 12/01 Wind Research Laboratory, University of Chicago

Figure 2.6. Tornado tracks and their associated cells for the NC-VA outbreak. Letters indicate the cell of the tornado's origin (after Fujita, Univ. of Chicago).

an observed cell's time and location to a documented occurrence of severe weather. If the reported severe weather associated with the thunderstorm cell was a tornado, then the cell was assigned a value based on the Fujita scale rating system (Fujita, 1981). In many cases more than one tornado was attributed to a single cell, in which case a weighted average of tornadic intensity was taken. Appendix 6.2 contains an excerpt from Fujita's study with an explanation of his rating scheme. Table 2.2 shows the weighted intensities of

Table 2.2. Modified Fujita Weighting Scale (after Schrab, 1988).

<u>Fujita Scale Rating</u>	<u>Modified Tornado Intensity Scale</u>	
	F_w	F_w^2
F0	1.00	1.00
F1	2.00	4.00
F2	3.00	9.00
F3	4.00	16.00
F4	5.00	25.00
F5	6.50	42.25

each tornado category. Since the Fujita scale is based on a natural logarithmic scale, the F_w^2 weightings in this table also shows this logarithmic relationship. A value of one was added to each F-scale category so that a log of F0 could be taken, shown as F_w in table 2.2. These values were then squared to get the weighted-squared Fujita scale, denoted as F_w^2 . Figure 2.7 shows that the results fell on a straight line when the natural logarithm of each value was taken. The x-axis shows $\ln(F_w^2)$, the weighted squared Fujita scale. The y-axis shows $\ln(F_w)$, the weighted modified Fujita scale. Note that the F5 F_w value in table 2.2 was increased from 6.00 to 6.50 (36.00 to 42.25 for

Figure 2.7. Natural log of modified weighted Fujita scale (F_w) versus natural log of weighted-squared Fujita scale (F_w^2) (after Schrab, 1988).

F_w^2) so that the distance between F4 and F5 shown in figure 2.7 was equal to the distance between F3 and F4 along both the x- and y-axes.

In order to account for the tornadic productivity of a given thunderstorm cell in an observed outbreak, a weighted mean square of all tornadoes connected with that particular cell was determined. For example, assume a cell spawned the following tornadoes: (1)F0 (2)F1 (1)F2 (3)F3 and (2)F4. This cell would then be assigned a weighted mean of 2.78 based upon the following calculation:

$$\frac{1(1) + 2(2) + 1(3) + 3(4) + 2(5)}{\text{Total Number of Tornadoes (9)}} = 2.78 \quad (2.1)$$

Similarly, the weighted squared mean of this cell would compute to a

value of 12.89 based upon the following calculation:

$$\frac{1(1) + 2(4) + 1(9) + 3(16) + 2(25)}{\text{Total Number of Tornadoes (9)}} = 12.89 \quad \{2.2\}$$

If a cell produced no tornadoes then a value of zero was assigned. This rating system was employed in all nine outbreak cases studied.

As the Fujita rating scale is subjective, it was difficult in some cases to rate a tornado's damage based on Storm Data. Since the Fujita rating system is the accepted way of classifying a tornado's strength, the inherent bias in this type of rating system is unavoidable.

2.3 Choice of Predictor Variables

The two parameters chosen to describe thunderstorm anvil behavior were UMAX and MDA, i.e. the anvil outflow strength and the measured storm relative deviation angle. These were estimated on McIDAS, by fitting to each thunderstorm cell observed by satellite an envelope enclosing the anvil outflow boundary as computed via a two-dimensional numerical model (Schrab, 1988).

Two other parameters, closely related to UMAX and MDA, were chosen to predict a thunderstorm's tornadic behavior: vertical wind shear and parcel buoyancy. Low-level vertical wind shear has been attributed to veering and increasing winds with height (Davies-Jones, 1983), an important effect in the role of mesocyclones in thunderstorms. Available buoyant potential energy, or instability, has also been found to be particularly important in influencing storm evolution and structure (Weisman and Klemp, 1982). For purposes of this research, this instability will be referred to as potential buoyant energy (PBE).

Further, the combination of low-level (0-4 km) vertical wind shear and parcel buoyancy has been shown to have a strong relationship to convective storm structure and evolution (Weisman and Klemp, 1982; Rasmussen and Wilhelmson, 1983).

To determine these latter two parameters, available proximity soundings to each observed cell were used, provided they were representative of the air mass in which the storm developed. Using McIDAS, the cell's latitude/longitude coordinates were obtained from the satellite imagery and plotted on an upper air station locator map. As an example, if the observed cell developed at 2100Z, the closest 1200Z upper air sounding was used to define the pre-storm environment of wind shear and PBE. Care was taken to choose a sounding that best described the air mass that defined that cell. However, many cells did not develop near any one station, so an average of two or more soundings near and/or upstream of the cell were taken. For purposes of this research, if a cell was within 50 nm of a sounding station it was assumed representative of that cell's environment. Also, if a cell developed soon after 0000Z, say 0100Z, the 1200Z sounding was used under the premise that the 0000Z sounding would not be available in "real-time" for a forecast to be made as to its tornadic potential (even though the 0000Z sounding may have been more representative than the 1200Z sounding).

This research did not account for any modifications to the sounding's profile during the course of time between balloon launches. That is, any type of air mass modification that may occur that could alter the profile of an available sounding was not considered. This

method was used even though air mass modification did occur during some of the case studies examined, and in some cases, had a profound effect when relating PBE and wind shear to tornadic intensities. This should be looked at for future research.

2.3.1 Determination of Low-Level Vertical Wind Shear

Rasmussen and Wilhelmson (1983) defined the low-level vertical wind shear as the mean shear in the lowest 4 km above ground level. This was expressed as:

$$\text{MEAN SHEAR} = \frac{\int_0^{4 \text{ km}} \frac{\partial \vec{V}}{\partial z} dz}{\int_0^{4 \text{ km}} dz} \quad (2.3)$$

The mean shear in equation 2.3 is approximated by computing the magnitude of the shear vector from each 200 m layer averaged over the lowest 4000 m. This method of integrating the shear vector magnitudes every 200 m over the 4 km layer and dividing by 4 km was followed in order to account for the possible existence of strong speed shear and turning (called looping) in the layer. The presence of looping in the lower layer indicates the existence of a low-level jet with winds backing somewhat and decreasing markedly in speed just above the jet (Rasmussen and Wilhelmson, 1983). Computing the mean shear as just a vector difference between the 0 and 4 km levels would tend to mask the presence of this looping. This would be important since large low-level shears are typically found in the soundings from tornado cases caused by the presence of large loop structures in the profile

(Rasmussen and Wilhelmson, 1983).

As an example, table 2.3 lists a sounding profile. Suppose shear was computed as a straight vector difference between the 0 and 4 km levels. This would give an estimate of the mean low-level vertical

Table 2.3 Typical Upper Air Sounding Profile

P (mb)	Wind Dir (deg)	Wind Spd (m/s)	Height (m)
1015	180	5.0	0.0
1000	185	9.0	15.0
850	195	25.0	1500.0
700	205	20.0	3000.0
600	215	15.0	4000.0
500	230	24.0	5800.0
400	230	30.0	7500.0
300	235	32.0	9550.0
100	250	26.0	16400.0

shear as $2.8188 \times 10^{-3} \text{ sec}^{-1}$. Whereas the mean low-level shear computed as an integrated sum over the entire 4 km layer would give the estimate as $7.9842 \times 10^{-3} \text{ sec}^{-1}$. Clearly, the large difference between these two values indicates that the looping present in this data profile is masked with the first method. Obviously soundings where the lowest 4 km wind data was missing could not be used in this research. Appendix 6.3 contains an explanation of and the source code for the program that processed the sounding data.

2.3.2 Determination of Potential Buoyant Energy (PBE)

PBE was computed, like shear, from available proximity soundings to developing cells. This sounding data was interpolated to 200 m levels and the PBE was computed from the following expression (Rasmussen and Wilhelmson, 1983):

$$PBE = g \int_{LFC}^{EL} \frac{T_P - T_E}{T_E} dz \quad \{2.4\}$$

where LFC is the level of free convection, EL is the equilibrium level, and the subscripts P and E are the parcel temperature and the environmental temperature respectively. The LFC is the height at which a parcel of air lifted dry-adiabatically from the surface until saturated and lifted saturation-adiabatically thereafter would first become warmer (less dense) than the environment (AWS, 1969). The parcel would then continue to rise freely above this level until it becomes colder (more dense) than the environment.

If the parcel is to be lifted then the LFC is the height where the moist adiabat taken from the LCL below intersects the sounding curve. If the parcel is heated then the LFC is the height where the moist adiabat taken from the CCL below intersects the sounding. The LCL is the height at which a parcel of air becomes saturated when lifted dry-adiabatically. The CCL is the point of intersection of a sounding with the saturation mixing ratio line corresponding to the average mixing ratio in the surface layer. The program that computes PBE uses an average mixing ratio over a mixed layer of 50 mb. This is the height of the base of cumuloform clouds which are produced by thermal convection solely from surface heating. The EL is the height where the temperature of a buoyantly rising parcel again equals the environmental

temperature, the height at where the moist adiabat from the LFC intersects the sounding above.

Computed from equation 2.4, PBE represents the maximum buoyant energy possible assuming the sounding profile does not change above the LFC. Hence, PBE is the positive area on a sounding, if one assumes that the convective temperature is reached (figure 2.8). Appendix 6.4 lists the program used to find PBE. The positive area of a sounding is

Figure 2.8. Positive area of a sounding defining Potential Buoyant Energy (PBE).

the area between the moist adiabat and the sounding between the LFC and the EL. This area is proportional to the amount of kinetic energy the parcel gains from the environment, whereas the negative area is the amount of kinetic energy that must be supplied to a parcel of air in a stable layer along an adiabat to maintain parcel ascent. Both positive area (PBE) and negative area values are output from the PBE program, and either represents the amount of potential buoyant energy in the sounding or the energy needed to make the sounding more potentially buoyant. For purposes of this research, PBE (positive area) is the

parameter of interest supplemented by low-level vertical wind shear to classify tornadic storms.

2.4 Description of Regression Techniques

Data from each outbreak case were plotted. Specifically, UMAX and MDA were plotted against each other with isolines of F_w superposed upon the plot. The plots were used to indicate what values of UMAX and MDA were needed to characterize a storm as tornadic or non-tornadic, and if so, how intense it would become. In addition, values of PBE and shear were plotted against each other in hopes of differentiating tornadic from non-tornadic storms.

2.4.1 Analysis of Plotted Rising-Ridge Surfaces

When a cell's UMAX and MDA were plotted against each other with respect to that cell's intensity, namely F_w , a standard surface arised. Figure 2.9 illustrates this relationship, called a "rising-ridge" surface (Box and Draper, 1987). This "rising-ridge" surface has a separation point, called a breakpoint value, that distinguishes cells from being tornadic from non-tornadic. As can be seen in figure 2.9, the tornadic intensity of the storms increase as one ascends the ridge. In this case, a separation point between tornadic and non-tornadic falls where UMAX equals 16 and MDA equals 20. In other words, any value of UMAX greater than or equal to 16 and MDA greater than or equal to 20 will determine a cell's behavior as being tornadic. In fact, depending on where any point falls on the surface one can find that cell's tornadic intensity as it pertains to that cell's breakpoint value. The lines of tornadic intensity (F_w) were drawn subjectively to

Figure 2.9. A "rising-ridge" surface defined by UMAX, MDA and F_w . The separation point, or breakpoint value, of UMAX=16 and MDA=20 defines the cutoff values needed for UMAX and MDA to fall on the "tornadic" surface.

the data points, trying to give a best fit of the lines to the data. These "eyeballed" lines describe the rising-ridge surface of the outbreak.

As a result, a different breakpoint value arose for each outbreak case. Consequently each outbreak's surface was oriented in space differently from the others, hence the nine cases had different breakpoint values. These different breakpoints led to correlation problems when all nine cases were combined into one grouped data set. In fact, when applied to an operational forecast scheme, one would have to know, a priori, the breakpoint value of a given storm in order to arrive at some prediction as to a cell's tornadic potential. Since we

do not know the breakpoint of a given outbreak until after it is over, this scheme cannot be operationally used to predict the tornadic intensities of thunderstorms.

2.4.2 Quadvariate Regression Model

A four-variable statistical model was developed in order to achieve one of the research goals set forth in this study: to arrive at some prediction of the expected tornadic intensity of a given thunderstorm cell by pre-determined measurement. This model involved a quadvariate regression scheme where, in addition to UMAX and MDA as predictors, PBE and low-level wind shear were added to predict the variance in tornadic intensities among the nine data cases. This model is described by the following equations:

$$\hat{y} = B_0 + B_1x_1 + B_2x_2 + B_3x_3 + B_4x_4 + \epsilon \quad (2.5)$$

and,

$$\begin{aligned} \hat{y} = & B_0 + (B_1x_1 + B_2x_2 + B_3x_3 + B_4x_4) + \\ & (B_{11}x_1^2 + B_{22}x_2^2 + B_{33}x_3^2 + B_{44}x_4^2) + \\ & (B_{12}x_1x_2 + B_{13}x_1x_3 + B_{14}x_1x_4 + \\ & B_{23}x_2x_3 + B_{24}x_2x_4 + B_{34}x_3x_4) + \epsilon \end{aligned} \quad (2.6)$$

where $\hat{y}$ is the response variable F_w or F_w^2 , x_1 , x_2 , x_3 and x_4 are the four predictor variables. Equation 2.5 is the linear regression model with 5 terms in the equation, whereas equation 2.6 is the quadratic regression model with 15 terms in the equation. In this regard, quadratic regression is not applicable in the individual outbreak cases

since in four of the outbreaks there are more variables (15 terms in the equation) than observations, resulting in an "overfit" of the model to the data. For the bivariate model, one would need to have 40 observations in the data set to overcome the overfit problem. Similarly, the quadvariate model would require at least 100 observations in the data set. In the remaining data cases, there were still not enough observations in the data set to justify using the quadratic model.

Quadratic regression was carried out only on the combined and stratified data sets. However, the same caveat exists: there are too few points in the data set to justify quadratic regression. As in the bivariate regression scheme, quadvariate analysis (linear and quadratic) was also carried out on the non-dimensionalized and stratified data sets in an attempt to improve R^2 , the coefficient of determination.

2.4.3 Stratification Technique

Since the grouping of the data into one data set did not significantly improve the coefficient of determination even after non-dimensionalization, another method was developed to eliminate the individuality of outbreak breakpoint values. Since each outbreak case had a different surface, and consequently, a different breakpoint, a method of grouping the outbreak cases by stratification was developed. This was done by computing the distance of each outbreak's breakpoint value from the origin. This distance was determined from the following formula:

$$d = (UMAX_{wp}^2 + MDA_{wp}^2)^{1/2} \quad \{2.7\}$$

Once the nine d-values were obtained, the cases were then grouped by how close each case's d-value was to each other's. This was then applied to multivariate regression models to assess how well the grouped data sets fit the models.

3. RESULTS OF STRATIFICATION TECHNIQUE

The analyses results for UMAX, MDA, shear and PBE are shown in appendix 6.5. It contains the following information about each cell per outbreak: observation time, upper air station(s) used in the shear and PBE analysis, maximum radial velocity (UMAX), measured deviation angle (MDA), low-level vertical wind shear and potential buoyant energy (PBE). In all but the North Carolina case, 1200Z soundings were used.

3.1 Analysis of UMAX and MDA to F_w

When the relationship between UMAX and MDA were plotted as a function of tornadic intensity, all nine outbreaks exhibited the rising-ridge pattern, but with different orientations with respect to one another. Figures 3.1 through 3.9 depict the plots of UMAX and MDA with respect to F_w . As a result of the disparity in spatially oriented plots, each outbreak resulted in a different breakpoint. Table 3.1 lists each outbreak's breakpoint and d-value.

Table 3.1. Breakpoint and D-Values of Each Tornado Outbreak

Outbreak Case		Breakpoint Value		Outbreak d-Value
Study		UMAX	MDA

Figure 3.1. Rising-ridge plot analysis of UMAX, MDA versus F_w for the Oklahoma outbreak of 26 April, 1984. Letters indicate the cell of the outbreak. Values are the tornadic intensities of the associated cells (F_w). Cells without values were non-tornadic.

Figure 3.2. Rising-ridge plot analysis of UMAX, MDA versus F_w for the Wisconsin-Illinois outbreak of 27 April, 1984. Letters indicate the cell of the outbreak. Values are the tornadic intensities of the associated cells (F_w). Cells without values were non-tornadic.

Figure 3.3. Rising-ridge plot analysis of UMAX, MDA versus F_w for the Iowa outbreak of 7 June, 1984. Letters indicate the cell of the outbreak. Values are the tornadic intensities of the associated cells (F_w). Cells without values were non-tornadic.

Figure 3.4. Rising-ridge plot analysis of UMAX, MDA versus F_w for the Nebraska outbreak of 10 May, 1985. Letters indicate the cell of the outbreak. Values are the tornadic intensities of the associated cells (F_w). Cells without values were non-tornadic.

Figure 3.5. Rising-ridge plot analysis of UMAX, MDA versus F_w for the Ohio-Pennsylvania-New York outbreak of 31 May, 1985. Letters indicate the cell of the outbreak. Values are the tornadic intensities of the associated cells (F_w). Cells without values were non-tornadic.

Figure 3.6. Rising-ridge plot analysis of UMAX, MDA versus F_w for the South Dakota outbreak of 28 July, 1986. Letters indicate the cell of the outbreak. Values are the tornadic intensities of the associated cells (F_w). Cells without values were non-tornadic.

Figure 3.7. Rising-ridge plot analysis of UMAX, MDA versus F_w for the Kansas outbreak of 18 September, 1986. Letters indicate the cell of the outbreak. Values are the tornadic intensities of the associated cells (F_w). Cells without values were non-tornadic.

Figure 3.8. Rising-ridge plot analysis of UMAX, MDA versus F_w for the Texas-Louisiana outbreak of 17 November, 1987. Letters indicate the cell of the outbreak. Values are the tornadic intensities of the associated cells (F_w). Cells without values were non-tornadic.

Figure 3.9. Rising-ridge plot analysis of UMAX, MDA versus F_w for the North Carolina-Virginia outbreak of 28 November, 1988. Letters indicate the cell of the outbreak. Values are the tornadic intensities of the associated cells (F_w). Cells without values were non-tornadic.

The isolines of F_w were subjectively drawn to fit the values of F_w to the surface of the plot. This "eyeballing" of the isolines to the data does not lend itself to scientific accuracy. It is only a descriptive analysis of how UMAX and MDA relate to tornadic intensity.

The breakpoint value of each outbreak case is based on the point between the "1" isoline and zero-values of F_w . In some cases (notably the OK and WI-IL outbreaks) an average breakpoint was determined when there was a large space between the non-occurrences and the F0 line. Note that the "1" isoline represents the beginning of tornado activity, or F0 scale, with each successive value of isoline corresponding to the F_w scale.

In order to determine which method of classifying tornadic intensities was best, i.e. F_w or F_w^2 , bivariate regression was performed on the nine individual cases involving the predictor variables UMAX and MDA. Linear regression analysis was carried out using F_w and F_w^2 as the response variables. The results of these analyses are shown in Table 3.2. These results indicate that the

Table 3.2. Percent of variation (coefficient of determination or R^2) in tornadic intensity (F_w and F_w^2) that can be explained by the predictor variables UMAX and MDA for linear bivariate regression.

Case		R^2		
		F_w	F_w^2	Difference
OK	(84117)	0.4065	0.3680	0.0385
WI-IL	(84118)	0.8948	0.8031	0.0917
IA	(84159)	0.7214	0.6412	0.0802
NE	(85130)	0.8861	0.8270	0.0591
OH-PA-NY	(85150)	0.7658	0.7267	0.0391
SD	(86209)	0.7058	0.7268	-0.0210
KS	(86261)	0.6326	0.5531	0.0795
TX-LA	(87319)	0.7193	0.7490	-0.0297
NC-VA	(88333)	0.7724	0.8254	-0.0530

linear bivariate regression has highly variable results from case to case and that F_w is a better indicator of tornadic intensity than F_w^2 , in most of the outbreak cases. On the average, F_w accounted for 72% of the variance in tornadic intensity by UMAX and MDA, whereas F_w^2 accounted for just over 69% of the variance.

One reason F_w was a better response variable than F_w^2 lies in the data. By looking at any of the plotted data of UMAX and MDA to F_w and F_w^2 , one observes there are more zero values than non-zero values. The statistical distribution of this and any other outbreak population tends to put the non-zero values in the tails of the distribution curve whereas the zeroes appear near the mean in a normal population. In terms of using F_w versus F_w^2 , F_w values are not as large as the F_w^2 results, and consequently do not embody as large a data distribution between zero and non-zero values. In other words, F_w values are not as prone to appear in the extreme regions of the tails as F_w^2 values tend to be, thereby eliminating some of the error in the statistical analysis.

Figures 3.10 through 3.13 show this distinction. These figures are three-dimensional plots of the predictor variables UMAX and MDA (x- and y-axis) to the response variable F_w or F_w^2 (z-axis). The plane that is depicted on each plot is the linear surface that best fits the data by the regression coefficients (intercept and parameter coefficients; see equation 1.1). Also plotted are the residuals of observed tornadic cells to the predicted F_w (or F_w^2) of that cell. As can be seen from the plots, the residuals are smaller in the F_w analysis than the F_w^2 analysis.

Figure 3.10. Three-dimensional plot of the regression analysis for the WI-IL outbreak. The predictor variables UMAX (x-axis) and MDA (y-axis) were plotted against the response variable F_w (z-axis). The letters above the linear regression plane were the tornadic cells actually observed for UMAX, MDA and F_w , with the shown departures of these cells from the plane.

Figure 3.11. Three-dimensional plot of the regression analysis for the WI-IL outbreak. The predictor variables UMAX (x-axis) and MDA (y-axis) were plotted against the response variable F_w^2 (z-axis). The letters above and below the linear regression plane were the tornadic cells actually observed for UMAX, MDA and F_w^2 , with the shown departures of these cells from the plane.

Figure 3.12. Three-dimensional plot of the regression analysis for the NC-VA outbreak. The predictor variables UMAX (x-axis) and MDA (y-axis) were plotted against the response variable F_w (z-axis). The letters above and below the linear regression plane were the tornadic cells actually observed for UMAX, MDA and F_w , with the shown departures of these cells from the plane.

Figure 3.13. Three-dimensional plot of the regression analysis for the NC-VA outbreak. The predictor variables UMAX (x-axis) and MDA (y-axis) were plotted against the response variable F_w^2 (z-axis). The letters above the linear regression plane were the tornadic cells actually observed for UMAX, MDA and F_w^2 , with the shown departures of these cells from the plane.

3.2 Analysis of Shear and PBE to FW

Shear and PBE were plotted against each other to see if they both exhibited a function of tornadic or non-tornadic distinction for each outbreak. By utilizing the same distinction line between tornadic and non-tornadic occurrences used by Rasmussen and Wilhelmson in 1983, each outbreak's observations were plotted to see how they fit the graph (figures 3.14 - 3.22). The results were promising, but some problems became evident. The Iowa outbreak did not show this distinction very well for tornadic cells B, C, J and J' as they fell in the non-tornadic region of the graph. Cell G fell in the meso-cyclone part of the graph, and cell D fell in the tornadic area. The Kansas outbreak did a little better, with two cells falling in the extreme tornadic area and two in the extreme non-tornadic region. These two "non-tornadic" cells developed in Colorado, and cells that developed there tend to be of a different variety, as PBE is not a very good indicator of instability in the high plains of the west (Rasmussen, 1988). The Wisconsin, South Dakota and Texas outbreaks showed excellent fits to the graph. Most of the others had good fits as well, but some cells fell in the meso-cyclone region and some fell in the tornadic region of the graph.

However, the Ohio-Pennsylvania-New York outbreak failed to show any connection of PBE and shear to tornadic activity. Not only were there no cells in the tornadic region, but none of the cells displayed very high PBE values. There was evidence, however, of strong low-level shear, particularly in the observed tornadic cells. Another thing to note is that although this was one of the largest outbreaks of the decade, PBE did not well characterize the situation. One of the

Figure 3.14. Potential Buoyant Energy (PBE) and low-level (0-4 km) vertical wind shear analysis for the IA outbreak. Letters indicate the cell of the outbreak. Undefined cells were tornadoic. Figure 3.22. Potential Buoyant Energy (PBE) and low-level (0-4 km) vertical wind shear analysis for the OH-PA-NY outbreak. Letters indicate the cell of the outbreak. Underlined cells were tornadic. From Rasmussen and Wilhelmson, 1983, the solid upper line separates tornado- from mesocyclone-producing storms. The region below the lower solid line represents non-tornadic storms. (after Rasmussen & Wilhelmson, 1983).

reasons may be due to the presence of strong capping inversions in the lower layer during this outbreak, thereby "choking" off the positive area (PBE) of the sounding. However once the inversion was broken, very strong instability resulted in the very explosive development of these storms.

Bivariate linear regression was similarly carried out on the nine cases with PBE and shear as the predictor variables and F_w and as the response variables. Table 3.3 lists the results of this analysis.

Table 3.3. Percent of variation (coefficient of determination or R^2) in tornadic intensity (F_w) that can be explained by the predictor variables PBE and shear for linear bivariate regression.

Case		R^2 FW
OK	(84117)	0.2852
WI-IL	(84118)	0.2581
IA	(84159)	0.5259
NE	(85130)	0.4266
OH-PA-NY	(85150)	0.1868
SD	(86209)	0.9766
KS	(86261)	0.1695
TX-LA	(87319)	0.0613
NC-VA	(88333)	0.0798

These results show a highly variable accounting for the variance in the data from case to case, even more so than UMAX and MDA did as predictors. Only 34% of the variance was accounted for when F_w was used as a response variable predicted by shear and PBE. However, as evident in the data, the coefficient of determination of shear and PBE to tornadic intensity did not even account for the accuracy that UMAX and MDA possessed in describing thunderstorm behavior. This could be due to many reasons, one of which is the temporal problem of having

only two soundings available per day (excluding more timely soundings taken during special research experiments) versus the almost real-time analysis available with satellite imagery in determining UMAX and MDA. The other problem is spatial, that is, the sounding spacing network in existence today is not very refined, especially in the mesoscale region of analysis. This is particularly apparent when one radiosonde station is used for many developing cells, one of which may produce a tornado. However, for whatever the reason, we are led to a very important point: PBE and shear, derived exclusively from pre-storm data are not reliable generalized discriminators of tornadic behavior.

3.3 Statistical Analysis of F_w to UMAX, MDA, PBE and Shear

A "fine tuning" in the coefficient of determination of tornadic intensity to thunderstorm characteristics was done by using a quadvariate regression model with UMAX, MDA, PBE and shear as the predictor variables and F_w as the response variable (equation 2.5). Table 3.4 shows the results of quadvariate linear regression analysis

Table 3.4. Percent of variation (coefficient of determination or R^2) in tornadic intensity (F_w) that can be explained by the predictor variables UMAX, MDA, PBE and shear for linear quadvariate regression.

NC-VA	(88333)	0.8030

on the nine outbreak cases. In contrast to the earlier bivariate results, the quadvariate linear regression was not as variable from case to case. Overall, F_w gave an estimate of tornadic intensity of 81%. In only one case, (OK), was the coefficient of determination drastically smaller than the other eight cases. This may be due to errors in the measurement of UMAX and MDA through the predominant use of poor resolution (4 km) IR satellite imagery over visible satellite imagery (1 km). Overall, three cases showed greater than 90% of the variance accounted for in the data, and six cases showed greater than 80% of the variance accounted for in the data.

Table 3.5 shows the overall comparison results of the two bivariate

Table 3.5. Percent of variation (coefficient of determination or R^2) in tornadic intensity (F_w) for linear regression of different regression schemes using UMAX, MDA, PBE and shear as the predictor variables.

Case	Coefficient of Determination (R^2)		
	UMAX/MDA	Shear/PBE	UMAX/MDA/Shear/PBE
OK (84117)	0.4065	0.2852	0.4756
WI-IL (84118)	0.8948	0.2581	0.9071
IA (84159)	0.7214	0.5259	0.8671
NE (85130)	0.8861	0.4266	0.9033
OH-PA-NY (85150)	0.7658	0.1868	0.8636
SD (86209)	0.7058	0.9766	0.9845
KS (86261)	0.6326	0.1695	0.7574
TX-LA (87319)	0.7193	0.0613	0.7230
NC-VA (88333)	0.7724	0.0798	0.8030

regression models and the quadvariate model. The apparent improvement in using the four variable model over the two variable model varied from case to case, from as little as 1% in the Wisconsin-Illinois case to as much as 15% in the Iowa outbreak. Overall the use of the quadvariate model over the bivariate regression model merely "fine-

tuned" the variation accounted for in the data.

3.4 Stratification of the Data

Up to now, the ability to relate the tornadic intensity of a given cell to a set of predictors depends on complete data. That is, once the breakpoint value of a given outbreak is known, then a reasonable hindcast as to that cell's tornadic intensity can be determined within that outbreak. However, as has been shown, the breakpoint varies from outbreak to outbreak (table 3.1). This does not lead to a very practical way of determining the possible tornadic intensities of thunderstorm cells if one does not know the breakpoint value beforehand, which makes forecasting them impossible.

Since each outbreak has a different breakpoint value and surface, the combined data was stratified based on each outbreak's d-value (see Table 3.1). Table 3.6 shows how the combined data set was stratified.

Table 3.6. D-value results of stratification of combined data set and their respective range within strata.

<u>Stratified Case</u>	<u>d-Value Range</u>	<u>d-Value Difference</u>
I (WI-IL; OH-PA-NY)	30.23 - 31.30	1.07
II (OK; IA)	17.00 - 19.21	2.21
III (SD; TX-LA)	20.52 - 21.47	0.95
IV (NE; KS; NC-VA)	12.21 - 13.40	1.19

Note that the range of d within a given case varied between 0.95 to 2.21, showing that the difference among a stratified group is small.

As was done with the individual outbreak cases, UMAX and MDA were plotted as a function of tornadic intensity within each stratified data set and all four exhibited a rising-ridge surface. Figures 3.23 -3.26

Figure 3.23. Rising-ridge plot analysis of UMAX, MDA versus F_w for the stratified data set I (OH-PA-NY; WI-IL). Letters indicate the cell of the outbreak, which are preceded by an O (OH-PA-NY) or a W (WI-IL). Values are the tornadic intensities of the associated cells (F_w). Cells without letters and values were non-tornadic.

Figure 3.24. Rising-ridge plot analysis of UMAX, MDA versus F_w for the stratified data set II (OK; IA). Letters indicate the cell of the outbreak, which are preceded by an O (OK) or an I (IA). Values are the tornadic intensities of the associated cells (F_w). Cells without letters and values were non-tornadic.

Figure 3.25. Rising-ridge plot analysis of UMAX, MDA versus F_w for the stratified data set III (SD; TX-LA). Letters indicate the cell of the outbreak, which are preceded by a S (SD) or a T (TX-LA). Values are the tornadic intensities of the associated cells (F_w). Cells without letters and values were non-tornadic.

Figure 3.26. Rising-ridge plot analysis of UMAX, MDA versus F_w for the stratified data set IV (NE; KS; NC-VA). Letters indicate the cell of the outbreak, which are preceded by a N (NE), a K (KS) or a C (NC-VA). Values are the tornadic intensities of the associated cells (F_w). Cells without letters and values were non-tornadic.

depict this relationship. As can be seen from the plots, a fairly good fit of the data arises due to this stratification. However, stratified case IV did not fit a normal, smooth surface as exhibited by the other cases. This may be due to analysis errors of UMAX and/or MDA.

In order to determine how well the slopes and intercepts of each outbreak surface matched each other, the outbreak's cells within each stratified data set were further classified as either tornadic or non-tornadic. That is, if a cell's F_w value was non-zero, then that cell was classified as tornadic (denoted as "1"). If the cell had a zero F_w then it was classified as non-tornadic (denoted as "0"). Further, outbreaks were given numbers within each stratified data set. That is, if there were two outbreaks in a given strata, then there were two numbers designating outbreak occurrence. Appendix 6.6 gives an explanation of the tests used for this statistical procedure. This type of classification was used solely to predict tornadic or non-tornadic occurrence, and not severity. Earlier it was shown that F_w was a better variable in denoting tornadic intensity than F_z^2 . Similarly, a classification of tornadic or non-tornadic occurrence in the data will further limit the range of values for F_w . This test showed that the outbreak slope surfaces within the stratified data sets were not different from one another (table 3.7), and that the groups of tornadic and non-tornadic cells were different from case to case. By picking a p-value of 0.05 (the smallest significant level at which our results would lead to a rejection of the hypothesis that the variables examined are not needed (in this case any p-value < 0.05),

Table 3.7. Type I sums of squares and p-values of UMAX, MDA, Outbreak and their interaction in determining whether outbreak intercepts were the same within a stratified data set.

Stratified Case I Variable	degrees of freedom	Type I Sums of Squares	p-value
UMAX	1	4.0212	0.0001
MDA	1	1.5810	0.0001
Outbreak	1	0.1704	0.1446
UMAX*Outbreak	1	0.0100	0.7195
MDA*Outbreak	1	0.3325	0.0447
Stratified Case II Variable	degrees of freedom	Type I Sums of Squares	p-value
UMAX	1	3.1958	0.0001
MDA	1	0.4267	0.0458
Outbreak	1	0.0248	0.6149
UMAX*Outbreak	1	0.0015	0.9001
MDA*Outbreak	1	0.3643	0.0632
Stratified Case III Variable	degrees of freedom	Type I Sums of Squares	p-value
UMAX	1	2.0389	0.0001
MDA	1	0.8485	0.0061
Outbreak	1	0.3045	0.0831
UMAX*Outbreak	1	0.0142	0.6984
MDA*Outbreak	1	0.0120	0.7225
Stratified Case IV Variable	degrees of freedom	Type I Sums of Squares	p-value
UMAX	1	1.7592	0.0001
MDA	1	1.8101	0.0001
Outbreak	2	0.2339	0.1835
UMAX*Outbreak	2	0.0522	0.6747
MDA*Outbreak	2	0.0528	0.6717

the results from table 3.7 show a strong difference in UMAX and MDA from outbreak to outbreak but not in outbreak intercepts (denoted as OUTBREAK in table 3.7). The interaction of outbreak upon UMAX and MDA (differences in slopes of UMAX and MDA) also shows little difference. This suggests that within a strata, outbreaks do not play a role in determining tornadic occurrence.

One can also look at the type I sums of squares to get an idea as to what may need to be included in the analysis. If the type I sums of squares is relatively high, then we would tend to keep that data. If it was low, then that data could be left out of the analysis. So, the type I sums of squares in table 3.7 shows that there are differences of UMAX, MDA among each stratified data set. This means that UMAX and MDA are good indicators of tornadic occurrence. However, outbreak intercepts among the stratified data sets are about the same, showing little difference in tornadic occurrence from outbreak to outbreak. Therefore, one would expect the data from one outbreak to overlay exactly on another case.

It should be noted that the above test was also done on tornadic severity (F_w) vice tornado occurrence for all the stratified cases. However, the results were not as obvious using F_w , since there may be some question as to whether or not the slopes may be different in the stratified cases.

By performing regression analysis on these four stratified groups of data, significant results appear. These are shown in table 3.8.

Table 3.8. Coefficients of determination from bivariate and quadivariate regressions of various orders for stratified data from combined data set using F_w as the response variable.

Case	Predictor	R ²	
		Linear	Quadratic
I	UMAX, MDA	0.7573	0.8626
	Shear, PBE	0.1596	0.2147
	UMAX, MDA, Shear, PBE	0.7984	0.9475
II	UMAX, MDA	0.5813	0.7976
	Shear, PBE	0.2047	0.4259
	UMAX, MDA, Shear, PBE	0.6641	0.9115

Table 3.8 (continued).

III	UMAX, MDA	0.6323	0.7850
	Shear, PBE	0.1981	0.3496
	UMAX, MDA, Shear, PBE	0.7343	0.9343
IV	UMAX, MDA	0.7206	0.8191
	Shear, PBE	0.1540	0.2919
	UMAX, MDA, Shear, PBE	0.7577	0.9263

The overall results from this table are summarized in table 3.9. The comparison of the linear regression analysis between individual and stratified data sets shows encouraging results. There was only a 5% difference in the overall percentage of variance explained by using UMAX and MDA as the predictors for F_w . Only a 7% difference ensued

Table 3.9. Overall percentage of variance explained (R^2) of linear bivariate and quadivariate regressions between stratified data sets and individual outbreak data sets using F_w as the response variable.

Outbreak Analysis	Average R^2	
	UMAX, MDA	UMAX, MDA, PBE, Shear
Individual Cases	0.7227	0.8094
Stratified Cases	0.6729	0.7386

Difference	0.0498	0.0708

when PBE and shear was added to the bivariate model. No comparison could be done with the quadratic regression analysis since it could not be used for the individual outbreak data sets.

In contrast to the regression results of the stratified data sets, regression was also carried out on the combined data set to see how the two data grouping schemes would differ.

For example, when the outbreaks were grouped into one data set and examined under a regression scheme the results were not good. First

and second order multivariate regression was done on the combined data set and it showed little significant results, as shown in table 3.10.

Table 3.10. Coefficients of determination (R^2) from bivariate and quadivariate regressions of various orders for combined data from all cases using F_w as the response variable.

Predictor	R^2	
	Linear	Quadratic
UMAX, MDA	0.5792	0.6003
Shear, PBE	0.0120	0.0605
UMAX, MDA, Shear, PBE	0.5809	0.6322

Even the addition of PBE and shear in the quadivariate model did little to improve the R^2 values. These poor results may be explained by the fact that each outbreak took place under different synoptic weather conditions. Furthermore, these poor results imply the non-conformity of the individual rising-ridge surfaces when overlaid.

In contrast to the test of surface slopes among individual stratified data sets, a similar test was performed on the one combined data set. Table 3.11 shows the results. Again picking a p-value of

Table 3.11. Type I (sequential) sums of squares and p-values of UMAX, MDA, Outbreak and their interaction in determining whether outbreak intercepts were the same within the combined data set.

Variable	degrees of freedom	Type I Sums of Squares	p-value
UMAX	1	11.9258	0.0001
MDA	1	3.0655	0.0001
Outbreak	8	3.0132	0.0001
UMAX*Outbreak	8	0.7257	0.3470
MDA*Outbreak	8	0.7801	0.2952

0.05 as significant, the results show that there are differences in

outbreak intercepts among the data, as well as a strong dependence on UMAX and MDA as predictors of tornadic occurrence. This is substantiated by the relatively high Type I sums of squares for UMAX, MDA and OUTBREAK. Therefore, one would not necessarily expect the data from one outbreak to overlay exactly on another case. These differences in surfaces explains the relatively poor regression results in the combined data set.

In an attempt to bring all nine cases into some type of common form, the data was non-dimensionalized by case breakpoint value. Table 3.12 shows the results of this procedure. As can be seen from this and table 3.10, regression results of the non-dimensionalized data improved somewhat over those of the combined data set, but not enough as compared to the results of individual cases.

Table 3.12. Coefficients of determination from bivariate and quad-variate regressions of various orders for non-dimensionalized combined data using F_w as the response variable.

Predictor	R ²	
	Linear	Quadratic
UMAX, MDA	0.6412	0.7147
Shear, PBE	0.0120	0.0605
UMAX, MDA, Shear, PBE	0.6437	0.7514

As can be seen from the analysis of stratified data sets and the combined and non-dimensionalized data sets, the stratification of the data yields good results when compared to the individual cases. This was especially true when examining the results from the combined and non-dimensionalized data sets to individual outbreaks. Therefore, this suggests that within these stratified groups, some similar type of

meteorological phenomena may be occurring in order to bring the response surfaces closer together (similar slopes and intercepts) within the strata.

4. CONCLUSIONS

The basic goal of this study was to eliminate the two-step process that Schrab (1988) and Anderson and Schrab (1988) described in relating UMAX and MDA in a bivariate regression model to predict tornadic intensities of thunderstorms. Thunderstorm anvil behavior parameterized by UMAX (the downstream mass flux of an anvil outflow plume) and MDA (the rightward deviation angle of the anvil from the storm-relative flow) showed a relationship on a plotted surface that distinguished tornadic from non-tornadic cells. The use of a four variable (quadvariate) regression model with UMAX, MDA, PBE and shear as the predictor variables was not sufficient to predict the tornadic intensity of a given observed cell, regardless of its outbreak family. Therefore, the elimination of the two-step process did not occur.

The first conclusion was that the best variable for denoting tornadic intensity was the weighted mean value (F_w). Better R^2 values resulted when F_w was used rather than a weighted mean square system of measurement, called F_w^2 . This was probably due to the data distribution occurring in the extreme tails of the distribution curve for F_w^2 . This was not the case in using F_w as a measure of tornadic intensity.

Another conclusion was a fine-tuning of the analysis results occurred with the use of the quadvariate model, due to the addition of PBE and low-level vertical wind shear. The amount of fine tuning varied from 1% to as much as 15%. Attempts to combine the data into one lumped group failed to improve the coefficient of determination. It fell to just over 58% with the four variable model. Non-

dimensionalization of this combined data set only improved R^2 slightly to 0.64. Only linear regression could be used due to the limited amount of observations available per outbreak.

The other conclusion was that the data could be combined in such a way as to improve the coefficient of determination. This was done by stratifying the data sets based on outbreak breakpoint value. Specifically, the distance of each individual outbreak's breakpoint value from the origin was computed. This led to the grouping into four stratified data sets. The stratification of combined data set yielded promising results. Linear regression gave encouraging results, especially when compared to the individual regression analysis. The bivariate predictors UMAX and MDA on stratified groups gave an average correlation of 67%, whereas the quadvariate model accounted for 74%. This came within 5% of the individual case bivariate regression results, and within 7% for the quadvariate regression analysis. This seemed to validate the idea that the stratified data sets best describes a certain outbreak situation. These situations may be different types of meteorological parameters such as mesoscale lows, mid-level disturbances, and squall line formation.

Quadratic regression could not be carried out on the stratified cases since the number of observations per strata were insufficient to overcome the problem of overfitting the data to the models. For bivariate regression analysis we need 40 observations to justify using quadratic regression. The quadvariate model will require at least 100 observations to justify the use of quadratic regression analysis.

5. FUTURE RESEARCH

Data stratification of the nine outbreak studies yielded promising results, especially when compared to the regression results of the combined data set. There seems to be a good relationship among outbreaks within strata, suggesting that other factors may be common to outbreak cases within each stratified data set. However, the breakpoint value of a given outbreak has to be found in order to classify it into one of the stratified data sets. As a consequence, the two-step process is still needed to predict tornadic intensities of observed thunderstorm cells.

In order to implement some sort of operational forecast to determine which observed cell will produce a tornado, further research must be done to try to find a way to predict the outbreak's breakpoint value. Some sort of analysis of these stratified groups is in order to relate what we now have to other known meteorological parameters. Work by Maddox and Doswell (1983) and Miller (1972) suggest that other meteorological phenomena may be present to explain the unique triggering mechanisms that occur from case to case. Table 5.1 lists some of these parameters.

Table 5.1. Summary of key parameters (after Miller, 1972)

Rank	Parameter	Weak (W)	Moderate (M)	Strong (S)
1	500 mb vorticity advection	Neutral or NVA	PVA-Contours Cross Vorticity Pattern $\leq 30^\circ$	PVA-Contours Cross Vorticity Pattern $> 30^\circ$
2	Stability- Totals Index	TI ≤ 50	50 < TI ≤ 55	TI > 55

Table 5.1. (continued)

Rank	Parameter	Weak (W)	Moderate (M)	Strong (S)
3	500 mb wind speed	WS $\leq$ 35 kt	35 < WS $\leq$ 50 kt	WS > 50 kt
4	300-200 mb wind speed (upper-level max)	WS $\leq$ 55 kt	55 < WS $\leq$ 85 kt	WS > 85 kt
5	850 mb wind speed	WS $\leq$ 20 kt	20 < WS < 35 kt	WS $\geq$ 35 kt
6	850 mb dewpoint	Td $\leq$ 8°C	8 < Td $\leq$ 12°C	Td > 12°C
7	850 mb temp ridge location	East of moist axis	Over moist axis	West of moist axis
8	700 mb temp no. change line(12-h)	Winds cross line $\leq$ 20°	Winds cross line > 20 & $\leq$ 40°	Winds cross line > 40°
9	700 mb dry intrusion	N/A or weak 700 mb winds	Winds from dry to moist intrude at angle of < 40° and are $\geq$ 15 kt	Winds intrude at an angle of $\geq$ 40° and are $\geq$ 25 kt
10	12-h surface pressure fall	< 1 mb	1 to 5 mb	> 5 mb
11	500 mb height change (12-h)	< 30 m	$\geq$ 30 m & $\leq$ 60 m	> 60 m
12	Surface pressure over threat area	$\geq$ 1010 mb	< 1010 mb and $\geq$ 1005 mb	< 1005 mb
13	Surface dewpoint	Td $\leq$ 55°F	55 < Td < 65°F	Td $\geq$ 65°F

Continuation of this research should include determining some of the parameters present in each outbreak (from table 5.1) by attempting to relate these parameters in some way (either by regression analysis or perhaps some sort of discriminant analysis) to each stratified data case. This may lead to some type of forecastable breakpoint value to relate observed cells to an already determined stratified surface. If some sort of common phenomena occur within a stratified data set, this may lead to a possible solution to this problem. Such criteria should

focus upon the important physical mechanisms leading to the development of strong storms within an environment. The importance of favorable surface patterns and pronounced thermal boundaries, mesoscale features such as vertical motion forced by lower-tropospheric warm air advection need to be further investigated.

Appendix 6.1

Distribution of Tornadoes, Intensities and Injuries

This appendix breaks out the distribution of tornadoes and their intensities associated with each thunderstorm cell at the observed time of development. Along with each cell's tornadic intensities, a list of deaths and injuries with that cell is included. All times given are Greenwich Mean Time (GMT).

Appendix 6.2

Fujita Tornado Scale Rating System

The Fujita-scale (F-scale) wind speed classification system was designed to assess tornado wind speeds in a standardized rating scheme. The following are F-scale damage specifications in relating the strength of a tornado to the apparent damage associated with its wind speed as represented by Fujita (1981):

- (F0) Gale Tornado 18-32 m s^{-1} (40-72 mph): Light damage. Some damage to chimneys; break branches off trees; push over shallow-rooted trees; damage sign boards.
- (F1) Moderate Tornado 33-49 m s^{-1} (73-112 mph): Moderate damage. The lower limit (73 mph) is the beginning of hurricane wind speed; peel surface off roofs; mobile homes pushed off foundations or overturned; moving autos pushed off the roads.
- (F2) Significant Tornado 50-69 m s^{-1} (113-157 mph): Considerable damage. Roofs torn off frame houses; mobile homes demolished; boxcars pushed over; large trees snapped or uprooted; light-object missiles generated.
- (F3) Severe Tornado 70-92 m s^{-1} (158-206 mph): Severe damage. Roofs and some walls torn off well-constructed houses; trains overturned; most trees in forest uprooted; heavy cars lifted off ground and thrown.
- (F4) Devastating Tornado 93-116 m s^{-1} (207-260 mph): Devastating damage. Well-constructed houses leveled; structure with weak foundation blown off some distance; cars thrown and large missiles generated.
- (F5) Incredible Tornado 117-142 m s^{-1} (261-318 mph): Incredible damage. Strong frame houses lifted off foundations and carried considerable distance to disintegrate; automobile-sized missiles fly through the air in excess of 100 m; trees debarked; incredible phenomena occur.
- (F6-F12) 142 m s^{-1} to Mach 1, the speed of sound. The maximum wind speeds of tornadoes are not expected to reach the F6 wind speeds.

Appendix 6.3

Low-Level Vertical Wind Shear Program Listing

Program Shear;

{

 This program computes vertical wind shear in several forms:

- Low-level vertical wind shear (0-4km) --
 Either as an integrated sum of 200m levels, or as a vector difference between the surface and 4000m. The integral of the shear vector magnitudes will indicate the presence of "looping" in the sounding profile, indicative of low-level jet influences.
- User-specified levels of vertical wind shear --
 Either as an integrated sum of 200m levels or as a vector difference between the two specified levels.
 These previous two are by input data file as created by McIDAS in format as specified in INFO procedure below.
- User-input winds and levels via keyboard interface

 This program will also plot a raob sounding profile from the McIDAS data input file on screen.

 This program will also convert the input data file from McIDAS format to a format used by the PBE program on MEAVAX, ready to download and use to calculate PBE.

 The program interpolates the input sounding data (T,Td,P,winds,Z) approximately every 200m (50 mb) and integrates it over the total height dz. This method of computing shear was based on the techniques used by Blechman in 1979 and also by Rasmussen & Wilhelmson in 1983.

 This program was written in Turbo Pascal 4.0, implemented on an IBM PC/XT/AT with EGA capability.

 This program contains the following external files, and must be included on the same disk drive and/or directory in order to run:

 Turbo Pascal 4.0 Drivers:

CRT.DOC	(CRT interface driver)
GRAPH.TPU	(Graphics drivers)
PRINTER.DOC	(Printer driver)
EGAVGA.BGI	(EGA graphics drivers)

 Shear Program Externals:

CONVMCID.AS	(PBE data conversion procedure)
PLOT.ROB	(Raob sounding plotting procedure)

PBE Program Listing

```

#include <stdio.h>
#include <math.h>
#define YES 1
#define NO 0
#define intrp_incr_Pa 500.0 /* Interpolation Increment, Pa */

/* This program computes CAPE in several forms; it follows similar
/* procedures to a routine written by E. Rasmussen at the University
/* of Illinois in 1983 to compute Potential Buoyant Energy (PBE).
/* There are several possible methods of computing PBE or CAPE:
/* lifting a parcel having potential temperature and mixing ratio
/* properties similar to air near the ground as determined
/* by a sounding, to the LCL and then to the LFC above which
/* CAPE is summed.
/* assuming low-level conditions are those of a mixed layer, with
/* the top of the mixed layer being at the CCL/LFC. The
/* mixed layer is represented on a sounding by the inter-
/* section of the mean low-level mixing ratio with the temp
/* sounding; mixed-layer temperature then being given by
/* constant potential temperature from this level. This is
/* closely approximated at the time of maximum temperature;
/* this is much more representative than the morning lifted-
/* parcel technique, since convection often peaks at that time
/* using low-level conditions represented by surface temperature
/* and dewpoint at the time of the onset of convection, and
/* assuming the mixing ratio (computed from the dewpoint) is
/* representative of the parcels feeding the convection
/*
/* This routine will compute CAPE (PBE) through the lifting method.
/*
/* Techniques for computation were designed based on the equivalent
/* graphical techniques on thermodynamic diagrams.
/*
/* Erik Rasmussen
/* Colorado State University 1/89
/*
/* Minor modifications were done to Erik's original program. Only
/* to input/output and one conditional was added to the interpo-
/* lation routine concerning missing Td values (-999). Other-
/* wise the program is intact as written by Erik.
/* Attempts to implement this program on a PC were uneventful.
/* Currently program resides on MEAVAX, and will run on any
/* VMS/VAX based machine.
/*
/* Dale R. Perry
/* North Carolina State University 3/89

Appendix 6.5

UMAX, MDA, PBE, Shear Results For All Nine Outbreaks

This appendix lists the predictor variables used in the regression schemes described in Chapter 2. Note analyses times are in Z, UMAX is m s^{-1} , MDA is in degrees, low-level shear is s^{-1} and PBE is $\text{m}^2 \text{s}^{-2}$. Raob stations denoted with an asterisk (*) indicate 00Z soundings, otherwise 12Z soundings were used in the analysis. Cells annotated with a plus sign (+) indicate tornadic cells.

Appendix 6.6

Explanation of Statistical Procedures and Tests

This appendix defines the statistical tests used in the procedure determining whether outbreak intercepts were the same in a given data set (Chapter 3). An explanation of the results is also given.

By using the statistical package SAS (SAS, 1985), a regression model was chosen relating only tornadic occurrence to the predictor variables UMAX and MDA. The classification of tornadic and non-tornadic occurrence was denoted as a "0" or a "1". If the observed cell in the data set had a positive value for F_w then that cell was classified as tornadic, or "1". If the cell had a value of 0 for F_w then the cell was classified as non-tornadic, or "0". For the purposes of the model used, this variable was denoted as GROUP. As a result, the variables UMAX and MDA describe how a constant slope fits the data.

In addition to the variables UMAX and MDA, another variable was put into the model, denoted as OUTBREAK, to classify outbreaks within the data set. A numbering system was used to designate one outbreak from another. For example, in the combined data set, the variable OUTBREAK had a value range of 1 through 9 corresponding to the particular outbreak in the data. This OUTBREAK variable then explains how the outbreak intercepts relate to one another. The interaction of UMAX and MDA upon OUTBREAK was also tested. This interaction basically describes how varying slopes of UMAX and MDA fit the data. In SAS notation, this model was run under the GLM procedure and was set up as the following:

```
PROC GLM;  
  MODEL GROUP = UMAX MDA OUTBREAK UMAX*OUTBREAK MDA*OUTBREAK;
```

By running this model on SAS, a number of test statistics result describing the statistical relationship of UMAX, MDA and OUTBREAK to tornado occurrence. One such test statistic is the p-value. Simply stated, it is the probability that the model test statistic would be greater than the actual computed test statistic (under the hypothesis that UMAX and MDA are not needed in the model). As a result, a small p-value would tend to support the analysis that the variables are not the same and would therefore be needed in the data. Conversely, a large p-value would mean that the variables are not needed in the analysis, and have little significance as to the outcome of the test.

Another way to determine the significance of a test is by the use of the Type I sums of squares, or sequential sums of squares. They are the incremental improvements in error sums of squares as each effect (or variable) is added to the model (SAS, 1985). If the Type I sums of squares is relatively high, then that effect would be kept in the data. If it was relatively low, then that effect could be left out of the model. For example, if three effects, or variables, are used in the model (UMAX, MDA and OUTBREAK) then the Type I sums of squares explains the significance of the desired effect as each effect is added to the model. An analysis output example is given in table 6.6.1.

This analysis shows that there is a difference in UMAX and MDA from outbreak to outbreak (hence the low p-value and the relatively high Type I sums of squares). Also, the variable OUTBREAK shows a strong difference from outbreak to outbreak, suggesting that each outbreak has a different intercept, and consequently, a different surface. However,

Table 6.6.1. Example of test of hypothesis output using SAS with the appropriate p-value and Type I sums of squares for the effect shown.

<u>Effect</u>	<u>degrees of freedom</u>	<u>Type I SS</u>	<u>p-value</u>
UMAX	1	11.9258	0.0001
MDA	1	3.0655	0.0001
OUTBREAK	8	3.0132	0.0001
UMAX*OUTB	8	0.7257	0.3470
MDA*OUTB	8	0.7801	0.2952

when the effects of UMAX and MDA upon OUTBREAK are added to the model, the differences in those relationships to the data appears insignificant.

The above analysis tells us that as the values of UMAX and MDA increase, so does the likelihood of a tornadic occurrence. This falls in line with the basic idea of the breakpoint value. That is, the higher the value of UMAX and MDA, the more likely that observation is going to fall on the rising-ridge surface describing tornadic intensity. Similarly, outbreaks are significantly different from one another, suggesting different surfaces are going to relate tornadic occurrence differently, and are therefore needed in the analysis.

Appendix 6.7

Statistical Results Using F_w^2
