ABSTRACT

A semi-empirical model for the Fourier synthesis of deepwater, wind-wave scenes has been constructed for the analysis of water-wave slope spectra. The main simplifying assumptions of this model are 1) fully-developed wind-wave surfaces are quasi-homogeneous, quasi-stationary and are therefore treatable by Fourier methods, 2) the subsurface is both optically and mechanically deep, and 3) the small range of spectral wave components defines a fetch-limited, small-amplitude condition. A nonlinear transformation of wave slope to reflected and refracted radiance in both horizontal and vertical polarizations was effected under the special conditions of Brewster-angle viewing under clear skies at a spectral wavelength of 460 nanometers. Seventy two syntheses were varied with respect to six distinct solar positions, four distinct wind directions, and three distinct wind velocities.

The synthetic wave scenes were analyzed via the forward Fourier transformation and their radiance magnitude spectra were compared with the original slope magnitude spectra of the initial synthesis in order to estimate the effects of the nonlinear radiance transformation on the recovery of the wave slope spectrum from imagery. Within the boundaries of this study, it was determined that 1) the limited results of Chapman and Irani [1981] have been generally verified, 2) the existence of an optimal imaging geometry for slope spectrum estimation is indicated, and 3) the presence of sub-resolution wave slopes creates a significant effect on wave slope spectra derived from imagery.

1.0 INTRODUCTION

The intent of this study is twofold:

1) The first goal is to construct a reasonable linear model to describe the interaction of wind-driven water waves with the two primary sources of natural illumination: the downwelling sun and sky radiance (of which a fraction is reflected in the direction of an overhead observer) and the upwelling back-scattered subsurface radiance (of which a fraction is refracted in the direction of an overhead observer). This linear model will be used to create synthetic scenes of wind-driven water waves and derive their radiance magnitude spectra.

2) The second goal is to analyze the spatial radiance distribution of the synthetic wave scenes with respect to sun position, wind direction, wind velocity, polarization, and sub-resolution slope variance in order to compare the magnitudes of error that arise from the treatment of the radiance image magnitude spectrum as a linearizable reconstruction of the slope magnitude spectrum of the imaged water surface.

This study is essentially an amplification and extension of

the work of Chapman and Irani [1981].

In the 1950s, the two unrelated fields of oceanography and photographic science both experienced a minor renaissance with the introduction of the concepts of stochastic processes and power spectral analysis that were first applied in communications engineering [Blackman & Tukey, 1958]. Power spectral analysis provided a powerful analytical tool to photographic science for evaluating image quality; likewise, power spectral analysis provided a linear, statistical mechanism to oceanography for evaluating the large number of deterministic theories concerning the development, propagation, and decay of water waves [Kinsman, 1965]. An excerpt of a letter from the oceanographer, Dr. Walter Munk, to Drs. Blackman and Tukey gives an indication of beneficial results that were obtained with the new methods:

"...we were able to discover in the general wave record a very weak low-frequency peak which would surely have escaped our attention without spectral analysis. This peak, it turns out, is almost certainly due to a swell from the Indian Ocean, 10,000 miles distant. Physical dimensions are: 1 mm high, a kilometer long." [Blackman & Tukey, 1958]

Oceanographers had previously developed a number of photographic techniques to capture and optically analyze large amounts of high-resolution, two-dimensional (2D) spatial

information about water-wave surface structure [Hulburt, 1934; Barber, 1949, 1954; Cox & Munk, 1954a, b; Schooley, 1954; Pierson, 1960]. It was not until the advent of the digital computer and the implementation of the digital Fast Fourier Transform (FFT) that oceanography was able to efficiently analyze the wave scene into its spectral components and derive the directional 2D spectrum for elevation and slope [Kinsman, 1965; Pierson & Stacy, 1973]. The current study is a continuation of existing research which analyzes digital images of water waves through digital simulations.

The current study builds upon the work of Chapman and Irani [1981]. They, in turn, extended the work of Stilwell [1969; Stilwell & Pilon, 1974] and Kasevich [1975; Kasevich et al., 1971, 1972] in an attempt to quantify the parametric nonlinearities that may exist between the slope magnitude spectrum of the water surface and the radiance magnitude spectrum of the water surface image - as a linearizable reconstruction of the slope magnitude spectrum of the actual water surface. The current study reconstructs the synthetic model of Chapman and Irani with some selected modifications and enhancements:

- 1) no sensor or path radiance model is introduced as the

intent of this study is to estimate only the effects of wave and illumination geometry on the nonlinear transformation of slope to radiance,

2) a correlation model is introduced to provide a conservative spatial filter for synthesizing the effects of sub-resolution wave-slope variance on the image spatial radiance distribution,

3) a subsurface upwelling refracted radiance model is introduced to provide an additional nonlinear element to the analysis and to more adequately model the slope spectra obtained from visible images,

4) the zenith angle of observation is set at the Brewster angle (relative to mean sea surface) in order to define the extent to which the nonlinear transformation is affected by vertically polarized radiance added by the variance of wave slopes, and

5) the analysis of normalized difference spectra is introduced in order to provide a more direct correspondence with the analysis of slope variance as calculated from integrated power spectra.

The remainder of the Introduction is organized into four sub-chapters:

Chapter 1.1 introduces the topic of wind-generated waves, with emphasis on the small nonlinearities that must be considered.

Chapter 1.2 is an overview of the development of realistic syntheses of water-wave scenes, with emphasis on synthetic radiance imagery.

Chapter 1.3 is an overview of the development of image analysis of water-wave scenes, with emphasis on wave-slope spectrum analysis.

Chapter 1.4 is a review of the pertinent research which precedes the current study, with emphasis on the development of the first-order theory. Extracts from the introductory analysis of Kasevich [1975] and Stilwell [1969] are presented, followed by an overview of both the simulation experiment of Chapman and Irani [1981] and the experimental design of the current study.

1.1 Introduction to Wind-Driven Water Waves

Fully three quarters of the planet is covered with a layer of water; except for the rare instances of sustained windlessness where the surface is smooth and specular, the water surface is disturbed by the addition of directional friction energy applied by wind passing over the surface. (Tides, Coriolis-force waves, earthquake-generated waves, and other very-long-period waves are not considered here.) Up to some maximum wind velocity, the disturbed surface remains analytic (infinitely differentiable) and can be described as a quasi-stationary, pseudo-Gaussian process [Kinsman,1965] with an approximate power elevation spectrum.

Figure 1.1:1 illustrates Dr. Kinsman's relative estimation of the power elevation spectrum describing the energy contained in the surface waves of the oceans. Note that energy, L^2 , is proportional to $|\text{elevation}|^2$.

The nonlinearities of real water-wave surfaces can be attributed to four dominant factors [Kinsman,1965; LeMehaute,1976]:

First, wind energy is added to the water in a directional

and time-variant manner. Cox and Munk [1954a,b] found the wave-slope distribution to be nearly Gaussian, as would be expected for a continuous wideband spectrum. However, the cross-wind distribution of slopes is symmetric and the along-wind distribution is slightly skewed so that the most probable wave slope is directed upwind, a result they attributed to directional wind stress.

FIGURE 1.1:1. Schematic representation of the energy contained in the surface waves of the oceans - in fact, a guess at the power spectrum. (from Kinsman, 1965)

Second, both gravitational and molecular forces act on material water waves to inhibit random generation of very-large-elevation waves and, in the derivative, random generation of very steep wave slopes. Also, the natural

propagation state of a high-amplitude, narrowband water wave is cycloidal rather than sinusoidal, i.e. with elongated flat troughs and shorter peaked crests. This cycloidal form diminishes as the sea state increases and spectral wave-component energy is transferred over a wider band of wave-numbers, but it does not disappear. Therefore, the wave surface is pseudo-Gaussian in that the elevation and slope distributions exhibit a slight kurtosis (peakedness) and a truncation of the large-variance components. Cox and Munk correlated their results with a Gram-Charlier representation of a Gaussian distribution to account for this slight skewness and kurtosis.

Figure 1.1:2 illustrates the cross-wind and along-wind distributions of wave slopes (from Cox & Munk, 1954b).

Note that the curves are normalized to equal areas.

Third, there is a nonlinear transfer of wave energy from the high-frequency components of the wave spectrum to the low-frequency components as a function of time, fetch, and sea state. As previously mentioned, there is some maximum wind velocity beyond which the water surface acquires excessive energy, which leads to instability and a consequent loss of analytic structure. A familiar manifestation is white-

capping of the waves. Up to this point of fully-developed sea state, the effect of wind energy is to generate small-amplitude capillary waves which tend to become dampened by surface tension and which impart energy to the lower-frequency waves upon which they are riding. In 1847, Stokes [1880] defined the maximum wave slope which each wave component could attain before it became unstable; each spectral component transferred energy to lower frequencies until saturation; if the lower regime was saturated, whitecapping resulted. Within the range of gravity waves, the maximum wave slope is approximately $1/7$. For capillary waves, the maximum wave slope can approach $1/1$. Chapter 2.2 will illustrate the fact that the greater part of the slope variance from a fully-developed wind-wave surface is due to capillary waves.

Fourth, water waves refract in the presence of subsurface obstacles just as light refract. in the presence of media with differing refractive indices. Refractive nonlinearities appear only when the ratio of wavelength to depth becomes large. As long as the deepwater condition is satisfied (i.e. the longest wavelength under consideration is small relative to depth) the wave surface remains linear with respect to subsurface refraction.

FIGURE 1.1:2. Facet slope-angle (beta) distribution probability for a wind-roughened sea, computed for various wind speeds by means of the Cox & Munk probability function. (from Sidran, 1981)

In sum, a linear model for a synthetic water surface would most accurately describe infinite-fetch, fully developed wind waves propagating over deep water and with steady homogeneous winds blowing in a constant direction at velocities well below the point of spectral saturation. The predominant discrepancy of a linear model is that the lack of directional skew allows a 180-degree ambiguity in the direction of wind propagation.

1.2 Image Synthesis of Water-Wave Scenes

An Overview

The subject of image synthesis is best introduced by Upson:

"Within computer graphics and animation, two major sub-disciplines have developed: graphics for entertainment or artistic purposes, and graphics for scientific or technical purposes. Computer scientists working on entertainment applications have emphasized the correct visual representation of natural phenomena and have developed ad hoc physical simulations to accomplish this. Computational scientists working in the physical sciences have devoted their efforts to the underlying physics for simulating phenomena, with little emphasis on the visual representation.

In recent years these two approaches have begun to reach the limits of their ability to work without each other. The realism required in entertainment animation is beyond that obtainable without physically realistic models. Similarly, numerical simulations in the physical sciences are complex to the point of being incomprehensible without visual representations." [Upson, 1987]

Progress in the image synthesis of natural phenomena is occurring within three overlapping lines of research:

- 1) geometric models which provide a more accurate model of natural texture and shape,
- 2) illumination models which provide a more accurate model of the physical interaction between light and matter, and
- 3) temporal models which provide a more accurate model of the equations of motion for natural systems.

Most research devoted to the realistic synthesis of water-wave scenes has occurred within the last decade as part of the general interest in rendering of complex natural phenomena by computer. Early artistic renderings concentrated on generating low oblique scenes with realistic surface texture but with little attention to correct illumination effects. Early scientific renderings concentrated on the generation of near-nadir scenes with correct radiometry in order to simulate remotely sensed oceanographic imagery having low spatial resolution.

Whitted [1980] created one of the earliest attempts at rendering water waves in his film "The Compleat Angler". The ripples on a flat pool surface were generated by 'bump mapping', where the surface normal was perturbed by a single sinusoidal function. Bump mapping was first introduced by Blinn [1978]. Information International used a similar technique with cycloidal waveforms to create a leader for Pyramid Films [1981]. Perlin [1985] amplified this technique by using 20 superimposed cycloidal waveforms, each radiating from randomly selected centers. The characteristic limitation of bump mapping is that the actual surface is flat; there is no change in surface height to correspond to the perturbation of a local normal vector.

Schacter [1980] developed a scalar texture model for realtime image generation of waves, using sums of three or fewer long-crested, narrowband noise waveforms. This stochastic geometric model was intended for realtime image synthesis of a variety of textured surfaces or random fields with no regard to the physics of surface-light interaction. Norton et al.[1982] employed frequency-limited (or 'clamped') analytical functions for the same purpose.

Max [1981] used a vectorized ray-tracing algorithm on a Cray-1 supercomputer to model optical reflection on water waves for use in a color animation film "Carla's Island". The wave-surface height field was modeled by superimposed traveling sine waves. Each ray was constrained to reflect off the water at most two times before it proceeded to other scene elements. However, no effort was made to accurately model the attenuated spectral radiance of the synthetic scene; a geometric rule-of-thumb approach was used to compute each pixel based on a weighted average of 'sun color' and 'sky color' that were input from an RGB (Red-Green-Blue) translation table.

In 1985, Ts'o and Barsky [1987] applied the Stokes

model of the sea surface and generated height fields by fitting beta-splines with parameters that yielded symmetric waves. This model simulated directional refraction of water waves due to interaction with the ocean floor. Peachey [1986] similarly implemented the Stokes model as a height field but used quadric surfaces to create asymmetry. This synthesis also used a particle-system model to simulate the effects of surf spray on a beach but without the effect of directional refraction. Peachey gave some thought to surface reflection of skylight but ultimately assumed a Lambertian approximation for rough surfaces in the calculation of pixel brightness. Fournier and Reeves [1986] reviewed the work of the previous authors and produced a Gerstner wave model that incorporated a wind field and a stochastic element to perturb the wave model in addition to the previously noted features. Even in this final product, reflection is simulated by a one-level ray trace with selective filtering of the RGB color 'spectrum'.

Fractal and sequential Markov-chain synthesis techniques have been developed to simulate the texture of many natural surfaces including ocean waves [Mandelbrot, 1977, 1988; Gagalowicz & Ma, 1985; Monne et al., 1981]. In general, these techniques are considered to produce poor synthetic

water-wave images. The main objection to the surfaces generated by these processes is that they are not continuously differentiable. The surface normal vector at a point can only be approximated via a neighborhood average. However, it is interesting to note (in the context of wave surfaces) that the mathematician Karl Weierstrass developed the first fractal function by describing an infinite series of superimposed harmonic sinusoids:

$$f(t) = (1)\cos(w*t)+(1/a)\cos(b*w*t)+(1/a^2)\cos(b^2*w*t)+\dots ,$$

to yield a series representation of a continuous yet non-differentiable function. In this particular case, the fractal dimension $d = \text{LN}(a)/\text{LN}(b)$.

Mastin et al.[1987] recognized the inadequacy of the fractal model for ocean scenes and instead treated water surfaces as filtered white-noise processes. For his filter, Mastin used a modified Pierson-Moskowitz, temporal-domain, elevation power spectrum for fully-developed, wind-driven seas. A white-noise surface was filtered in the frequency domain and then inverse-Fourier-transformed to create the synthesized wave image. The surfaces were animated by varying the phase of the frequency components between each

frame, based on the dispersion relation between phase velocity and wave frequency. Mastin employed a simple illumination model to render the scenes but indicated that "incorporation of Fresnel's law into the reflectance model would probably enhance image quality."

Borrego and Machado [1985] used essentially the same filter technique as Mastin but with a Pierson-Neumann spectrum. They wrote their images to photographic film and then analyzed the film via the optical Fourier transformation and optical cross-correlation in order to compare synthetic results with real photographs of the sea. They did not use any illumination model - density values on film corresponded to surface height - since their analysis was only a first-order approximation.

Attempts to combine a water-wave surface model with correct radiometry are fewer in number:

Chapman and Irani [1981] attempted to quantify the error magnitudes associated with linearizing the relationship between the spatial frequency spectrum of an image and the slope spectrum of the actual water surface. Their radiometric model, though incomplete, is the most comprehen-

sive found within this survey. It will be described in detail in the Methods section as their combined model provides the point of departure for the current study.

Wilf and Manor [1984] applied the Chapman and Irani model to a restricted case: the simulation of water-wave images in the far infrared. They simplified their model with the assumption of a Forward Looking Infra-Red (FLIR) sensor having limited spatial resolution and sensitivity. Schwartz and Don [unpublished] and Masuda et al. [1988] also limited their models to the far infrared with the intent of simulating the angular effect of emissivity on sea temperature variation due to wind-roughened water.

It is apparent from this overview that the field of image synthesis, with emphasis on rendering of water waves, is less than a decade old. The integration of radiometry within these syntheses has occurred infrequently and for a limited objective in each instance.

1.3 Image Analysis of Water-Wave Scenes

An Overview

In 1925, Schumacher made oblique stereo-pairs from a ship with the intent of measuring the variability of wave heights. The utility of this method was severely limited due to many factors: 1) the camera baseline was restricted to the length of the ship; 2) waves in the foreground obstructed waves in the background; 3) backsides of waves were not visible; and 4) there was a lack of 'ground' control on open seas for height determination - the errors are especially pronounced from an oblique perspective [Pos,1988].

In 1933, Hulburt [1934] made polarized and unpolarized oblique photographs of sun glitter on sea waves to measure the polarization of light at sea with respect to surface roughness, sun angle, and weather conditions. Because the widths of glitter patterns correlate to the maximum slope of the sea surface, Hulburt was able to demonstrate that waves in the North Atlantic varied from 15 degrees inclination when winds were blowing at 3 knots up to 25 degrees inclination at 18 knots.

Sawyer [1949] mounted a Sonne strip camera on a fast

low-flying airplane to photograph narrow strips of the sea surface and measure the directional spectrum of the waves. The field of view was too narrow to capture significant amounts of surface data orthogonal to the flightline. The accuracy of the spectral estimate decreased with the angle from the flightline.

Also in 1949, Barber [1949,1954] analyzed single photographs of sea surfaces to determine wave direction but he was unable to determine the two-dimensional (2D) spectrum due to the computing limitations of the time. At this point, it became apparent that an essential requirement for future analysis of water-wave surfaces was to have near-vertical, high-resolution, high-contrast images covering large areas. The intent was to photographically capture significant information about the largest range of spatial frequency components without perspective distortion or hidden surface detail. It also became apparent that the analysis of large amounts of spatial information required the power of a digital computer.

In 1951, Cox and Munk [1954a,b] measured the wave-slope distributions of the sea surface from aerial photographs of sun-glitter patterns. They computed the distribution from

the measured variation of radiance within a glitter pattern instead of computing maxima from the pattern boundaries as done by Hulburt. Four cameras were flown from a single airplane at altitudes of 2000 feet, with two used as imagers and two used as radiometers. Their image analysis was quite sophisticated; it accounted for sun diameter, angular reflectivity, lens falloff, film sensitivity, exposure calibration, and ultimately provided a first-order relationship between film density and directional wave-slope probability.

In 1953, Schooley [1954] performed a simplified version of the Cox and Munk experiment by taking flash photographs of a river surface from a 45-foot bridge elevation at night. The main limitation of his experiment was the probable inhomogeneity of the water surface due to limited fetch and the presence of surrounding obstacles.

In 1954, medium-altitude (3000 ft) stereophotography was employed by Marks and Ronne [1955] to generate stereopairs of sea surfaces. Two airplanes carried radio-synchronized cameras and a surface ship acted as 'ground' control in the photographs. Elevations were photogrammetrically measured at discrete points and the sampled elevation array was then auto-correlated (the sampling distance determined

the desired spectral resolution). This experiment marks the first recorded use of a digital computer to calculate the directional 2D spectra of water waves. The work of Cote et al. [1960] enhanced this basic technique. More recent stereophotogrammetric efforts include Holthuijsen [1983a,b] and Pos et al. [1988]. Elements of this later work include methods to render the water opaque so that a more exact calculation of the height field can be made.

During the 1950s and early 1960s, Longuet-Higgins [1952-1962; Cartwright & Longuet-Higgins, 1956] elaborated on the results of Cox and Munk to formulate the statistical theory of patterns, paths, number, frequency, and distributions of specular reflection points on randomly moving surfaces. Stilwell [1969; Stilwell & Pilon, 1974] correlated the statistics of sea-surface images to the wave-slope statistics of the actual sea surface. Under the assumptions of uniform sky radiance, optimized viewing geometry, and small surface slopes, Stilwell derived the relationship between the film transmittance of an imaged surface point and the range component of the wave slope at that surface point. He further demonstrated a linearizable relationship between the spatial image spectrum and the imaged surface slope spectrum. Kasevich [1975] extended Stilwell's model

to second order to develop an optimization criterion for the relationship. Chapman and Irani [1981] took this work one step further by applying a synthetic model and executing a limited quantification of the error magnitudes associated with the parametric dependence of this linear model. This work will be further detailed in Chapter 1.4.

Sheres [1980] developed a novel technique for remotely sensing surface-flow velocities based on imagery of monochromatic wavetrains of known frequency (such as those generated by a motor boat) propagating over the region of interest. His work demonstrated that the wavelength and direction of two different wavetrains generated all the required information to calculate surface flows. Gotwols and Irani [1980] developed a similar technique to determine the phase velocity of short gravity waves.

Exotic sensors using LASER [Palm et al., 1977; Schau, 1978; Abshire & McGarry, 1987] and LIDAR [Weinman, 1988] have been used to extract directional spectra and surface backscatter data at higher wavenumbers (i.e. the capillary wave regime). Synthetic Aperture Radar (SAR) imagery has been used to estimate spectra, phase velocities, and propagation directions at lower wavenumbers (i.e. the gravity wave re-

gime) [Monaldo & Lyzenga,1986; Monaldo & Kasevich,1982; Carlson,1984]. Also, Long Wave Infrared (LWIR) sensors have been used to calculate spatial spectra of ocean-surface temperature [Saunders,1967,1968; McLeish,1970].

Lybanon [1985] reported on the implementation of an automated image-analysis system by the U.S. Naval Ocean Research & Development Activity (NORDA). The Interactive Digital Satellite Image Processing System, or IDSIPS, can automatically derive the sea-surface slope statistics from sun-glitter images through analysis of the imaging geometry. As a late example of the practical application of water-surface spectra determination, Fisher [1986] analyzed four sun-glitter images taken from the space shuttle Challenger (STS-41G) to locate acoustically important oceanographic features in support of hydro-acoustical sensor placement.

It is apparent from this overview that, in six decades, the methods of water-surface imaging have moved from surface ships to airplanes to satellites and spacecraft. Likewise, the measurement and analysis of the resulting imagery have undergone a corresponding increase in computational power and sophistication.

1.4 Review of Pertinent Literature

A comprehensive review would include the work of Stilwell and Pilon [1974], and Kasevich et al. [1971,1972]. The emphasis of this earlier work is on the analysis of coherent optical processing techniques as applied to photographic emulsions of wave scenes. Kasevich [1975] provides a general introduction to the first-order theory subsequent to the development of his approximate geometric-optics second-order theory to estimate the optimum viewing geometry for the obtainment of reasonable spectra. Stilwell [1969] provides additional development of image analysis with respect to the law of Malus subsequent to performing an optical analysis to derive directional energy spectra. Only the first-order theory is reviewed here; a review of the second-order theory is beyond the scope of this study since the theory of Kasevich assumes simplified approximations for both Fresnel reflectivity and sky radiance distributions. However, the most general results of the second-order theory can be compared, with caution, to the results of this study. Any second-order theory that is developed for this geometric problem loses definiteness because the spatial distributions for natural radiance are independent; no general solution can be specified [Stilwell,1969]. This is the prime motiva-

tion for the simulation and analysis of geometric effects through empirical models.

Review of Kasevich [1975]

The essential requirement for the determination of slope spectra from wave images is to have the spatial modulation of the image be proportional to the wave profile. Kasevich uses the example of a transparency with film exposure, E , defined over its linear region by

$$E(y) = [f_0(y)^{(-\gamma/2)}] * [1 + f(y)/f_0(y)]^{(-\gamma/2)} \quad [1.4:1]$$

where

$$E(y) = f_0(y) + f(y), \quad [1.4:2]$$

and

γ = the film gamma,

such that

$f_0(y)$ = the mean exposure on film,

and

$f(y)$ = the exposure modulation due to scattering of radiance from specular wave-slope facets.

This example is given for a two-dimensional case.

If $f_0(y) \gg f(y)$, then Equation [1.4:1] can be expanded

in a binomial series to yield the approximation

$$E(y) \approx [f_0(y)^{(-\gamma/2)}] * [1 - (\gamma/2) * f(y)/f_0(y)]. \quad [1.4:3]$$

The estimation of the slope spectrum from the forward Fourier transform of the image requires that $f(y)$ be linear with respect to the wave slope dz/dy , where z is the surface elevation. This condition can only be approximately satisfied because of the nonlinearity of 1) the spatial radiance distributions found in nature, 2) the Fresnel reflectivity variation with respect to incidence angle, and 3) the refraction of upwelling subsurface radiance in the direction of the observer.

Review of Stilwell [1969]

For a small wave-slope angle β , the small-angle approximation is:

$$\beta = \text{ATAN}(dz/dy) \approx dz/dy, \quad [1.4:4]$$

where β is the fundamental parameter for extracting wave-slope spectra from imagery. The law of Malus defines the radiance observed at azimuth angle θ as a simple function of Fresnel reflectivity and incident radiance:

$$L_0(\theta, \beta, \omega) = L(\mu) * R(\omega), \quad [1.4:5]$$

where

$L_0(\theta, \beta, \omega)$ = the observed reflected radiance,

$L(\mu)$ = the incident radiance to be reflected,

$R(\omega)$ = the Fresnel reflectivity (for any arbitrary polarization),

θ = the zenith angle of observation,

β = the slope of the reflecting surface,

μ = the zenith angle of the incident radiance,

and

ω = the angle of incidence,

such that

$$\omega = \theta - \beta \quad [1.4:6]$$

and

$$\mu = \omega - \beta. \quad [1.4:7]$$

Figure 1.4:1 illustrates the angular relations in two dimensions.

The variation of observed radiance with respect to a change of surface slope $d\beta$ at some point is

FIGURE 1.4:1. Angular relations for the 2D case.

$$\begin{aligned} \frac{dL(\theta)}{d\beta} = & \frac{dL(\mu)}{d\mu} R(\omega) \frac{d\mu}{d\beta} \\ & + L(\mu) \frac{dR(\omega)}{d\omega} \frac{d\omega}{d\beta}. \end{aligned} \quad [1.4:8]$$

If β is a small angle and

$$\omega \approx \mu, \quad [1.4:9]$$

then

$$\begin{aligned} \frac{dL(\theta)}{d\beta} = & [L'(\mu) R(\omega) \\ & + L(\mu) R'(\omega)] \frac{d\omega}{d\beta}, \end{aligned} \quad [1.4:10]$$

where the prime (') denotes the first derivative with respect to the argument. With the assumption that the water surface remains analytic, the small-angle linear approxima-

tion holds in the Fourier transform for wave-slope angles (beta) up to at least 30 degrees [Stilwell, 1969].

Review of Chapman and Irani [1981]

The intent of the work of Chapman and Irani was to quantify the parametric dependencies of errors inherent in linearly relating a wave-slope magnitude spectrum to the corresponding radiance image magnitude spectrum. Their approach was to simulate radiance images of sea-like surfaces in two dimensions. Their simulation utilized models of the sea surface, the sky radiance distribution, and the non-linear transfer function that transforms surface slope to radiance. They determined that the two-dimensional simulation was computationally expensive so only a small number of geometries were investigated. However, they initially used a simpler one-dimensional model of a ± 15 -degree sinusoidal surface propagating in a single direction along the sensor field in order to survey various imaging geometries for potential synthesis and analysis in two dimensions.

Figure 1.4:2 illustrates the two-dimensional methodology for image synthesis and error analysis used by Chapman and Irani. This methodology is described in detail in Chapters 2.1 through 2.8.

FIGURE 1.4:2. Methodology of error estimation in two dimensions. (from Chapman & Irani, 1981)

Chapman and Irani used two figures of merit derived from signal analysis to describe the nonlinearity of the slope-to-radiance transformation. The first figure of merit is the ratio of the fundamental component to the DC component which they termed the contrast of the wave image. The second figure of merit is the square root of the power in the upper harmonics divided by the power in the fundamental, which they termed the Total Harmonic Distortion (THD) of the wave image. An optimal imaging geometry for measuring slope statistics would maximize contrast and minimize THD, based upon their terminology. These figures of merit were computed for the results of their one-dimensional model. To quote Chapman and Irani:

"...these figures of merit do not represent realistic contrasts or distortion statistics for sea surface imaging because the distribution of slopes over a sinusoid differs substantially from the approximately Gaussian distribution of sea surface slopes." [Chapman & Irani, 1981]

Their initial results indicated that the figures of merit showed a substantial, asymmetric dependence on slope azimuth for certain geometries and may misrepresent the utility of a particular geometry.

Chapman and Irani then applied their two-dimensional synthesis and analysis to six selected geometries with the

intent of evaluating the azimuthal dependence of their figures of merit. Their two-dimensional results indicated that 1) nonlinearity is largely independent of wavenumber, 2) nonlinearity remains relatively low (error < 3 dB) over a relatively wide range of azimuth (100-120 degrees) around the sensor azimuth, and 3) nonlinearities increase within 30-40 degrees of the cross-field direction.

Experimental Design of the Current Study

As earlier stated, the current study is essentially an amplification and extension of Chapman and Irani as developed from a proposed statement of work:

"An exhaustive evaluation of our radiance modulation model would involve: 1) simulating the geometry of a surface area; 2) transforming that surface geometry into an image using a particular set of optical conditions; 3) estimating the slope spectrum of the simulated surface and the spectrum of the image; 4) repeating steps 1-3 for all other possible imaging geometries; and 5) comparing each image spectrum with the corresponding slope spectrum to obtain estimates of the error arising from nonlinearity. This, in fact, is impractical because there are a large number of parameters to be varied, and, for any set of these parameters, the error computation involves a large number of operations." [Chapman & Irani, 1981]

The intent of this study is to develop and execute a test design which provides a minimal yet optimal set of parameters to both verify the limited results of Chapman and

Irani and to complete a more detailed parametric surface exploration.

For their two-dimensional analysis, the experimental design of Chapman and Irani was of the order $1 \times 3 \times 2$ factors relative to the current study, which is of the order $3 \times 4 \times 6$ factors:

Wind Friction Velocity - 12.0, 36.0, and 60.0 cm/sec versus 12.0 cm/sec. These three velocities define the envelope of the linear wind-wave model.

Wind Azimuth - $+90:-90$, $+45:-135$, $0:180$, and $-45:135$ degrees (with ambiguity) versus $+90:-90$, $+30:-120$, and $0:180$ degrees (with ambiguity).

Sun Position - $(0,0)$, $(0,53.2)$, $(45,53.2)$, $(90,53.2)$, $(135,53.2)$, and $(180,53.2)$, where the coordinates are (azimuth angle, zenith angle) in degrees, versus $(90,45)$ and $(135,45)$.

The experimental design of the current study spans the complete range of azimuthal geometries in increments of 45 degrees.

The zenith angle of observation for the current study model is set at the mean Brewster angle (53.2 degrees at 460 nm) (versus 60.0 degrees at 800 nm in the Chapman and Irani model) so that the effect of vertically polarized radiance due to wave-slope deviations from the mean surface can be compared with the observed horizontally polarized radiance. Only the horizontally polarized radiance was computed in the Chapman and Irani study.

In addition, the effect of upwelling subsurface radiance is incorporated into the current study model in order to estimate the effect that refracted radiance may have on the nonlinearity of the reconstructed slope spectrum.

Also, the effect of sub-resolution wave slopes is incorporated into the current study model in order to account for the spatially filtered wave-slope spectrum that exists beyond the maximum sampling frequency of the model.

Figure 1.4:3 illustrates the differences between the two studies, based on the combinations of synthetic imaging geometries that are analyzed in two dimensions.

FIGURES 1.4:3(a) & (b). 2D imaging geometries used in the current study (a) versus the Chapman and Irani study (b).

In summation, the experimental design for the current study requires the analysis of 72 distinct synthetic imaging combinations versus 6 combinations in the previous study. The analysis of these synthetic results will provide more complete information on the geometric effects of slope spectrum reconstruction than the simplified one-dimensional analysis in the previous work of Chapman and Irani [1981].

2.0 METHODS

Overview

The current study model uses a two-dimensional Pierson-Stacy elevation power spectrum to create a synthetic wind-wave-slope surface that conforms to the results of a number of statistical studies [Cox & Munk, 1954a,b; Longuet-Higgins, 1957; Pierson & Stacy, 1973]. Downwelling skydome (solar and skylight) radiance for clear skies and upwelling subsurface radiance for clear, deep water are both synthetically created from analytic models. These synthetic radiance distributions are decomposed into their polarized components.

The synthetic radiance image is generated by first calculating the surface-slope distribution of the synthesized water surface and then applying the law of Malus to linearly map the radiance distributions, the polarized Fresnel reflection coefficients, and the surface projection coefficients to the surface-slope distributions to compute the reflected and refracted polarized radiance from each sample area in the direction of observation.

Figure 2.0:1 illustrates the methodology for image synthesis and error analysis used in the current study.

Chapman and Irani [1981], in their error computations of the linear estimation of surface-slope spectra from image spectra, assumed that the nonlinearity of the slope-to-radiance transfer function was the principal source of error. They did note other possible sources of error but chose not to incorporate them in their study. The current study attempts to include those sources of variation which are directly or indirectly attributable to the geometric effect of water surfaces on the modulation of observed radiance:

- 1) Perspective Distortion
- 2) Variation of the Sensor Response Function
- 3) Spatial and Spectral Filtering

No sensor model is implied in this synthesis other than the existence of a spatial Nyquist frequency and a geometric location for a viewpoint. Chapman and Irani stated "we assume digital processing techniques are used so that perspective distortion and trends in the response function over the field of measurement can be removed prior to obtaining the image spectra" and "we assume that the optical modulation transfer function of the camera adequately filters the surface radiance spectrum and thereby eliminates aliasing errors." This synthesis does, however, incorporate a corre-

lation model to account for the spatially filtered, high-frequency wave-slope spectrum that exists beyond the maximum spatial sampling frequency.

4) Upwelling Radiant Energy

5) Scattered Radiant Energy

No atmospheric model is implied in this synthesis. However, a model for subsurface absorption and scattering is incorporated, providing radiance variation due to refraction of upwelling surface radiance by surface waves. The model of Chapman and Irani assumed that the surface is viewed 15-60 degrees from nadir so that surface reflection predominates. Also, they assumed that their camera was viewing through clear air and sensing in the near-infrared region so that the effects of path radiance and refracted subsurface radiance could be ignored.

6) Wave Shadows

The work of both Saunders [1967] and Goodell [1971] was reviewed in regard to potential models which compensate for wave shadowing or "hiding". The current linear model, as developed, adequately incorporates the effect described by Goodell for the established zenith angle of observation, the mean Brewster angle. To quote Goodell:

Although the effect is apparently reversed for near-zenith-viewing imagery, the modeling approach is the same for any angle of observation. In Figure 2.0:2, the slope distribution is mapped to sky coordinates; in the current study model, skydome radiance is mapped to slope coordinates.

It is intuitive that the effects of wave shadowing diminish as the observation point approaches zenith. Because the majority of wave slopes are less than 30 degrees, the effect of wave shadowing on Brewster-angle-viewing imagery (53.2 degrees from zenith) is assumed to be insignificant.

7) Multiple Reflections

Only an elaborate Monte Carlo simulation or multiple-ray-tracing model could account for multiple reflections, simulations which are beyond the scope of this linear-model study. The assumption for this synthesis is that the probability of multiple reflections in near-nadir imagery is negligible.

Definition of Model Terms

The following list is a brief glossary of the terms used in the synthetic image model. These terms are formally defined in Chapters 2.1 through 2.8.

α = azimuth angle to (wind-wave) surface normal

β = zenith angle to (wind-wave) surface normal

D_0 = scalar squared difference (error), integrated over both wavenumber (k) and azimuth (ϕ)

$D_1(k)$ = 1D difference (error) spectrum with respect to wavenumber (k), integrated over azimuth (ϕ)

$D_1(\phi)$ = 1D difference (error) spectrum with respect to azimuth (ϕ), integrated over wavenumber (k)

$D_2(k_x, k_y)$ = 2D difference (error) spectrum

H = horizontally polarized fraction of radiance

$H_0(x, y)$ = horizontally polarized, reflected & refracted synthetic radiance image

$H_1(x, y)$ = horizontally polarized, reflected synthetic radiance image

$H_3(x, y)$ = $H_1(x, y)$ without the incorporation of sub-resolution wave-slope model

I = 3D incident radiance vector

k = dummy variable for scalar wavenumber

$k_{x,y}$ = scalar wavenumber relative to spatial coordinate axes

K = 2D vector wavenumber = (k_x, k_y)
 L_g = reflected radiance due to sun glitter
 L_p = atmospheric path radiance
 L_r = total reflected sky (+ sun) radiance = $L_s + L_g$
 L_{ref} = reference Lsky radiance at zenith
 L_s = reflected radiance due to skylight
 L_{sky} = downwelling radiance from sky (including sun)
 L_u = upwelling radiance above water surface = $L_r + L_w$
 L_w = upwelling subsurface refracted radiance above surface
 $L0(x,y)$ = total (unpolarized) reflected & refracted synthetic radiance image
 $L1(x,y)$ = total (unpolarized) reflected synthetic radiance image
 $m_{x,y}(x,y)$ = (wind-wave) slope component arrays
 μ = zenith angle to reflecting sky element
 μ_0 = angle from sun to sky element
 $M_{x,y}(k_x, k_y)$ = (wind-wave) slope-component magnitude spectra
 ν = azimuth angle to reflecting sky element
 ν_0 = angle between vector parallel to direction of polarization and projection of vector to surface plane
 $N(k_x, k_y)$ = synthetic image radiance magnitude spectrum
 N = 3D surface normal vector
 ω = angle of incidence

ϕ = azimuth angle to point of observation (180 deg)
 = dummy variable for azimuth angle
 ϕ_0 = azimuth angle to sun
 ψ = multiplicative depolarization factor
 $P_{2D}(k_x, k_y)$ = (wind-wave) elevation power spectrum
 $Pr(\beta, \alpha)$ = (wind-wave) slope probability distribution
 $R(\omega)$ = Fresnel reflectivity (arbitrary polarization)
 R_0 = unpolarized Fresnel reflectivity at normal incidence
 R = 3D reflected radiance vector
 $S_{2D}(k_x, k_y)$ = (wind-wave) slope power spectrum
 $S_{x,y}(k_x, k_y)$ = (wind-wave) slope-component power spectra
 θ = zenith angle to point of observation (53.2 deg)
 θ_0 = zenith angle to sun
 T_a = atmospheric transmittance
 T_w = transmittance through water
 v_{fric} = friction velocity of wind at water surface
 v_{1950} = velocity of wind at height $z=1950$ cm above surface
 V = vertically polarized fraction of radiance
 $WGN(k_x, k_y)$ = white-noise spectrum
 $wind_az$ = azimuth angle to dominant wind direction (with
 180-degree ambiguity)
 x, y = spatial coordinates
 z = height above mean water surface

2.1 Radiometric Model for Image Synthesis

The total radiance reaching an overhead radiometric sensor can be defined by,

$$L_{tot} = (L_u * T_a) + L_p, \quad [2.1:1]$$

where

L_u = the spectral upwelling radiance just above the water surface in direction of the sensor,

T_a = the transmittance of the intervening atmosphere between the water surface and the sensor,

and

L_p = the spectral path radiance due to light scattered in the direction of the sensor by the intervening atmosphere.

In general, L_p is much larger than L_u across the visible and infrared spectrum. The estimation of L_p must be accurate within 1% in order to estimate L_u within 10%. This is known as the 'atmospheric correction problem' and is a well-defined subject of research. However, this synthesis does not include an atmospheric model since it is the variation of L_u with respect to several independent geometries that is the object of study. Therefore, this synthetic model will assume a perfectly non-absorbing, non-scattering atmosphere

and will set $T_a = 1.0$ and $L_p = 0.0$. This simplification reduces the radiometric equation to:

$$L_{tot} = (L_u * 1.0) + 0.0 = L_u \quad [2.1.2]$$

for the duration of this study. More sophisticated models may vary T_a and L_p and may include a sensor model for spectral/spatial/temporal attenuation and distortion as well. An alternative perspective on this study is to consider that the model creates a synthetic radiant object rather than an image since no part of an imaging chain (including the intervening atmosphere) is modeled; we are interested only in the spatial effects of the water surface on the reflected/refracted radiance in the direction of a hypothetical distant sensor.

The above surface radiance L_u can be decomposed into three terms,

$$L_u = L_g + L_s + L_w, \quad [2.1:3]$$

where

L_g = the above-surface radiance due to reflected sunlight (commonly known as sun glitter),

L_s = the above-surface radiance due to reflected skylight,

and

L_w = the above-surface radiance due to subsurface upwelling radiance propagating across the water surface.

Most oceanographic imaging has been directed at estimating L_w , as this term conveys information about water color and the factors which affect water color (non-aqueous constituents and water temperature, to name a few). For this reason, the large radiance due to glitter L_g has been generally avoided by the judicious selection of a minimizing geometry. However, reflected skylight L_s cannot be geometrically avoided; instead, L_s has usually been considered to be constant by assuming that a uniformly radiant skydome reflecting off a uniformly rough water surface yields an approximately Lambertian condition. This is one of the few instances where poor spatial resolution can be used to advantage. The reflected skylight term is then usually collected with the path radiance term:

$$\begin{aligned} L_{tot} &= L_w * T_a + (L_s * T_a + L_g * T_a + L_p) \\ &= L_w * T_a + (L_s * T_a + 0.0 + L_p) \\ &= L_w * T_a + (L_p') \end{aligned} \quad [2.1:4]$$

Thus, estimation of L_w has typically been reduced to cal-

culating T_a and L_p' and applying a linear atmospheric correction.

This synthetic model does not assume that L_w is the pre-eminent datum to collect: for information about the surface geometry, it is important to establish a relation between L_u and surface slope. In this context, the reflected radiance terms, L_g and L_s , are re-collected under the common term,

$$L_r = L_g + L_s \quad [2.1:5]$$

where

L_r = the above-surface spectral radiance due to the reflected skydome, since, as the surface varies its slope, the surface normal vector points to the skydome independent of the position of the sun on the skydome.

In this study, an optimal imaging geometry provides for the accurate estimation of the slope magnitude spectrum over the broadest range of possible water-surface slope spectra. The general approach to this estimation is to maximize the spatial contrast of L_r and either minimize or correct for the spatial variation of L_w .

2.2 Fourier Synthesis of Wind-Wave Surfaces

The geometric model for Fourier synthesis of wave-slope surfaces closely follows the model of Chapman and Irani [1981] with one exception: the often substantial slope variance that exists above the spatial Nyquist frequency is calculated and the radiometric effect of this sub-resolution slope variance is introduced within the illumination models.

Specification of a 1D Elevation Power Spectrum

The first step is to specify a 1D wave elevation power spectrum. Several spectra were previously cited: Pierson-Neumann [Borrego & Machado, 1985; Pierson-Moskowitz [Mastin et al., 1987], and modified Pierson-Stacy [Chapman & Irani, 1981]. For this study, the original 1D Pierson-Stacy power spectrum is employed for two reasons: 1) the spectral scale is spatial wavenumber [radians per centimeter or just /cm] and 2) Pierson and Stacy [1973] went into great detail in their report to attempt to correlate their spectrum with the empirical results of other researchers, including the Cox and Munk [1954a,b] photographic study.

The equations of the 1D wave elevation power spectrum $P(k)$ come directly from Pierson and Stacy [1973]. $P(k)$ is

defined over five spectral regions:

P_1 = the gravity wave-gravity equilibrium spectral range,

$$P_1(k) = (a/2*k^3)*EXP(-b*g^2/(v_{1950}^4*k^2))$$
$$\text{for } 0 < k < k_1, \quad [2.2:1]$$

P_2 = the Kitaigorodskii spectral range,

$$P_2(k) = a/(2*SQRT(k_1)*k^{2.5})$$
$$\text{for } k_1 < k < k_2, \quad [2.2:2]$$

P_3 = the Leykin-Rosenberg spectral range,

$$P_3(k) = (a*d)/(2*(k_3^P)*(k^{3-P}))$$
$$\text{for } k_2 < k < k_3, \quad [2.2:3]$$

P_4 = the capillary spectral range,

$$P_4(k) = (a*d)/(2*k^3)$$
$$\text{for } k_3 < k < k_{nu}, \quad [2.2:4]$$

and

P_5 = the Cox viscous cut-off range,

$$P_5(k) = (E/(nu*g))*v_{fric}^3*k_{max}^6/k^9$$
$$\text{for } k_{nu} < k < \text{infinity}, \quad [2.2:5]$$

where

$$d = (1.274 + (0.0268*v_{fric}) + (6.03E-5*v_{fric}^2))^2, \quad [2.2:6]$$

$$k_1 = (k_2*v_{min}^2)/v_{fric}^2, \quad [2.2:7]$$

$$k_{nu} = (0.5756*SQRT(v_{fric})*k_{max})/(d^{1/6}), \quad [2.2:8]$$

and

$$p = LOG(d/(v_{fric}/v_{min}))/LOG(k_3/k_2), \quad [2.2:9]$$

such that

$a = 0.0081$ = the Phillips constant [unitless],

$b = 0.74$ [unitless],

$E/(nu*g) = 1.473E-4$ [unitless],

$g = 980.0$ = the acceleration of gravity [cm/sec²],

$k_2 = 0.359$ [rad/cm],

$k_3 = 0.942$ [rad/cm],

$k_{max} = 3.63$ [rad/cm]

$v_{min} = 12.0$ [cm/sec] = the minimum friction velocity defined by the Pierson-Stacy model,

v_{1950} = the wind velocity at 1950 cm above water level [cm/sec], and

v_{fric} = the wind friction velocity at the water surface (i.e. $z = 0$ cm).

v_{fric} and the wind velocity v [cm/sec] at height z [cm] have an empirical correspondence under the assumption of a neutrally stratified atmosphere:

$$v(z) = (v_{\text{fric}}/0.4)*\text{LN}(z/z_0) \quad [2.2:10]$$

and

$$z_0 = (0.684/v_{\text{fric}}) + (4.28\text{E-}5*v_{\text{fric}}^2) - 0.0443 \quad [2.2:11]$$

Values for v_{fric} , v_{1950} , as well as v_{250} , v_{1000} , and v_{1250} are interpolated from values tabulated by Pierson and Stacy. (Refer to V_DATA.DAT input data file in Appendix III.)

Figure 2.2:1 graphs $k*P(k)$ versus $\text{LOG}_{10}(k)$ for friction velocities of 12.0, 36.0, and 60.0 cm/sec, to illustrate of the effect of wind velocity on the character of the elevation power spectrum. Note that most of the power is located in the gravity wavenumber region, i.e. below $k = 0.002/\text{cm}$. The curve for 12.0 cm/sec has a maximum value of 30.0 cm^2 .

Specification of a 2D Directional Spreading Function

The 2D power spectrum is created via a directional spreading factor $D(k, \phi)$ that attenuates the 1D spectrum at the azimuth angle ϕ from the upwind/downwind directions:

$$P_{2D}(k, \phi) = P(k)*D(k, \phi) \quad [2.2:12]$$

The equations of the 1D wave elevation power spectrum $P(k)$

FIGURE 2.2:1. The Pierson-Stacy 1D elevation power spectrum $k*P(k)$ versus $LOG10(k)$.

come directly from Pierson and Stacy [1973] with a small modification to allow rotation of the 2D spectra relative to the wind azimuth $wind_az$.

The directional spreading function is defined:

$$D(k, \phi, wind_az) = (A*(1-B)) + (B*C) \quad [2.2:13]$$

where

$$A = (8/(3\pi)) * (D^2), \quad [2.2:14]$$

$$B = \text{EXP}(-g^2/(2*k^2*v_{1950}^4)), \quad [2.2:15]$$

and

$$C = (A*D+0.5)/\pi \quad [2.2:16]$$

such that

$$D = \text{COS}(\text{wind_az}-\text{phi}). \quad [2.2:17]$$

Creation of the Slope-Component Spectra

The third step is to derive the two slope-component spectra from the scalar power spectrum. The 2D spectrum must first be normalized by k over the range of wavenumber:

$$P_{2D}'(k, \text{phi}) = P(k) * D(k, \text{phi}) / k \quad [2.2:18]$$

since

$$P(k) = \int P_{2D}'(k, \text{phi}) * k * d\text{phi} = \int P_{2D}(k, \text{phi}) * d\text{phi}. \quad [2.2:19]$$

The two slope-component spectra are obtained by multiplying the scalar 2D elevation spectrum by the squares of the orthogonal components of the wave vector K that are aligned with the image coordinate system (x, y) :

The slope power spectrum is

$$S(k, \text{phi}) = k^2 * P_{2D}'(k, \text{phi}), \quad [2.2:20]$$

which leads to

$$S_x(k_x, k_y) = k_x^2 * P_{2D}'(k, \phi) = k_x^2 * P_{2D}'(k_x, k_y) \quad [2.2:21]$$

and

$$S_y(k_x, k_y) = k_y^2 * P_{2D}'(k, \phi) = k_y^2 * P_{2D}'(k_x, k_y), \quad [2.2:22]$$

since

$$|K| = \text{SQRT}(k_x^2 + k_y^2) = k \quad [2.2:23]$$

and

$$\begin{aligned} P_{2D}'(K) * dK &= P_{2D}(k_x, k_y) * k * dk \\ &= P_{2D}(k * \text{COS}(\phi), k * \text{SIN}(\phi)) * k * dK \\ &= P_{2D}(k, \phi) * k * dk d\phi \\ &= P_{2D}'(k, \phi) * dk d\phi. \end{aligned} \quad [2.2:24]$$

The square roots of the slope-component power spectra yield the corresponding slope-component magnitude spectra, which are used as filters when generating the synthetic slope arrays:

$$M_x(k_x, k_y) = \text{SQRT}(S_x(k_x, k_y)) \quad [2.2:25]$$

and

$$M_y(k_x, k_y) = \text{SQRT}(S_y(k_x, k_y)). \quad [2.2:26]$$

Creation of a Frequency-Domain White Noise Image

The fourth step is to create a scalar matrix of spatial white noise, i.e. uniformly distributed, uncorrelated random

values with unit magnitudes ranging between $+\pi$ and $-\pi$. The Fourier transform of this matrix yields a complex phase matrix with conjugate symmetry about its central ordinate:

$$\int_{-1}^{+1} [\text{wgn}(x,y)] = \text{WGN}(k_x, k_y) \quad [2.2:27]$$

Frequency-Domain Filtering and Back Transformation

WGN is filtered by M_x and M_y in the frequency domain to create the two complex Fourier transforms of the synthesized wave-slope components. The inverse Fourier transform yields the two slope-component arrays:

$$m_x(x,y) = \int_{-1}^{-1} [M_x(k_x, k_y) * \text{WGN}(k_x, k_y)] \quad [2.2:28]$$

and

$$m_y(x,y) = \int_{-1}^{-1} [M_y(k_x, k_y) * \text{WGN}(k_x, k_y)]. \quad [2.2:29]$$

Both m_x and m_y are real scalar arrays of slope components because of the conjugate symmetry.

Conversion to Slope Magnitude and Slope Azimuth

The fifth and final step is to convert the two slope-component arrays into a slope magnitude array $\beta(x,y)$ and a slope azimuth array $\alpha(x,y)$, where β is the maximum

slope at the coordinate (x,y) and alpha is the azimuth angle to the direction of beta. The angles alpha and beta are related to m_x and m_y by the geometric relations:

$$\text{TAN}(m_x) = \text{TAN}(\beta) * \text{COS}(\alpha) \quad [2.2:30]$$

and

$$\text{TAN}(m_y) = \text{TAN}(\beta) * \text{SIN}(\alpha). \quad [2.2:31]$$

Therefore, the maximum slope magnitude of an array facet is

$$\beta = \text{ATAN} [\text{TAN}(m_x)^2 + \text{TAN}(m_y)^2] \quad [2.2:32]$$

and the azimuth angle in the direction of the maximum slope is

$$\alpha = \text{ATAN} [\text{TAN}(m_y) / \text{TAN}(m_x)]. \quad [2.2:33]$$

Figures 2.2:2 through 2.2:4 illustrate the 2D Pierson-Stacy elevation magnitude spectra for friction velocities of 12.0, 36.0, and 60.0 cm/sec, respectively. The spectra are oriented with wind azimuth = -45 deg (or +135 deg with ambiguity).

FIGURES 2.2:2-4. Elevation magnitude spectra, $\sqrt{P(k_x, k_y)}$.

Figures 2.2:5 through 2.2:7 illustrate the 2D Pierson-Stacy slope magnitude spectra for friction velocities of 12.0, 36.0, and 60.0 cm/sec, respectively. The spectra are oriented with wind azimuth = -45 deg (or 135 deg with ambiguity).

Figures 2.2:8 through 2.2:10 illustrate the x-components of the above slope spectra. Figures 2.2:11 through 2.2:13 illustrate the y-component slope spectra. The spectra are oriented with wind azimuth = -45 deg (or 135 deg with ambiguity).

Figures 2.2:14 through 2.2:16 illustrate the sample slope distributions $\text{Pr}(\beta, \alpha)$ for synthetic realizations using the above slope spectra. The spectra are oriented with wind azimuth = -45 deg (or 135 deg with ambiguity).

FIGURES 2.2:5-7. Slope magnitude spectra, $M_0(k_x, k_y)$.

FIGURES 2.2:8-10. X-components of slope magnitude spectra.

FIGURES 2.2:11-13. Y-components of slope magnitude spectra.

FIGURES 2.2:14-16. Sample slope probability distributions, $\Pr(\beta, \alpha)$.

Calculation of Total and Component Slope Variance

The slope variance is calculated from the 1D slope power spectrum for a specified range of wavenumber:

$$\text{VAR}(k_1, k_2) = \int_{k_1}^{k_2} S(k) * dk = \int_{k_1}^{k_2} k * S(k) * d\text{LN}(k) \quad [2.2:34]$$

The unresolved (i.e. both x- and y-components combined) slope variance is calculated from the 2D slope power spectrum for a specified range of wavenumber:

$$\text{VAR}(k_1, k_2) = \iint_{\vec{k}_1}^{\vec{k}_2} S(k, \phi) * dk d\phi = \iint_{\vec{k}_1}^{\vec{k}_2} S(k_x, k_y) * dk_x dk_y \quad [2.2:35]$$

Likewise, the x-component and y-component slope variance can be calculated by substituting S_x or S_y for S in Equation [2.2:35].

The 2D distribution of slopes in the downwind and crosswind directions correlate well with the results of Cox and Munk [1954a,b] and this is one measure of the adequacy of the Pierson-Stacy model. However, Pierson and Stacy [1973] suggest that the optical system used by Cox and Munk acted as a high-frequency spatial filter on the reflected

radiance from the sea surface. Pierson and Stacy concluded that the calculation of variance from the integration of their power spectrum over k and ϕ yielded variances which fit reasonably well with the Cox and Munk model when they imposed an upper bound of $k = 1.2$ radians per centimeter. This corresponds to a wavelength of 5.24 centimeters. To maintain consistency between the results of two previous efforts, this model assumes a maximum spatial frequency of $k = 1.2$ radians per centimeter.

Figure 2.2:17 graphs $k \cdot S(k)$ versus $\text{LOG}(k)$ for three friction velocities, 12.0, 36.0, and 60.0 cm/sec. This graph has the interesting property that the area under the curve equals the total variance and the area between two wavenumbers equals the fraction of the total variance between the two wavenumbers, as specified in Equation [2.2:34]. The wavenumber range sampled by the current study model is located between the two vertical lines.

Figure 2.2:18 graphs the fractional and total slope variance over the friction velocity range from 12.0 to 60.0 cm/sec. The lower line represents the integration of variance up to $k_1 = 0.0375/\text{cm}$. k_1 is the fundamental spatial frequency for

FIGURE 2.2:17. The 1D Pierson-Stacy slope power spectrum $k*S(k)$ versus $LOG10(k)$.

the current study model, that is

$$k_1 = k_{max}/(n/2) = (1.2/cm)/(64/2) = 0.0375/cm \quad [2.2:36]$$

The middle line represents the integration of variance up to $k_2 = 1.2/cm = k_{max}$. k_{max} is the maximum spatial frequency

for the current study model. The upper line represents the integration of variance over the entire range of wavenumber. The points represent the measurements of Cox and Munk [1954b].

FIGURE 2.2:18. Slope Variance versus Friction Velocity.

Figures 2.2:1, 2.2:17, and 2.2:18 are identical in magnitude to Figures 8.3, 8.4, and 9.1 of Pierson and Stacy [1973]. Note that there is a large fraction of the total slope

variance above $k = 1.2/\text{cm}$. For this and preceding studies, this fraction represents the sub-resolution slope variance; its effect on the spatial attenuation of the reflected and refracted radiance will be introduced into this study by a correlation filter model described in Chapter 2.5.

2.3 Synthesis of Skydome Downwelling Radiance

Chapman & Irani Model

Chapman and Irani [1981] incorporated a combination of the modified clear-sky luminance model of Hopkinson [1954] and the pure Rayleigh-scattering polarization model. The analytic Hopkinson model is defined:

$$L_{\text{sky}}(\mu, \nu) = L_{\text{ref}} * A * B \quad [2.3:1]$$

where

$L_{\text{sky}}(\mu, \nu)$ = the downwelling radiance at skydome coordinates (μ, ν) ,

μ = the zenith angle to the skydome location $[0: +90 \text{ deg}]$,

ν = the azimuth angle to the skydome location $[-180: +180 \text{ deg}]$,

$L_{\text{ref}} = L_{\text{sky}}(0, 0)$ = the reference radiance at zenith, [2.3:2]

$$A = (1 + \cos(\mu_0)^2) / (1 - \cos(\mu_0)^2), \quad [2.3:3]$$

$$B = 1 - \exp(-0.32 * \sec(\mu)), \quad [2.3:4]$$

and

$$\begin{aligned} \cos(\mu_0) = & \cos(\theta_0) * \cos(\mu) \\ & + \sin(\theta_0) * \sin(\mu) * \cos(\nu - \phi_0) \end{aligned} \quad [2.3:5]$$

such that

μ_0 = the angle from the sun to a sky element,

θ_0 = the zenith angle to the sun,

and

ϕ_0 = the azimuth angle to the sun.

Hopkinson's model was one of the earlier responses to a 1953 CIE proposal to establish a standard, analytic clear-sky radiance distribution to serve as a basis for daylight factor calculations. A broadband telephotometer was modified to measure the integrated radiance over a 5-degree Instantaneous Field Of View (IFOV). The actual measurements used in this model were made under the clear blue skies of Stockholm (approximately 60 degrees North latitude).

Current Study Model

This study uses the current CIE standard, analytic clear-sky radiance distribution [CIE,1973] for the sole reason that it is a current, accepted standard:

$$L_{\text{sky}}(\mu, \nu) = L_{\text{ref}} * A * B / C \quad [2.3:6]$$

where

$$A = 0.91 + 10 * \text{EXP}(-3 * \mu_0) + 0.45 * \text{COS}(\mu_0)^2, \quad [2.3:7]$$

$$B = 1 - \text{EXP}(-0.32 / \text{COS}(\mu)), \quad [2.3:8]$$

and

$$C = 0.274 * (0.91 + 10 * \text{EXP}(-3 * \theta_0) + 0.45 * \text{COS}(\theta_0)^2). \quad [2.3:9]$$

All other parameters are as previously defined. Although

both the CIE model and the Hopkinson model provide broadband spectral radiance values, the results from the CIE model must be used with caution when applied to the narrowband spectral radiance in the vicinity of the peak solar spectral radiance, particularly in the vicinity of 460 nanometers. Chapman and Irani [1981] applied the Hopkinson model to their model requirement for a near-infrared narrowband distribution and noted that "measurements of sky radiance which we have made show [L_{ref}] varies more than a factor of 3 for apparently clear skies."

This study requires only a reasonable relative spatial distribution of radiance and does not attempt to acquire absolute radiance values. Therefore, the convention used in this study sets the value of L_{ref} such that the radiance at the solar location is equal to 100.0 in arbitrary units of radiance. All other radiance values can be expressed as a relative percentage of the total radiance in the vicinity of the sun.

Figures 2.3:1 and 2.3:2 illustrate two of the 11 synthetic total skydome radiance distributions used in this study, for a solar azimuth of -45 degrees and solar zenith angles of 0.0 and 53.2 degrees, respectively. The arrows in these

(and following) figures point to zero azimuth.

FIGURES 2.3:1-2. Synthetic skydome radiances distributions.

Polarized Rayleigh Scattering Model

The fraction of the unpolarized solar radiance that is horizontally polarized by Rayleigh scattering in the atmosphere is defined:

$$H = 0.5*(1-\text{psi})+\text{psi}*\text{COS}(\text{nu}_0)^2 \quad [2.3:10]$$

where

$$\text{psi} = 0.94*(1-\text{COS}(\text{mu}_0)^2)/(1+\text{COS}(\text{mu}_0)^2), \quad [2.3:11]$$

and

$$\begin{aligned} \text{nu}_0 = & \text{ACOS}[\text{SIN}(\text{theta})*\text{COS}(\text{theta}_0) \\ & - \text{SIN}(\text{theta}_0)*\text{COS}(\text{theta})*\text{COS}(\text{phi}-\text{phi}_0)/\text{SIN}(\text{mu}_0)]. \end{aligned} \quad [2.3:12]$$

Likewise, the fraction of the unpolarized solar radiance that is vertically polarized by Rayleigh scattering in the atmosphere is defined:

$$V = 0.5*(1-\text{psi})+\text{psi}*(1-\text{COS}(\text{nu}_0)^2). \quad [2.3:13]$$

All other parameters are as previously defined: nu_0 is the angle between the vector parallel to the direction of polarization and the projection of that vector onto the surface coordinate plane. psi includes the multiplicative depolarization term defined by Coulson [1975] to account for anisotropy of scattering.

Figures 2.3:3 and 2.3:4 illustrate the horizontally polarized component of the total radiance distributions illustrated in Figures 2.3:1 and 2.3:2.

Figures 2.3:5 and 2.3:6 illustrate the vertically polarized component of the total radiance distributions illustrated in Figures 2.3:1 and 2.3:2.

FIGURES 2.3:3-4. Horizontally polarized radiance components.

FIGURES 2.3:5-6. Vertically polarized radiance components.

2.4 Synthesis of Subsurface Upwelling Radiance

Introduction

Existing linear or linearizable models for subsurface upwelling radiance employ one or more limiting assumptions:

- 1) the existence of a flat water surface,
- 2) an homogeneous subsurface profile,
- 3) a single-scattering approximation (i.e. clear or shallow water),
- 4) direct solar illumination only, and/or
- 5) diffuse sky illumination only [Aas,1987; Gordon et al., 1975; Gordon & McCluney,1975; Philpot,1987; Zaneveld,1982].

The minimum subsurface model for this synthesis must assume an homogeneous deepwater subsurface profile in order to simplify several radiometric and mechanical considerations:

- 1) the bottom is not visible and therefore not a radiometric factor,
- 2) surface waves do not mechanically refract (as they would in shallow water) and impart energy to the bottom,
- 3) the interaction of wave energy with subsurface waters is sufficient to make the inherent optical properties of the subsurface homogeneous at all radiometrically significant

depths, and

4) the subsurface is homogeneous to a sufficient optical depth in order to assume that the subsurface hemispheric radiance distribution (the 'subdome') is spatially invariant with respect to the image sample area of the water surface, i.e. the model assumes that each image sample area on the water surface 'sees' the same subsurface radiance distribution.

The calculation of upwelling subsurface radiance in the presence of a non-smooth water surface is complicated by several factors:

- 1) attenuation and refraction of the above-surface downwelling radiance by the rough water surface,
- 2) absorption and back-scattering (single or multiple) of the below-surface downwelling radiance due to the inherent optical properties of the water and its constituents,
- 3) attenuation and refraction of the below-surface upwelling radiance by the rough water surface, and
- 4) localized total internal reflection of the below-surface upwelling radiance where the angle between the surface normal vector and the upwelling radiance vector exceeds the critical angle (48.8 degrees at 460 nanometers).

A complete synthetic model for upwelling subsurface radiance would fully accommodate its parametric dependence on the four inherent optical properties of natural waters [Gordon et al., 1975]:

a = the absorption coefficient,

b = the scattering coefficient,

c = the attenuation coefficient, and

B(theta) = the volume-scattering coefficient,

with the following inter-relations:

c = b + a , and

$$b = 2\pi \int_0^{\pi} B(\theta) \sin(\theta) d\theta.$$

Two nonlinear integrations would be applied to accommodate attenuation of a non-flat water surface. The first integration would angularly distribute the refracted downwelling surface radiance based upon the slope distribution of the total surface area of the image. The second integration would angularly distribute the refracted upwelling subsurface radiance based upon the individual slope distribution of each image sample area.

In essence, at least three independent nonlinear operations would be required to compute the subsurface upwelling radiance; one intermediate operation for the single-scattering model. The only successful technique that can adequately model this level of complexity (and higher) is a Monte Carlo simulation [Plass & Kattawar, 1969], a method which is beyond the scope of this study.

Chapman & Irani Model

No subsurface model was defined by Chapman and Irani [1981] because they included the assumption of spectral sensing in the infrared where transmittance through water approaches zero.

Current Study Model

The approach for this study is to employ the results of previous Monte Carlo simulations as ad hoc analytic models. Results have been published by Plass, Kattawar and Guinn [1975, 1976] and will be used with the following assumptions:

- 1) the results are valid in a narrowband spectral region centered at 460 nanometers (which is near the wavelength of maximum transparency for clear water),
- 2) the optical depth τ of water is 10 at this wavelength,
- 3) the bottom layer has unit absorption, and

4) the results are valid over a broad band of wind velocities centered at 1030 cm/sec (measured at a height of 1950 cm). (This is equivalent to a friction velocity of 36 cm/sec for an homogeneous wind profile.)

Figures 2.4:1 through 2.4:5 illustrate the Monte Carlo results of Plass, Kattawar and Guinn [1976] for solar zenith angles of 0, 15, 32, 57, and 80 degrees, respectively.

The upwelling subsurface radiance observed just above the surface is given the following approximate analytic expression relative to L_{ref} , the reference sky radiance at zenith:

$$L_w(\beta, \alpha) = L_{ref} * R_0 * C * (1 + \cos(A * \beta))^2 / 2.0 \quad [2.4:1]$$

where

$L_w(\beta, \alpha)$ = the upwelling subsurface radiance observed at the wave-slope coordinates (β, α) ,

β = the maximum wave-slope angle $[0 : +90 \text{ deg}]$,

α = the azimuth angle to the wave-slope angle β $[-180 : +180 \text{ deg}]$,

$L_{ref} = L_{sky}(0,0)$ = the reference radiance at zenith, [2.4:2]

$R_0 = 0.0208$ = the unpolarized Fresnel reflectivity at normal

FIGURES 2.4:1-5. Monte Carlo scattering results. (from Plass, Kattawar & Guinn, 1976)

incidence at 460 nanometers, [2.4:3]

$C = 0.32 \times 10^B$, [2.4:4]

$A = \cos(\theta_0)^2$, [2.4:5]

and

$B = \sin(1.1 \times \theta_0) \sqrt{3}$ [2.4:6]

such that

θ_0 = the zenith angle to the sun.

Note that this model has no dependence on ϕ_0 , the azimuth angle of the sun.

Again, this study requires only a reasonable relative spatial distribution of radiance and does not attempt to compute absolute radiance values. Therefore, the value of L_{ref} is set such that the radiance at the solar location is equal to 100.0 in arbitrary units of radiance. All other radiance values can then be expressed as a percentage of the total radiance in the vicinity of the sun.

Figures 2.4:6 and 2.4:7 illustrate the two synthetic total subdome radiance distributions for solar zenith angles of 0.0 and 53.2 degrees, respectively.

FIGURES 2.4:6-7. Synthetic subdome radlance distributions.

Depolarized Random Scattering Model

Both Beckmann and Spizzichino [1963] and Konnen [1985] give evidence that the effect of rough water surfaces on the propagation of polarized downwelling radiance through the surface is a depolarization, either through multiple reflections or turbulent refraction. Therefore, this model will assume equal fractions of horizontally and vertically polarized radiance:

$$H = V = 0.5$$

[2.4:7]

Figures 2.4:8 and 2.4:9 illustrate the identical horizontally and vertically polarized components of the total upwelling subsurface (subdome) radiance distributions illustrated in Figures 2.4:6 and 2.4:7.

FIGURES 2.4:8-9. Horizontally and vertically polarized components of the synthetic subdome radiance distributions.

2.5 Synthesis of Reflected Skydome Radiance

Chapman & Irani Model

Chapman and Irani [1981] incorporated a variant of the law of Malus into their calculation of reflected skydome radiance:

$$L_r = R * L_{sky}, \quad [5.2:1]$$

where

R = the Fresnel reflectivity (for arbitrary polarization),

and

L_{sky} = the sky radiance (for arbitrary polarization).

Their paper does not indicate whether the attenuation due to surface-slope projection was incorporated in their model.

Current Study Model

The radiance reflected from the water surface is calculated by the same method used by Cox and Munk [1954a] and Saunders [1967]:

Consider a small specular facet of the sea surface with area dA that is inclined from the zenith by the angle β . The projection of the facet onto a horizontal surface is

$$dA_h = dA \cdot \cos(\beta). \quad [2.5:2]$$

Likewise, the actual area of the sloping facet is

$$dA = dA_h \cdot \sec(\beta). \quad [2.5:3]$$

The projection of the actual facet area onto a plane normal to the incident radiance is

$$\begin{aligned} dA_i &= dA \cdot \cos(\omega), = dA \cdot \cos(\theta - \beta) \\ &= dA_h \cdot \sec(\beta) \cdot \cos(\omega), \end{aligned} \quad [2.5:4]$$

where

ω = the angle of incidence,

and

θ = the zenith angle of reflection.

Consider the probability distribution for surface slopes:

$$\Pr(\beta, \alpha) = \Pr(s_x, s_y) = \Pr(dz/dx, dz/dy) \quad [2.5:5]$$

where

α = the azimuth angle to maximum slope angle β ,

and

$dz/dx, dz/dy$ = the slope components unique to β and α such that

$$dA_h = dx \cdot dy, \quad [2.5:6]$$

$$\text{TAN}(s_x) = \text{TAN}(dz/dx) = \text{TAN}(\beta) * \text{COS}(\alpha), \quad [2.5:7]$$

and

$$\text{TAN}(s_y) = \text{TAN}(dz/dy) = \text{TAN}(\beta) * \text{SIN}(\alpha). \quad [2.5:8]$$

The projection of the reflected radiance normal to the plane of reflection can then be defined in surface-slope coordinates (β, α) for any small, specular surface facet of slope = $\beta(\alpha)$:

$$\begin{aligned} L_r'(\beta, \alpha) &= L_r(\beta, \alpha) * \text{COS}(\theta) \\ &= R(\omega) * L_{\text{sky}}(\mu, \nu) * \text{COS}(\omega) * \text{SEC}(\beta), \end{aligned} \quad [2.5:9]$$

where

$R(\omega)$ = the Fresnel reflectivity of the water facet (for arbitrary polarization),

and

$L_{\text{sky}}(\mu, \nu)$ = the incident radiance of the skydome from the direction (μ, ν) that is reflected normal to the defined plane of reflection ($\theta = 53.2$ deg, $\phi = 180$ deg) for both polarizations. (The calculation of the incident vector coordinates from the reflection and surface normal vector coordinates is defined at the end of this chapter.)

The mean reflection radiance perceived by an observer at the reflection coordinates is similarly defined:

$$\begin{aligned}
\langle L' \rangle &= \langle L_r \rangle * \cos(\theta) \\
&= \int \int R(\omega) * L_{\text{sky}}(\beta, \alpha) * \Pr(\beta, \alpha) \\
&\quad * \cos(\omega) * \text{SEC}(\beta) * d\beta d\alpha \quad [2.5:10]
\end{aligned}$$

over the full distribution of surface slopes. This value, combined with the small contribution due to refraction, is computed as the central ordinate of the radiance magnitude spectrum, $M(0,0)$, as an ensemble average of spectra. Because the reflection vector (i.e. line of sight) is fixed with respect to the other geometries, L_r can be linearly mapped to surface-slope coordinates (β, α) once the skydome radiance distribution is uniquely determined.

Figure 2.5:1 illustrates the mapping of the function, $\text{SEC}(\beta)$, to the surface-slope coordinates (β, α) . For this illustration, the function was truncated at $\text{SEC}(60^\circ)$ for values of β greater than 60 degrees. Note also that the function is not computed for values of β where $(\omega - \mu) = (\theta - \omega) > 90^\circ$, i.e. the regions where surface slopes are not visible with respect to the line of sight.

Figure 2.5:2 illustrates the mapping of the function, $\cos(\omega)$, to the surface-slope coordinates (β, α) .

FIGURE 2.5:1. Map of $SEC(\beta)$ to coordinates (β, α) .

FIGURE 2.5:2. Map of $COS(\omega)$ to coordinates (β, α) .

Figures 2.5:3 and 2.5:4 illustrate the mapping of Fresnel reflectivity, $R(\omega)$, to surface-slope coordinates (β, α) for horizontal and vertical polarizations, respectively.

Figures 2.5:5 and 2.5:6 illustrate the mapping of skydome radiance, $L_{\text{sky}}(\mu, \nu)$, to surface-slope coordinates (β, α) for horizontal and vertical polarization, respectively. The solar zenith angle θ_0 in this example is 0 degrees. The original L_{sky} distributions in skydome coordinates (μ, ν) are illustrated in Figures 2.3:3 and 2.3:4.

Figures 2.5:7 and 2.5:8 illustrate the mapping of the reflected skydome radiance, L_r' , to the surface-slope coordinates (β, α) for horizontal and vertical polarization, respectively. The solar zenith angle θ_0 in this example is 0 degrees.

FIGURE 2.5:3. Map of Fresnel reflectivity, $R(\omega)$, to coordinates (β, α) for horizontal polarization.

FIGURE 2.5:4. Map of Fresnel reflectivity, $R(\omega)$, to coordinates (β, α) for vertical polarization.

FIGURE 2.5:6. Map of skydome radiance, $L_{sky}(\mu, \nu)$, to coordinates (β, α) for vertical polarization.

FIGURE 2.5:7. Map of reflected skydome radiance, L_r' , to coordinates (β, α) for horizontal polarization.

FIGURE 2.5:8. Map of reflected skydome radiance, L_r' , to coordinates (β, α) for vertical polarization.

Correlation of Sub-Resolution Wave-Slope Variance

The maximum wavenumber of the current study model is $k_{\max} = 1.2$ per centimeter to coincide with the results of other studies [Cox & Munk, 1954a,b; Pierson & Stacy, 1973]. This corresponds to a sample surface area of

$$A_h = 2.6 \text{ cm} \times 2.6 \text{ cm} = 6.76 \text{ cm}^2 \quad [2.5:11]$$

which is defined in the literature as the Cox-Munk window.

Because slope spectra (cite Figure 2.2:13) reveal significant slope energy between $k = 1.2/\text{cm}$ and $k = 30 \text{ }^\circ/\text{cm}$, it is important to model the effect of this sub-resolution variance on the reconstruction of wave-slope spectra. However, it is unreasonable to synthesize large surfaces with sampling windows of the order $A_h = 1.0 \text{ mm}^2$, as required to consider $k = 30$ per centimeter. Previous investigators [Chapman & Irani, 1981; Wilf & Manor, 1984; Schwartz & Hon, unpub.] all employed the Kirchhoff approximation for reflection from rough surfaces [Kajiya, 1985; Beckmann & Spizzichino, 1963], which essentially replaces a rough surface facet by its mean tangent plane. This approximation is valid only if the rough sub-resolution surface is of low curvature. However, for wind-driven water-wave surfaces, it

is exactly the spectral region above $k > 1.0$ per centimeter where all the spectral energy of curvature exists.

Figure 2.5:9 illustrates $k^3 \cdot S(k)$ versus k , the curvature power spectrum (after Pierson & Stacy, 1973). It is apparent that the Kirchoff approximation is not optimum for this particular circumstance.

FIGURE 2.5:9. The 1D Pierson-Stacy curvature power spectrum $k^3 \cdot S(k)$ versus $\text{LOG}_{10}(k)$.

Current Study Model

To quote Stilwell and Pilon:

"The subresolution waves, especially those in the capillary regime, can have significant slopes. Since they are unresolved on the film, the intensity variations of the sky are partially smoothed. This effect can be observed by examining the reflection of a cloud in a ruffled water surface. As a result the small waves can smooth the sky luminance distribution and allow the use of photographic procedures on days in which the sky is far from a monotonic luminance function. Contingent only on the distribution of sub-resolution waves being homogeneous, the effective luminance distributions may extend the environmental conditions under which optical transforms are useful."
[Stilwell & Pilon, 1974]

An alternative method, then, for introducing the effect of sub-resolution wave slopes is to assume an homogeneous distribution and use it as a correlation filter to smooth the reflected skydome radiance. The correlation is nonlinear if executed in reflected skydome coordinates (μ, ν). However, a linear correlation is possible if executed in surface slope coordinates (β, α).

The unresolved directional wave-slope variance for the wavenumber range $k > 1.2/\text{cm}$ is calculated directly from the Pierson-Stacy model. A directional bivariate normal Gaussian distribution is calculated as a function of along-wind slope variance, cross-wind slope variance, and wind azimuth:

$$Pr'(\beta, \alpha) = \exp(-(L^2 + M^2)/2) / (2\pi \cdot DEV_A \cdot DEV_C), \quad [2.5:12]$$

where

$$L = \tan(\beta) \cdot \cos(\text{wind_az} - \alpha) / DEV_A, \quad [2.5:13]$$

and

$$M = \tan(\beta) \cdot \sin(\text{wind_az} - \alpha) / DEV_C, \quad [2.5:14]$$

such that

$$DEV_A = \text{SQRT}(\text{along-wind slope variance}),$$

$$DEV_C = \text{SQRT}(\text{cross-wind slope variance}),$$

and

wind_az = the wind azimuth (with 180-degree ambiguity).

The directional distribution of sub-resolution wave slopes, $Pr'(\beta, \alpha)$, is then correlated with the reflected sky-dome radiance, $L_r'(\beta, \alpha)$,

$$\begin{aligned} L_r''(\beta, \alpha) &= \int \int L_r'(b, a) \cdot Pr'(b - \beta, a - \alpha) \cdot da db \\ &= L_r'(\beta, \alpha) \star \star Pr'(\beta, \alpha), \end{aligned} \quad [2.5:15]$$

which follows directly from Equations [2.5:9] and [2.5:10].

(The $\star \star$ denotes the double correlation operation.)

Note that because the sub-resolution wave-slope distribution is assumed to be both homogeneous and symmetric about its central ordinate, Equation [2.5:15] could also be implement-

ed as a double convolution operation:

$$L_r''(\beta, \alpha) = L_r'(\beta, \alpha) \star \star Pr'(\beta, \alpha) \\ = L_r'(\beta, \alpha) \bullet \bullet Pr'(\beta, \alpha). \quad [2.5:16]$$

Figure 2.5:10 is the sub-resolution wave-slope distribution for a friction velocity of 12.0 cm/sec and a wind azimuth of -45 deg (or +135 deg with ambiguity).

Figures 2.5:11 and 2.5:12 illustrate the correlation of L_r' , the reflected skydome radiance (Figures 2.5:7 and 2.5:8), with Pr' , the sub-resolution wave-slope distribution.

FIGURE 2.5:10. Sub-resolution wave-slope distribution Pr' for $v_{fric} = 12.0$ cm/sec and $wind_az = -45$ deg.

FIGURE 2.5:11. Effect of correlation of L_r' with sub-resolution wave-slope distribution Pr' (horizontal polarization).

FIGURE 2.5:12. Effect of correlation of L_r' with sub-resolution wave-slope distribution Pr' (vertical polarization).

Calculation of Reflection Angular Coordinates

The angular coordinates that describe the ray path due to reflection can be calculated if two of three vectors (the surface normal vector N , the incident vector I , and the reflection vector R) are known.

Figure 2.5:13 illustrates the geometric relations and nomenclature for the current study model.

The reflection vector is fixed in this model. The observer is located at an azimuth angle ϕ of 180 degrees and zenith angle θ of 53.2 degrees (the Brewster angle) relative to the point of observation. The reflection vector R can be resolved into its unit vector coordinates in (x,y,z) space:

$$R_x = \sin(\theta) \cdot \cos(180 \text{ deg}), \quad [2.5:17]$$

$$R_y = \sin(\theta) \cdot \sin(180 \text{ deg}), \quad [2.5:18]$$

and

$$R_z = \cos(\theta). \quad [2.5:19]$$

The surface normal vector N and the incident vector I can be similarly resolved:

$$N_x = \sin(\beta) \cdot \cos(\alpha), \quad [2.5:20]$$

$$N_y = \sin(\beta) * \sin(\alpha), \quad [2.5:21]$$

and

$$N_z = \cos(\beta); \quad [2.5:22]$$

$$R_x = \sin(\mu) * \cos(\nu), \quad [2.5:23]$$

$$R_y = \sin(\mu) * \sin(\nu), \quad [2.5:24]$$

and

$$R_z = \cos(\mu). \quad [2.5:25]$$

Because the vector N must be in the plane containing I and R and because it must also bisect the angle between I and R , the following equations have unique solutions:

$$IN = RN = \cos(\omega), \quad [2.5:26]$$

$$IR = \cos(2\omega), \quad [2.5:27]$$

$$N = (R - I) / (2\cos(\omega)), \quad [2.5:28]$$

and

$$R = N * 2 * \cos(\omega) - I. \quad [2.5:29]$$

FIGURE 2.5:13. 3D geometric relations and nomenclature for the current study model.

2.6 Synthesis of Refracted Subsurface Radiance

Chapman & Irani Model

No refracted subsurface radiance model was defined by Chapman and Irani [1981] because they included the assumption of spectral viewing in the infrared where the transmittance of water approaches zero.

Current Study Model

As defined in Chapter 2.4, the upwelling subsurface radiance model of Plass et al. [1976] provides the radiance just above the ocean surface as a function of zenith angle of observation. Therefore, no angular refraction model is required. Only attenuation due to surface projection (as described in Chapter 2.5) needs to be considered:

The projection of the refracted radiance normal to the plane of observation can be defined, in surface-slope coordinates (beta, alpha) for any small, specular surface facet of slope:

$$L_w'(\text{beta}, \text{alpha}) = L_w(\text{beta}, \text{alpha}) * \text{COS}(\text{omega}) * \text{SEC}(\text{beta}) [2.6:1]$$

where

$L_w(\text{beta}, \text{alpha})$ = the refracted subsurface radiance observed at wave-slope coordinates (beta, alpha),

and

ω is as previously defined.

Figure 2.6:1 illustrates the mapping of L_w' , the refracted subsurface radiance, to the surface-slope coordinates (β , α) for identical horizontal and vertical polarizations, respectively. The solar zenith angle in this example is 0 degrees. The original unattenuated upwelling subsurface radiance distribution, L_w , is illustrated in Figure 2.4:8. Note that the the function, $\text{SEC}(\beta)$, was truncated for values of β greater than 60 degrees (as in Figure 2.5:1), in order to maintain the scale of the illustration.

FIGURE 2.6:1. Map of refracted subsurface radiance, L_w' , to coordinates (β , α) for both polarizations.

Correlation of Sub-Resolution Wave-Slope Variance

No correlation of the refracted radiance is required for the current study model since the Monte Carlo simulation of Plass et al. [1976] has already incorporated the effect of wave slopes.

2.7 Generation of Synthetic Radiance Imagery

The integrated current study model can generate any combination of these synthetic radiance conditions:

- 1) Horizontal, Vertical polarization, or Both (unpolarized),
- 2) Reflected, Refracted radiance, or Both, and
- 3) Sub-resolution wave-slope attenuation (On or Off).

Because of Brewster-angle viewing relative to the mean sea surface, an initial assumption of the current study is that the effect of vertically polarized radiance is at a minimum and a comparison of horizontally polarized radiance spectra with unpolarized radiance spectra is sufficient to demonstrate the effect of vertical polarization. A second assumption is that the effect of upwelling subsurface refracted radiance is small relative to reflected radiance and a comparison of reflected radiance spectra with combined (reflected + refracted) radiance spectra is sufficient to demonstrate the effect of refracted radiance. A third assumption is that horizontally polarized, reflected radiance spectra synthesized without the sub-resolution wave-slope correlation filter will emulate the synthetic results of Chapman and Irani [1981].

The following radiance images (and their magnitude spectra) are synthesized in support of the current study:

$H1(x,y)$ = Horizontally polarized, reflected radiance image,

$L1(x,y)$ = Total (unpolarized), reflected radiance image,

$H0(x,y)$ = Horizontally polarized, reflected and refracted radiance image,

$L0(x,y)$ = Total (unpolarized), reflected and refracted radiance image, and

$H3(x,y)$ = $H1(x,y)$ without the incorporation of the sub-resolution wave-slope correlation filter model.

The following pages illustrate individual realizations of synthetic images that were generated in support of the current study. All examples are $L0$ images with contrasts normalized relative to a discrete 32-level gray scale: black corresponds to zero radiance and white corresponds to the maximum pixel radiance of the image. Only these examples are discrete: the actual syntheses are real scalar arrays.

Figures 2.7:1 through 2.7:3 illustrate synthetic images generated by filtering the same white noise array with slope spectra for $v_{fric} = 12.0, 36.0, \text{ and } 60.0$ cm/sec, respectively. $wind_az = 135$ deg (-45 deg) and sun is at zenith.

FIGURE 2.7:1. L0 image.

$v_{\text{fric}} = 12.0 \text{ cm/sec}$
 Max pixel radiance L0 = 1.526
 Avg pixel radiance H1 = 0.578
 Avg pixel radiance H3 = 0.528
 Avg pixel radiance V1 = 0.032
 Avg pixel radiance L1 = 0.610
 Avg pixel radiance H2 = 0.106
 Avg pixel radiance V2 = 0.106
 Avg pixel radiance L2 = 0.212
 Avg pixel radiance H0 = 0.684
 Avg pixel radiance V0 = 0.138
 Avg pixel radiance L0 = 0.822

FIGURE 2.7:2. L0 image.

$v_{\text{fric}} = 36.0 \text{ cm/sec}$
 Max pixel radiance L0 = 1.894
 Avg pixel radiance H1 = 0.602
 Avg pixel radiance H3 = 0.564
 Avg pixel radiance V1 = 0.050
 Avg pixel radiance L1 = 0.652
 Avg pixel radiance H2 = 0.105
 Avg pixel radiance V2 = 0.105
 Avg pixel radiance L2 = 0.210
 Avg pixel radiance H0 = 0.707
 Avg pixel radiance V0 = 0.155
 Avg pixel radiance L0 = 0.862

FIGURE 2.7:3. L0 image.

$v_{\text{fric}} = 60.0 \text{ cm/sec}$
 Max pixel radiance L0 = 1.737
 Avg pixel radiance H1 = 0.579
 Avg pixel radiance H3 = 0.574
 Avg pixel radiance V1 = 0.054
 Avg pixel radiance L1 = 0.633
 Avg pixel radiance H2 = 0.105
 Avg pixel radiance V2 = 0.105
 Avg pixel radiance L2 = 0.210
 Avg pixel radiance H0 = 0.684
 Avg pixel radiance V0 = 0.159
 Avg pixel radiance L0 = 0.843

The synthetic image in Figure 2.7:4 is a different synthetic realization (i.e. different white noise spectrum) using the same parameters as Figure 2.7:1. Note both the similarity of the image and its statistics to that of Figure 2.7:1.

FIGURE 2.7:4. L0 image.

$v_{\text{fric}} = 12.0 \text{ cm/sec}$
Max pixel radiance L0 = 1.523
Avg pixel radiance H1 = 0.578
Avg pixel radiance H3 = 0.526
Avg pixel radiance V1 = 0.031
Avg pixel radiance L1 = 0.609
Avg pixel radiance H2 = 0.106
Avg pixel radiance V2 = 0.106
Avg pixel radiance L2 = 0.212
Avg pixel radiance H0 = 0.684
Avg pixel radiance V0 = 0.137
Avg pixel radiance L0 = 0.821

The final example in Figure 2.7:5 has $v_{\text{fric}} = 60.0 \text{ cm/sec}$ and wind_az is now 0 degrees.

FIGURE 2.7:5. L0 image.

2.8 Slope Spectra Analysis of Synthetic Images

Analysis of slope spectra involves several related figures of merit that are all based upon the difference in slope spectral response between the original slope magnitude spectra used in the synthesis and the final synthetic image magnitude spectra resulting from the nonlinear transformation of wave slope to radiance. These figures of merit can be correlated to either wave slope variance or the difference in wave slope variance.

The first figure of merit is the 2D difference (or error) spectrum $D_2(k, \phi)$. An ensemble average of four independent spectral realizations of the same synthetic geometry is calculated and the fundamental component $N'(0,0)$ (that represents the mean image radiance) is then removed.

$$N'(k, \phi) = \sum_{i=1}^4 N_i(k, \phi) \quad [2.8:1]$$

$$N''(k, \phi) = N'(k, \phi) - N'(0,0) \quad [2.8:2]$$

where

N - the magnitude spectrum of the synthetic radiance image,

k - wavenumber,

and

ϕ = azimuth angle.

The modified image magnitude spectrum, $N(k, \phi)$, is normalized so that the peak response matches the peak response of the original slope magnitude spectrum $M_0(k, \phi)$. The motivation is to provide a scaled difference (error) spectrum to illustrate the nonlinearity in slope spectral response of $N_{\text{norm}}(k, \phi)$ relative to $M_0(k, \phi)$ over the domains of wavenumber and azimuth.

$$N_{\text{norm}}(k, \phi) = N(k, \phi) / \text{MAX}(M_0(k, \phi)) \quad [2.8:3]$$

$$D_2(k, \phi) = M_0(k, \phi) - N_{\text{norm}}(k, \phi) \quad [2.8:4]$$

Note that coordinates k and ϕ are specified here for the consistency of this discussion only. The actual arrays used in this study are specified by rectangular spatial frequency (wavenumber) coordinates (k_x, k_y) such that

$$D_2(k_x, k_y) = D_2(k \cdot \cos(\phi), k \cdot \sin(\phi)). \quad [2.8:5]$$

The second and third figures of merit are the 1D squared difference (error) spectra $D_1(k)$ and $D_1(\phi)$. The motiva-

tion is to provide a scaled 1D variance spectrum to illustrate the nonlinearity in spectral response of $N_{\text{norm}}(k)$ relative to $M_0(k)$ over the domain of wavenumber only, and of $N_{\text{norm}}(\phi)$ relative to $M_0(\phi)$ over the domain of azimuth.

$$D_1(k) = \int |D_2(k, \phi)|^2 d\phi \quad [2.8:6]$$

$$D_1(\phi) = \int |D_2(k, \phi)|^2 dk \quad [2.8:7]$$

The fourth figure of merit is the squared integrated value of the difference (error) in slope spectral response D_0 . The 2D difference (error) spectrum $D_2(k, \phi)$ is integrated with respect to both azimuth ϕ and wavenumber k . The motivation is to provide a single number to describe the nonlinearity in slope spectral response in the calculation of the variance of N_{norm} , i.e. the estimate of the variance of M_0 , relative to the actual slope variance of the original (input) spectrum.

$$D_0 = \int \int |D_2(k, \phi)|^2 dk d\phi. \quad [2.8:8]$$

The cross-wind and along-wind squared differences are also calculated:

$$D_{0c} = \int \int |D_2(k, \phi) * \sin(\text{wind_az} - \phi)|^2 dk d\phi, \quad [2.8:9]$$

and

$$D_{0a} = \int \int |D_2(k, \phi) * \cos(\text{wind_az} - \phi)|^2 dk d\phi. \quad [2.8:10]$$

These figures of merit are determined for each of four differentially polarized variations of the same synthetic image:

H1(x,y) - Horizontally polarized, reflected radiance image,

L1(x,y) - Total (unpolarized), reflected radiance image,

H0(x,y) - Horizontally polarized, reflected and refracted radiance image,

L0(x,y) - Total (unpolarized), reflected and refracted radiance image, and

H3(x,y) - H1(x,y) without the incorporation of the sub-resolution wave-slope correlation filter model,

where

$$N_{ji}(k_x, k_y) = \left| \int^{-1} IM_i(x, y) \right|$$

for $IM=H1, L1, H0, L0, H3$ and $i=1-4$. [2.8:11]

Because of the large number of spectra to be processed, the Results will include only the D1 and D0 data.

3.0 RESULTS AND DISCUSSION

The D_1 results (slope variance versus wavenumber; slope variance versus azimuth) are listed in Appendix I. These results provide the most graphic illustration of the wave-slope error generated by the parametric variation of wind azimuth, solar position and wind velocity. The D_0 results (partial and total integrated slope variance) are listed in Appendix II. The D_2 difference (error) spectra (from which the D_1 and D_0 results are derived) are not included with this report to avoid cumbersome detail (i.e. 360 graphic examples of three-dimensional difference/error spectra).

3.1 Discussion of D_0 Results

Please refer to the D_0 results in Appendix II.

Parametric Variation of Mean Radiance

The mean radiance reflected/refracted in the direction of observation is the central ordinate of the forward Fourier transform of the radiance image and is calculated for each imaging geometry and for each of five polarized radiance conditions:

H1 - reflected horizontal radiance,

L1 - reflected total (horizontal + vertical) radiance,

H0 - reflected & refracted horizontal radiance,

L0 - reflected & refracted total radiance, and

H3 - reflected horizontal radiance without the sub-resolution wave-slope model (essentially a reconstruction of the Chapman & Irani synthesis.)

H3 will be compared with H1 as an examination of the effect of sub-resolution wave slopes on model results.

As expected, the following conditions are observed:

1) The mean radiance is maximum when the imaging geometry favors specular reflection of the sun, i.e. the solar position is azimuth angle $\phi_0 = 0.0$ deg and zenith angle $\theta_0 = 53.2$ deg (denoted (ϕ_0, θ_0) for the remainder of this discussion). The second highest mean radiance is observed where the sun is at zenith (i.e. $(0,0)$). Mean radiance decreases as sun azimuth varies from 0 degrees.

2) Under the conditions of maximum solar reflection and $v_{\text{fric}} = 12.0$ cm/sec, the slightly disturbed water surface yields a mean radiance of approximately 1.98 for L0 (averaged over the four wind azimuths). This value compares favorably with the theoretical L0 value of 2.62 when the surface is a totally flat, specular surface. Mean radiance drops to 1.75 when $v_{\text{fric}} = 36.0$ cm/sec and drops to 1.50 when $v_{\text{fric}} = 60.0$ cm/sec. As the surface becomes rougher, the probability of reflecting facets having zero slope decreases and less of the direct solar radiance is reflected.

3) Under the conditions of maximum solar reflection and $v_{\text{fric}} = 60.0$ cm/sec, mean radiance is highest (1.57 for L0) when the dominant wind azimuth wind_az is orthogonal to the plane of reflection and lowest (1.45 for L0) when wind_az is parallel to the plane of reflection. As the surface becomes

rougher due to wind, the slope distribution increases its spread along the azimuthal plane of the wind defined by wind_az. When wind_az is orthogonal to the plane of reflection, there is a greater probability that a facet will reflect radiance from the skydome near the plane of reflection than when wind_az is parallel to the plane. With the sun located in this plane, the probability that a facet will reflect radiance from the vicinity of the sun is greater when wind_az is orthogonal. This effect can be observed, to a lesser degree, for all sun orientations in the plane of reflection. The effect diminishes as v_{fric} decreases because of the lower directional attenuation of the dominant low-frequency waves.

Demonstration of Statistical Model Stability

Comparisons of symmetric test cases with three different solar geometries provide an indication of the statistical stability of the complete model.

TABLE 3.1:1. Symmetric test cases and their parameters.

Comparison 1	Comparison 2	Comparison 3	v_{fric}
12 and 24	07 and 19	11 and 23	12 cm/sec
60 and 72	55 and 67	59 and 71	36 cm/sec
36 and 48	31 and 43	35 and 47	60 cm/sec
Sun (0,53.2) Coord	(0,0)	(180,53.2)	

The three sets of test cases have mirror symmetry with respect to observation: the sun is in the plane of reflection ($\phi_0 = 0$ or 180 deg) but the dominant wind azimuths wind_az for the comparison cases are directed 45 degrees away from the the plane of reflection and differ in sign only. The respective test cases should demonstrate similar statistics based on the ensemble average of the magnitude spectra of the four synthetic scenes within each test case.

Mean radiances (the ensemble DC components) are similar to within $\pm 0.32\%$ among all comparisons. There does not appear

to be any correlation between average percent difference and solar geometry even though the mean radiance diminishes as the geometry moves away from maximum solar reflection.

The ensemble fundamental components differ more than expected and this is an indication that a larger ensemble may be one additional requirement for statistical stability.

For these three geometries, the fundamental components are similar to within ± 10% among all comparisons. This may be a poor choice of imaging geometry for statistical validation

because the contrast ratios (fundamental/DC components) are not the highest among the full set of test cases. The main consideration that applies to these particular geometries is that a nearly saturated image (i.e. a very high DC component relative to the remainder of the spatial spectrum) skews the confidence of spectral estimation in favor of the DC component, a parameter which has an expected value of zero in the slope spectral estimate, i.e. the water surface is expected to have a mean slope of zero. However, there does appear to be a correlation between a decrease in the mean radiance with a decrease in the average percent difference (and therefore increased statistical confidence) in the fundamental components. A fundamental consideration for this method is to determine an optimal geometry which removes spectral energy from the DC component and distributes it across the rest of the spatial spectrum with the intent of increasing the statistical stability of the non-DC portion of the spectrum.

Correlation of Contrast Ratio with Slope Variance

As explained in the Methods section, the DC component of the radiance image magnitude spectrum is removed and the remaining image spectrum is normalized with respect to the input slope magnitude spectrum M_0 by a geometric scaling

factor between the peak slope components. The difference between the two spectra is then defined as the error, or difference, spectrum. Integration of the squared error over both wavenumber and azimuth yields the D_0 results, the total slope variance due to errors/differences between the two spectra.

The contrast of the wave image was defined by Chapman and Irani as the ratio of the fundamental component to the DC component and was used as a figure of merit in their error analysis. A comparison of the contrast ratio of the image spectrum with the resulting integrated squared deviation (variance) from its difference spectrum demonstrates a good correlation between high contrast and low error. A simple matrix is presented, where the contrasts of the images for each geometry (with the exception of H3) are ranked from 1 to 4 (high contrast to low contrast) and the corresponding D_0 results are likewise ranked from 1 to 4 (low to high error).

TABLE 3.1:4. Rank correlation matrices for contrast ratio vs. slope variance.

		CONTRAST				
		1	2	3	4	
V	1	22	1	1	0	$v_{\text{fric}} = 60.0 \text{ cm/sec}$
A	2	1	18	3	2	
R	3	1	3	14	6	
	4	0	2	6	16	

		CONTRAST				
		1	2	3	4	
V	1	17	1	0	6	$v_{\text{fric}} = 36.0 \text{ cm/sec}$
A	2	1	14	8	1	
R	3	1	7	13	3	
	4	5	2	3	14	

		CONTRAST				
		1	2	3	4	
V	1	9	4	5	6	$v_{\text{fric}} = 12.0 \text{ cm/sec}$
A	2	2	10	6	6	
R	3	4	9	6	5	
	4	9	1	7	7	

The above results display a high correlation at $v_{\text{fric}} = 60.0$ cm/sec and increasing loss of correlation as v_{fric} decreases. This can be explained as a result of decreasing statistical confidence and increasing ambiguity among contrast values and D_0 values. For $v_{\text{fric}} = 60.0$ cm/sec, the differences between contrast ratios and D_0 values are generally on the order of $\pm 10\%$; for $v_{\text{fric}} = 36.0$ cm/sec, the differences are often less than $\pm 5\%$; for $v_{\text{fric}} = 12.0$ cm/sec, the dif-

ferences are often less than $\pm 1\%$. With the assumptions 1) that the fundamental component (the numerator of the contrast ratio) has an average model error tolerance of $\pm 6\%$ (based on the analysis of Table 3.1:3) and 2) the corresponding D_0 value may have a similar tolerance, it is reasonable to consider that the confidence of unambiguous rank-ordering should decrease for values at and below $v_{\text{fric}} = 36.0$ cm/sec.

Determination of Optimal Imaging Geometry

Figure 3.1:1 provides a graphic comparison of the D_0 values for each geometry. The intent of this comparison is to determine those imaging geometries which provide the lowest integrated squared errors (slope variance) for all sampled variations of dominant wind azimuth wind_az and friction velocity v_{fric} .

Within this limited sample space, the unambiguous selection for optimal imaging of wind-wave slopes is a geometry which requires the sun to be directed 135 degrees away from the azimuth of reflection (i.e. observation) or, by complement, 45 degrees away from the solar azimuth of maximum specular reflection. The D_0 results for this geometry are generally lowest for all polarized conditions.

FIGURE 3.1:1. Range of slope variance (error^2) versus test case number (slope variance expressed as $\text{slope}^2 \times 10^{-3}$).

The second choice of imaging geometry places the sun at the position of maximum specular reflection but this is an ambiguous selection because other geometries provide lower D_0 results for particular values of wind_az and v_{fric} .

This result, from two-dimensional analysis of the current study model, is in full agreement with the results of the one-dimensional survey of Chapman and Irani [1981] and demonstrates a secondary validation of their approach.

Effect of Subsurface Refraction on Slope Variance

The following conditions are observed:

1) The effect of refraction on slope variance is minimal when contrast ratios are high relative to the set of all test cases. It was expected that the additional nonlinearity created by refraction in the transformation of slope to radiance would consistently generate higher slope variances in H0 and L0 relative to H1 and L1. However, the stronger correlation between contrast and slope variance tends to swamp any effect created by subsurface refraction.

2) As expected, the effects of refraction are most noticeable when the sun is furthest away from point of maximum

specular reflection, i.e. when the proportion of refracted radiance relative to reflected radiance is largest. In these test cases, the contrast ratios approach a minimum among all test cases and the slope variances approach a maximum. The large differences between H1 and H0 and between L1 and L0 confirm that the decrease in contrast and increase in slope variance are both due to the effect of refraction on the minimum reflection cases.

Effect of Polarization on Slope Variance

A comparison of H1 with L1 indicates no apparent correlation between polarization and slope variance. Again, the stronger correlation between contrast and slope variance tends to swamp any effect created by differences in polarization. It was expected that the decrease in mean radiance from L1 to H1 would be offset by an increase in contrast and consequent decrease in slope variance. No such effect was discernible among this small sample. Because of Brewster-angle viewing, the effect due to the addition of vertically polarized radiance should be at a minimum among all observation geometries.

3.2 Discussion of D_1 Results

Please refer to the graphic D_1 results (slope variance versus wavenumber; slope variance versus azimuth) in Appendix I. Note that the slope variance for H1 is plotted as a solid line; L0 is plotted as a dashed line; H3 is plotted as a dotted line.

Slope Error as a Function of Wavenumber

The following conditions are observed:

- 1) For $v_{\text{fric}} = 12.0$ cm/sec, the major source of slope error occurs in the vicinity of the dominant, low-spatial-frequency peak centered near $k = 0.12$ rad/cm.
- 2) With the sole exception of the optimal imaging geometry (as determined in Chapter 3.1), the higher-spatial-frequency slope errors increase relative to the error peak near $k = 0.12$ rad/cm as v_{fric} increases.
- 3) With the sole exception of the optimal imaging geometry, the higher spatial frequencies (above $k = 0.12$ rad/cm) are the dominant source of slope error at $v_{\text{fric}} = 60.0$ cm/sec.

4) At the optimal imaging geometry, the major source of slope error remains in the vicinity of the dominant, low-spatial-frequency peak centered near $k = 0.12$ rad/cm for all values of v_{fric} .

5) At the optimal imaging geometry (and at the geometry of maximum solar reflection), the plots of H1 and L0 (as well as the unplotted L1 and H0 data) closely approximate each other within the set of test cases. The same plots within the other imaging geometries tend to approximate each other at $v_{\text{fric}} = 12.0$ cm/sec and then deviate from each other at higher values of v_{fric} .

Variation of H3 with Respect to Wavenumber

H3 represents the results based on the model of Chapman and Irani where no sub-resolution wave-slope model is incorporated. H1 represents results based upon the inclusion of a radiance attenuation model to add the effect of sub-resolution wave slopes on scene radiance.

The following conditions are observed:

1) H3 does not demonstrate a good correlation with any of the model parameters as a function of wavenumber. Within the

limited scope of this experiment, H3 appears to be independent of the model parameters as a function of wavenumber.

2) As expected, H3 maps most closely with H1 when $v_{\text{fric}} = 12.0$ cm/sec. The correlation filter that is used to attenuate radiance as a function of the sub-resolution wave-slope distribution provides a nearly impulse response at $v_{\text{fric}} = 12.0$ cm/sec than at higher values of v_{fric} and the resulting difference between the H1 and H3 radiance models is slight.

3) Within the constraint of optimal imaging geometry, H3 maps closely to H1, L1, H0, and L0 when $v_{\text{fric}} = 12.0$ cm/sec but deviates significantly at higher values of v_{fric} . The most general trend to note is that the slope error associated with H3 becomes much larger relative to the other four radiance conditions as wavenumber increases.

4) Within the constraint of maximum solar reflection geometry, H3 maps closely to H1, L1, H0 and L0 at higher values of v_{fric} but deviates when $v_{\text{fric}} = 12.0$ cm/sec. This effect is opposite to that observed in 3) above.

The demonstrated independence of H3 as a function of wavenumber is also in agreement with the results of Chapman

and Irani. However, the significant result to note is that the other four radiance conditions do demonstrate a definite correlation with wavenumber at the optimal imaging geometry. This correlation is also exhibited in the geometry of maximum solar reflection, although to a lesser degree.

Slope Error as a Function of Azimuth

The following conditions are observed:

- 1) There is a definite azimuthal dependence between slope variance and the parameters of solar azimuth and dominant wind azimuth. This dependence is most readily observable in the two most optimal imaging geometries.
- 2) When $v_{\text{fric}} = 12.0$ cm/sec and wind_az is in the plane of reflection, a dominant error lobe is observable which has an orientation within 20 degrees of the azimuth orthogonal to the sun position. A minor error lobe is observable in the azimuthal plane of the sun, i.e. approximately orthogonal to the dominant lobe.
- 3) When $v_{\text{fric}} = 12.0$ cm/sec and wind_az is varied, the error lobes redistribute so that the dominant errors angularly skew toward the plane of the dominant wind azimuth.

4) As v_{fric} increases, the error lobes tend to angularly spread out so that the dominant errors redistribute between the solar azimuth and the dominant wind azimuth.

Variation of H3 with Respect to Azimuth

The following conditions are observed:

1) The H3 results follow the general trends outlined in Chapter 3.2 above. As discussed with respect to wavenumber, H3 maps closely to the results of the other four radiance conditions when $v_{\text{fric}} = 12.0$ cm/sec.

2) Where H3 deviates significantly from the other four conditions, the additional slope error is observed to align with the plane of the solar azimuth. This result is most noticeable within the two most optimal geometries.

The demonstrated dependence of H3 as a function of azimuth is also in general agreement with the limited results of Chapman and Irani. However, the results for H1, L1, H0, and L0 demonstrate a more consistent correlation with the variation of model parameters.

4.0 CONCLUSION

The results of the current study have established three main conclusions: 1) the limited results of Chapman and Irani [1981] have been generally verified, 2) the existence of an optimal imaging geometry for slope spectrum estimation is indicated, and 3) the enhanced model, incorporating the effects of sub-resolution wave slopes and subsurface refraction on observed radiance, demonstrates a significant effect on wave-slope spectra derived from imagery.

The most conclusive result is the analytic determination of the region containing an optimal geometry for the estimation of wave-slope spectra from imagery under the specified conditions of this study. Through the use of an integrated set of analytic models, the variation of a limited number of parameters has predicted the magnitude of slope variation as a function of azimuth and wavenumber. These predictions exceed the capability of a deterministic second-order theory. While this study has been directed toward a generalization of the Chapman and Irani study, the generalized model requires a more complete exploration of the parametric surface.

Suggestions for Further Research

There are several potential directions for further research which will build upon this study. The types of research fall into two main categories: 1) comparison of the analytic model with empirical data derived from a physical experiment and 2) refinement and extension of the parametric surface exploration of the analytic model.

Physical Experiment

It is obvious that an analytic model requires empirical results to verify its predictions. However, the complexity of this model and its limited utility presumes that the real world problem has an even higher level of complexity. The requirement still exists for the execution of a controlled experiment to calibrate the various techniques that attempt to measure the two-dimensional elevation/slope spectra of large water surfaces under natural conditions.

Refinement of the Analytic Model

The current study verified the limited results of Chapman and Irani [1981] and amplified their method to execute an only slightly larger exploration of the paramet-

ric surface. There are many assumptions in this model which remain to be tested through a vigorous exploration of the currently unvaried parameters:

- sample size and $k_{\max}$
- ensemble size
- radiant wavelength and index of refraction
- zenith angle of observation

Also, other analytic functions await comparison with the current analytic model and with existing empirical data:

- input elevation spectrum
- clear sky versus cloudy sky radiance
- clear water versus turbid water refraction
- sub-resolution wave-slope distributions
- Gram-Charlier versus Gaussian

A secondary (and more vigorous) approach to the simulation of wave shadowing could also be explored: the elevation power spectrum is available for the generation of synthetic height arrays which can be used to modify the radiance distributions at each surface element. A comparison of the current synthesis with this nonlinear masking technique and with real imagery could potentially verify the utility of the current synthesis at increasingly larger zenith angles of observation.

Additionally, a refined exploration of the current parameter set might establish an even more optimal imaging geometry. The results of the current study have placed the new point of departure at a solar azimuth angle 45 degrees from the point of maximum specular reflection. Small variations of solar azimuth and solar zenith angle from this point may isolate the ideal image geometry for slope spectrum estimation.

Finally, the method of analysis can be more robust. The current study deviates from the Chapman and Irani study with respect to the choice of figures of merit. However, the current study is consistent with the earlier study with respect to the implied assumption that the output radiance magnitude spectrum should be compared with the undecomposed slope magnitude spectrum. There is evidence [Stilwell, 1969; Kasevich, 1975] that the x-component slope magnitude spectrum alone or a linear combination of the two slope-component magnitude spectra may yield a more accurate synthetic representation of the radiance magnitude spectrum. A more detailed analysis, using results from the current study model, could verify this theory and provide a more accurate tool for the estimation of wave-slope spectra from imagery.

APPENDIX I - D₁ Results

The two-dimensional graphic results for the 72 combinations of solar position, dominant wind azimuth, and wind friction velocity are presented in Appendix I. Each page presents the graphic variation of wind friction velocity for a single combination of solar position and dominant wind azimuth:

$v_{fric} = 12.0$ cm/sec (Slope Variance versus Wavenumber)
(Slope Variance versus Azimuth)

$v_{fric} = 36.0$ cm/sec (Slope Variance versus Wavenumber)
(Slope Variance versus Azimuth)

$v_{fric} = 60.0$ cm/sec (Slope Variance versus Wavenumber)
(Slope Variance versus Azimuth)

Each set of four pages presents the graphic variation of dominant wind velocity $wind_az$ for a single solar position:

First Page	$wind_az = 0$ deg (or 180 deg with ambiguity)
Second Page	$wind_az = 45$ deg (or -135 deg with ambiguity)
Third Page	$wind_az = 90$ deg (or -90 deg with ambiguity)
Fourth Page	$wind_az = 135$ deg (or -45 deg with ambiguity)

The graphic variation for the six solar positions is then presented in the following order:

First Set	$\phi_0 = 0$ deg	$\theta_0 = 0.0$ deg
Second Set	$\phi_0 = 45$ deg	$\theta_0 = 53.2$ deg
Third Set	$\phi_0 = 90$ deg	$\theta_0 = 53.2$ deg
Fourth Set	$\phi_0 = 135$ deg	$\theta_0 = 53.2$ deg
Fifth Set	$\phi_0 = 180$ deg	$\theta_0 = 53.2$ deg
Sixth Set	$\phi_0 = 0$ deg	$\theta_0 = 53.2$ deg

APPENDIX II - D₀ Results

The one-dimensional graphic results for the 72 combinations of solar position, dominant wind azimuth, and wind friction velocity are presented in Appendix II.

The D₁ results for each test case are organized in the following format:

PARAMETERS - The format for the input file PARM.DAT is defined in Appendix III.

MAGNITUDE ARRAY SCALING FACTORS - For each of the five radiance conditions, the parameters are defined:

- XX(0,0) = Mean Radiance
- High = Peak Radiance for $k > 0$
- Factor = Geometric Scaling Factor between Peak Radiance and Peak Slope Magnitude

INTEGRATED VARIANCE FROM POWER SPECTRA - The variance is calculated from S0, the input slope spectrum, and for each of the five normalized radiance spectra.

- A,C,S - Along-Wind, Cross-Wind, & Summed Variance
- X,Y,S - Cross-Field, Along-Field, & Summed Variance

INTEGRATED SQUARED DEVIATION FROM DIF SPECTRA - The variance is calculated from the error (difference) spectra between S0, the input slope spectrum, and each of the five normalized radiance spectra.

- A,C,S - Along-Wind, Cross-Wind, & Summed Variance
- X,Y,S - Cross-Field, Along-Field, & Summed Variance

6.3 Appendix III - FORTRAN 77 Code

The input data files, FORTRAN programs, and FORTRAN subroutines that were created in support of this study are listed as follows:

Input Data Files

PARM.DAT
V_DATA.DAT

FORTRAN Programs

SURF.FOR
LIGHTBLUE.FOR
LIGHT.FOR
ANALYS.FOR
PSVARY.FOR

FORTRAN Subroutines

ALPHA.FOR
ALPHAS.FOR
CHECKERBOARD.FOR
DARKNESS.FOR
DEEPBLUE.FOR
DIST_GEN.FOR
FFT2D.FOR
PLT2DFILE.FOR
PLT2DOUTPUT.FOR
PLT3DFILE.FOR
PLT3DINPUT.FOR
PLT3DOUTPUT.FOR
PSVARY1.FOR
PSVARY2.FOR
RALPH.FOR
RIMP.FOR
SEA_SPEC.FOR
SKYBLUE.FOR
SKYMAP.FOR
SPREADVARY.FOR
WGN_SPEC.FOR
WGN2D.FOR
WIND.FOR

Input Data Files
