Ultra-Low Loss Optical Fiber Characterization System Development

Final Report for Naval Research Laboratory Project Number 65-9017-88

1 June 1990

VPI&SU Project No. 230-11-110f-104-352298
U.S. SFRC No. N00014-88-K-2013

Principal Investigator: Dr. R.O. Claus
Report Prepared by: R.G. May and K.D. Bennett

Fiber & Electro•Optics Research Center
Bradley Department of Electrical Engineering
Virginia Polytechnic Institute and State University
Blacksburg, VA 24061-0111

1.0 Introduction

The NRL IR System 1 is an automated optical bench designed for the measurement of spectral attenuation, differential modal attenuation, and numerical aperture of zirconium fluoride infrared optical fiber. It was developed by the Fiber & Electro-Optics Research Center at Virginia Tech under contract to NRL, and is a specially adapted version of a commercially available FOA-2000, a silica fiber characterization system manufactured by Photon Kinetics of Beaverton, Oregon.

1.1 Measurements performed by the NRL IR System 1

1.1.1 Spectral Attenuation

The system measures spectral attenuation over the range from 600 nm to 4 µm. Launch conditions are overfilled for multimode fibers with core diameters up to 150 µm and with numerical apertures up to 0.24. The fiber vacuum chucks can accept fibers with outside diameters up to 200 µm. The attenuation is derived by performing a cut-back test.

1.1.2 Differential Modal Attenuation

The system can measure differential modal attenuation (DMA) on step-index multimode fibers. Launch conditions are restricted by manually placing apertures that restrict the launch numerical aperture (NA) to a narrow range, thereby exciting a limited mode group in the optical fiber. Attenuation values are derived by performing a cutback test. The DMA apertures and the range of NA for each aperture follows:

Aperture #	NA Range
#1	.04
#2	.08
#3	.10
#4	.13
#5	.15
#6	.18
#7	.20
#8	.04<NA<.08
#9	.08<NA<.13
#10	.11<NA<.17
#11	.14<NA<.21

DMA tests for graded-index fibers have not been implemented in the current version of the system software, but the system may be easily adapted for this test. In order to achieve the correct restricted launch for graded index fibers,

the launch spot size must be restricted as well as the numerical aperture. To restrict the spot size, an aperture of the correct diameter must be placed in the spot restrictor carriage holder (see Figures 1 and 2), and the DMA software must be changed to engage the spot restrictor. The spot restrictor aperture is demagnified 100/9 times when it is imaged onto the input fiber end. The current spot restrictor aperture (390 μm diameter) achieves a spot size of 35 μm on the end of the fiber. This represents the minimum spot achievable at 2.5 μm wavelength since it is approximately the diffraction limit for the infrared lenses at that wavelength.

1.1.3 Numerical Aperture

The system will measure the numerical aperture of step and graded-index fibers, up to a value of 0.24. Due to the low radiance of the lamp source, the measurement procedure uses a scanning knife-edge, rather than a scanning aperture in the far-field as specified in EIA FOTP #47. The knife edge technique is an adaptation of an EIA procedure for determining the mode field diameter of a single mode fiber. In this procedure, a knife edge is scanned across the far field output of the fiber, and a lens is used to collect the light passed by the knife edge and direct it to the detector. The computer reads the output of the detector at the lock-in amplifier, which is effectively the integrated power as a function of far field angle. This data is then differentiated and smoothed to yield the far field radiation pattern of the fiber. From this far field the numerical aperture is derived. A criterion of 5% of maximum intensity is used to determine the numerical aperture.

1.2 System specifications

1.2.1. Fiber limitations

The system provides overfilled launch conditions for multimode fibers with core diameters up to 150 μm and numerical apertures up to 0.24. The differential modal attenuation procedure is currently set up for step index fibers only.

1.2.2. Detector noise (RMS values)

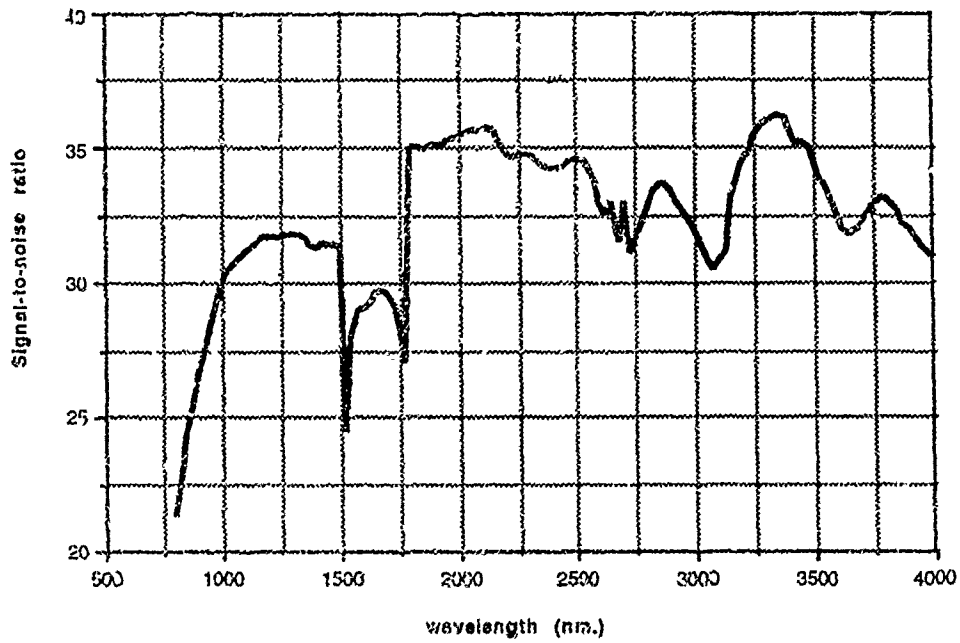
The following values for the average detector noise were measured using the "SUB low_init_check" subroutine in the FOA-2000 QC software package.

Thermoelectrically cooled Germanium detector: 0.66 μV
Liquid nitrogen cooled Indium Antimonide detector: 0.7 μV

1.2.3. Spectral signal-to-noise

After the values for detector noise given above were determined, the FOA-2000 QC software was used to measure the spectral signal-to-noise by

running the "SUB Spec_snoise" subroutine. A one-meter piece of fluoride fiber (from NRL spool number 891019) was used to give a representative value for coupling losses into a fluoride fiber. The results are graphed below.



Graph 1. Spectral signal-to-noise ratio

1.2.4 Lamp drift

The FOA-2000 QC software subroutine titled "SUB Lamp_drift" was used to measure the drift of the lamp output as detected by both the germanium (Ge) detector and the indium antimonide (InSb) detector. This test measured the detector output every twenty seconds over a duration of 60 minutes. The test indicated that the germanium detector drifted by -0.002 dB per five minutes. The indium antimonide detector was measured to drift by 0.004 dB per five minutes when the test was performed immediately after filling the InSb dewar with liquid nitrogen. The same test was repeated 1.5 hours after filling the dewar, and the drift was reduced to 0.002 dB per five minutes, indicating the need to prefill the dewar approximately 2 hours before running any critical tests.

2.0 How the IR System 1 differs from the Photon Kinetics FOA- 2000

The NRL IR System 1 differs from the commercially available Photon Kinetics FOA--2000 with the addition or substitution of several key components. They are:

a. A three-grating monochromator, with a stepper motor to select the grating,

b. custom design diffraction limited infrared lenses,

c. a quartz-tungsten lamp with extended spectral window envelope,

d. additional cutoff filters for the extended range of the monochromator,

e. infrared neutral density filters to accommodate the range of the monochromator,

f. a liquid nitrogen cooled indium antimonide detector for the range from 1.8 μm to 4.0 μm,

g. vacuum chuck V-grooves to accommodate the larger fiber diameter of the infrared fiber,

h. special annular apertures for DMA measurements,

i. a numerical aperture measurement technique that uses a knife edge rather than a pinhole to scan the far field,

j. software that has been adapted to account for the differences in hardware.

2.1. Monochromator

The monochromator is a Jarrell Ash Monospec® 27 with three gratings that may be interchanged by moving a turret. The gratings are summarized as

grating freq.	blaze Λ	λ range	avg. dispersion	spectral bandpass
600 gr/mm	1 μm	.6 to 1.79 μm	6 nm/mm	3 nm
300 gr/mm	2 μm	1.8 to 2.69 μm	12 nm/mm	6 nm
150 gr/mm	4 μm	2.7 to 4.0 μm	24 nm/mm	12 nm

The approximate spectral bandpass figures assume that the output slit size is 0.5 mm.

The monochromator wavelength selector is automated with a stepper motor. The step angle on the motor is 1.8 degree per step, and it takes 200 steps for one complete revolution. The Monospec® 27 has an analog wavelength counter which is calibrated to the 1200 groove/mm grating. To obtain the proper wavelength for each grating, the counter reading must be multiplied by 2, 4, and 8 for the 600 groove/mm , 300 groove/mm, and 150 groove/mm

gratings, respectively. One complete revolution on the wavelength selector corresponds to 25 nm of wavelength scan for a 1200 groove/mm grating. The gear ratio between the monochromator and stepper motor is 3:1. The number of steps on the motor required to scan 1 nm using the 1200 groove/mm grating can be calculated by the formula,

$$G \cdot \frac{N_m}{W_s},$$

where N is the number of motor steps per revolution, W is the wavelength scan per revolution on selector, and G is the gear ratio between the monochromator and stepper motor. The 1200 groove / mm grating requires 24 steps for a 1 nm scan. The 600 groove / mm, 300 groove / mm, and 150 groove / mm gratings require 12 steps / nm, 6 steps / nm ,and 3 steps / nm, respectively.

2.2. Infrared Lenses

The infrared lenses were designed and constructed by Infrared Optics, Inc. of Farmingdale, NY. They are multi-element lenses fabricated of barium fluoride and lithium fluoride, or zinc sulfide. The lenses were designed to correct for most spherical aberrations between 0.6 and 4.0 μm, with a spot size of 35 μm at 2.5 μm wavelength. The physical dimensions and focal lengths of the lenses were designed to be identical to the standard lenses used in the FOA--2000, in order to facilitate their replacements. The lens parameters are summarized in Figure 2.

2. 3 Quartz-Tungsten Lamp

A Ushio Model no. JC12V-50W H20 G/1.0 tungsten halogen lamp is used for the white light source. This lamp utilizes a special quartz envelope which has an extended transmittance out to 4.0 μm.

2.4 Cutoff Filters

Since the Jarrell-Ash monochromator has a greater spectral range than the original FOA--2000 monochromator, it was necessary to add additional cutoff filters to eliminate second- and higher-order spectra from the longer wavelengths. The filter numbers and their cut-on wavelengths are listed below.

Filter No.	Cut-on Wavelength
1	540 nm
2	850 nm
3	1525 nm
4	2175 nm
5	3150 nm

2.5 Infrared Neutral Density Filters

The neutral density filters in the original FOA-2000 are specified only for operation over the limited spectral range of that instrument. They were replaced in the NRL IR System 1 with neutral density filters design for used in the infrared up to 4.0 μm.

The attenuation of each filter was measured over the range from 800 to 4000 nm using a modified version of the FOA-2000 QC software subroutine SUB Attn_calib. The results of the ND filter calibration tests are given in Appendix A. The attenuation is not very uniform over the spectral range. The ND filters are not used in any spectral attenuation, differential modal attenuation, or numerical aperture tests on the instrument, because of the low radiance of the lamp, eliminating the need to attenuate the output of the lamp. It is possible that the calibration values given there could be incorporated into a look-up table in the system software, such that any time a ND filter is used at some wavelength, then the measured attenuation of that filter at that wavelength is recalled for use in calculations. The original FOA-2000 software however does not easily lend itself to incorporating such a feature, so that including it would entail an effort of moderate difficulty.

2.6 InSb Detector

A liquid nitrogen-cooled indium antimonide (InSb) detector manufactured by Infrared Associates is used to cover the spectral range from 1800 to 4000 nm. The system software automatically switches between the Ge detector and the InSb detector at 1800 nm. The preamplifier used for the InSb detector is an Infrared Associates model PPA-15-IS. The schematic for the InSb detector power supply is given in Appendix B.

2.7 Vacuum Chucks for 200 μm OD fiber

The original FOA-2000 vacuum chucks can only accommodate fibers with outside diameters (OD) up to 140 μm. These chucks have been replaced with ones that can accommodate fibers with up to 200 μm OD.

2.8 Annular Apertures for Differential Modal Attenuation Measurements

Numerical aperture launch restrictors have been adapted to include annular apertures, which are used for launching high order modes in step index fibers, for differential modal attenuation tests. Launch conditions are restricted by manually placing apertures that restrict the launch numerical aperture (NA) to a narrow range, thereby exciting a limited mode group in

the optical fiber. Attenuation values are derived by performing a cutback test.

2.9 Knife edge numerical aperture measurements

Due to the low radiance of the lamp source, the measurement procedure uses a scanning knife-edge, rather than a scanning aperture in the far-field as specified in EIA FOTP #47. The knife edge technique is an adaptation of an EIA procedure for determining the mode field diameter of a single mode fiber. In this procedure, a knife edge is scanned across the far field output of the fiber, and a lens is used to collect the light passed by the knife edge and direct it to the detector. The computer reads the output of the detector at the lock-in amplifier, which is effectively the integrated power as a function of far field angle. This data is then differentiated and smoothed to yield the far field radiation pattern of the fiber. From this far field the numerical aperture is derived. A criterion of 5% of maximum intensity is used to determine the numerical aperture.

2.10 Major changes in the FOA-2000 software

2.10.1 DMA Measurement

The software has been rewritten so that multiple wavelength scans can be performed in such a way that only one cutback is required. A few new subroutines were created to enable this change in the measurement procedure. A description of their operation is included in the discussion below.

SUB Fibertest2: As with the Far Field test, the user is first queried as to the source of the data which he wishes to view. That is, he may indicate that a new test is to be performed, or that data from a previous run is to be reviewed. Previous data may either be data which was collected earlier in the day (computer on continuously) and is present in the dynamic memory buffer, or data which is stored on a diskette. This query takes place by calling the subroutine FNDatasource, which returns a 0 if a new test is desired, 1 if memory in the buffer is desired, or 2 if the routine Retrieve is to be called to access data on diskette. If either 1 or 2 are returned to Fibertest2, data is loaded into the array called "Dmaattendata", the test portion of the routine is skipped, and the data is plotted on the screen. More details about the plot are below.

SUB Dmarun: First the user is queried about which numerical aperture restrictor to use (including #0 = no restrictor). This is performed by calling the routine FNGetristrictor, which first lists the restrictor numbers and their corresponding NA range, then uses the FNGetint to determine and return the (integer) restrictor number. The first restrictor number is stored in the (0,1) position of the array "Dmarundata" (see supplemental sheet 1), while subsequent numbers, up to 11, are stored in (0,2), (0,3), and so on.

The wavelengths to scan, and the total number of wavelengths to scan, n, are shared with this routine through the common block /Wavelength/ command. The number of wavelengths is stored in the (0,0) position of "Dmarundata." The (1,0) position of this array contains the fiber length, while the (2,0) position holds the number of DMA runs performed. The wavelength scan is then performed on the long or "run" piece of fiber, and the voltages are stored in the column beneath the restrictor number, in the row corresponding to the wavelength at which the voltage was read.

After each before-the-cutback scan, the user is asked to see if another DMA run (i.e., another NA range) is desired; if yes, the new restrictor number is requested, time given to insert the restrictor, and the program returns to the wavelength scan portion and continues as before.

If no more NA ranges are desired, the user is directed to cutback the fiber, being careful to leave the input end undisturbed. The routine Outalign is then called to align the output end. The first restrictor used before cutback is requested, and a short or "ref" fiber wavelength scan is performed. The voltage data here is now stored in columnar form in an array called "Dmarefdata," which has the same (0,0), (1,0), (2,0) entries as "Dmarundata."

It should be understood that before the first wavelength scan on the long fiber, the signal on the detector (through the fiber) is read using the LED source. This is taken as an alignment reference. After the scan for each DMA run, the alignment is again checked, and if it has varied by more than 1%, the user is informed and given the choice of re-doing that particular scan, exiting the test, or proceeding. The same type procedure is used to insure integrity of the input fiber end alignment after the cutback is performed.

SUB Dmacomp: The data from the two arrays are passed through a COM statement to this routine, where the calculation is performed to determine the spectral attenuation for each NA range (represented by respective restrictor number). This outcome of the computation is stored in an array named "Dmaattendata," while the wavelengths used for the scan are stored in the positions (1,0) - (n,0) , i.e., the first column of this array. As explained in the supplemental sheet 2, the (0,0) position of this array contains both the number of wavelength scans n, and the number of DMA runs performed, m.

SUB Dmaplotprep: Next the user is queried as to which column of data he wishes to view (i.e., which restrictor). His choice column is loaded into the second column of the array Specattdata, while the wavelengths are loaded into the first column. The fiber ID number, including the restrictor number and fiber length are loaded into the string Specatt_id$. Then the routine Specatplot is called to plot the particular column of data requested, and operates in the same way as an ordinary spectral attenuation plot as

described by Photon Kinetics in their software listing remarks. If at any point the "STORE DATA" option is entered, the program exits the plot, enters the Archive subroutine, and stores the contents of the array "Dmaattendata," and then returns the user to the main menu. To further review data, such as the loss results of other restrictors, the "Recall data" option must be chosen from the DMA menu.

2.10.2 Far Field Measurement

This test was changed to run from its own menu, and allow the user the option to smooth the data by averaging a variable number of points. The attached flow chart may aid in understanding the logic.

Presuming a new test is specified, the knife edge will scan across the collimated far field pattern, moving to gradually cut off the power reaching the detector. A normalized version of the data from this scan is held in an array called "Farfield;" it is considered the "raw" data, and is plotted against scanner position. This data can be differentiated to obtain an actual far field output pattern, or can be smoothed directly. When the Differentiate option is chosen, the raw data is first loaded into an array called "Fframdata." Then it is differentiated, corrected to account for a small angle approximation, renormalized, and stored in an array "Ffdiffdata," which is again plotted on screen. In addition, the routine Numaper is called to calculate the numerical aperture, which is displayed below the plot. At this point the user may smooth the differentiated data, or return to the raw data plot. If the Smooth Data option is chosen, he is asked for the number of points to average, the data smoothing routine Ffsmooth is called, and the smoothed, normalized version of the data is stored in an array called "Ffsmoothdata." This is plotted on the display, along with a recalculated value of numerical aperture. Further smoothing may then be performed on the raw, differentiated, or smoothed data, and plotted accordingly.

It may be noted that when the raw data is smoothed, at present the smoothed version may not be differentiated, only viewed. Because the "smoothed" raw data actually appeared to be less smooth than the actual raw data, and because of ambiguities introduced into the numerical aperture calculation due to smoothing, this was not further modified, though is would be relatively straightforward to do so. Furthermore, an alternate routine has been sketched out (included) by George McCabe which would fit the data to a Gaussian distribution and look for the 5% points there. In the end, this might offer a more repeatable method to obtain a value for the numerical aperture.

2.10.3 Program Organization

Lines relevant to unused tests were purged in many, but not all, places in the system software. Large blocks such as the FibertestX subroutines and

associated routines were deleted, but remnants exist in other places due to not wanting to alter the "foasetup" file and the way it is stored. All lines relevant to the Near Field test were retained.

2.10.4 Fiber Alignment

The Inalign and Outalign routines have been altered so that the first time either are called, the alignment is performed, and a counter variable is set equal to 1. At the end of the alignment, the final voltage on the Ge detector is read and held in the first position of a variable array, called Sig(1). The routine then returns and aligns the fiber a second time, and holds the new final voltage in Sig(2). These two voltage values are then compared, and if they differ by more than 1%, the user is told so, and given the option of continuing anyway, or returning to re-align. If the latter is chosen, then eventually Sig(3) and Sig(2) are compared as before and so on. At present, the maximum number of alignments that can be performed in this way is 10.

3.0. Normal Operating Procedures

This section describes the daily procedures required for proper normal operation of the system.

3.1. Turn-on procedure

The proper sequence for bringing the system up is outlined below.

a. Turn on the FOA-2000 control panel by turning the key on the front panel.

b. Turn on the EG&G 5207 lock-in amplifier.

c. Turn on the red (illuminated) switch on the power supply.

d. Check the voltage of the preamp batteries in the power supply chassis. To do this, switch the small toggle switch labeled "Meter" to either 1 or 2. There are two sets of batteries, labeled 1 and 2, respectively. One set is normally connected to the preamp while the other is held in reserve, or is being recharged. The voltage of the set in use should read greater than 11 volts. Switch the batteries on by turning the switch labeled "Preamp Batteries" to the set with the higher voltage. If the other set shows a voltage below 11 volts, connect the two battery chargers to the connectors labeled "CHARGERS" on the back of the power supply unit. The reserve batteries will be charged automatically.

   Important: Switch the "Meter" switch to "off" after checking the batteries. If it is left on , the discharge of the batteries will be accelerated.

e. Make sure that the InSb detector dewar is filled with liquid nitrogen. When refilling the dewar, it is not necessary to shield the detector from room light. The lens that covers the detector face does not transmit light of a wavelength below 1.0 μm. For minimal drift, the dewar should be filled two hours before any important measurements.

f. Load and run the system software, as describe below.

3.2. Software set-up

Place the disk labeled "DISK #1 (AUTOBOOT)" in the left hand drive (drive 0) of the computer. Turn the monitor, disk drive, printer, and computer on. When the computer prompts, remove the autoboot disk and replace it in drive 0 with the system software disk. The system software will execute automatically, and present the user with a menu.

3.3. Fiber End Preparation

For proper use of the vacuum fiber chucks and the elastomeric fiber clamps, it is necessary to strip at least two inches of jacket from the fiber end. The best location for positioning the clamp on the fiber can be gauged by using the two short strips of black tape on the fiber shelf. The distance from the tape to the edge of the fiber shelf is the proper length of bare fiber that should extend from the fiber clamp.

3.4 Important Commands

Here we list several convenient commands that may be executed from the HP computer.

Command	Effect
Stop	To stop execution of the system software because something is wrong.
Call Menu	To access the main menu.
Call Nextwave	To have the unit set to a particular wavelength. For example, to set the wavelength to 850 nm, execute "CALL WAVELENGTH(850)". See the note "IMPORTANT" below.
Call Fibertest1	To run the spectral attenuation test directly from the keyboard without having to access it from the main menu.
Call Fibertest2	To run the differential modal attenuation test directly from the keyboard.
Call Fibertest3	To run the numerical aperture test directly from the keyboard.
Call Clearup	Clears the GPIB bus and resets the phase on the lock-in amplifier.
Run	To reinitialize the FOA-2000 control panel. This must be done each and every time the control panel is turned off and on again. If the FOA-2000 control panel is turned on, then the system software must be restarted in order to reinitialize the Z-80 uprocessor in the FOA–2000 control panel. In order to do this, stop the program execution (it may be necessary to hit the break

key), and then type "RUN" and press the return key. It is not sufficient to "CALL MENU." The system software must be restarted. After restarting the software, the "Equipment Preset" routine should be run.

Call F2000send ("INSB")

Connects the InSb detector to the lock-in amplifier, and sets the mirrors to direct the fiber output to the InSb detector.

Call Cleardata — To clear all data from the memory buffer. This should be called befrore running the first test on a new fiber if other fibers were run since the machine was turned on.

IMPORTANT: To set the monochromator to a desired wavelength, it is necessary to use the "CALL NEXTWAVE" command instead of using the front panel control. The system software will then insure that the correct grating, cutoff filter, and detector are set up. In addition, the software calculates the proper setting for the monochromator shaft and automatically sets it there. The control panel should only be used to make minor (<50 nm) adjustments in the wavelength displayed on the control panel LED display.

4.0. Maintenance

4.1 Alignment Procedure for NRL IR System 1

4.1.1 Definitions:

The x direction is perpendicular to the beam direction, and parallel to the bench surface. The y direction is perpendicular to both the beam direction and the bench surface. The z direction is parallel to the beam direction.

The IR target is an aluminum piece with cross-hair lines etched on it. Its base should just fit into the milled slots (to assure lateral consistency), and have a cross-hair marked directly over the center of the slot at a height of 1 3/8 inches above the surface of the bench (not the slot).

4.1.2. Main LED Beam Path.

a. Remove lenses 1, 2, 3, 4 from the bench. Select LED on the front panel, with the launch spot out. Using the IR target, align the LED beam all the way around the bench to the camera. Start by engaging LASER 1 on the front panel. When this is done, the mirror in BS2 will switch out to allow the beam to pass through BS2. In addition, the stepper motor driving the monochromator turret will attempt to turn the shaft. This is expected, so don't be concerned by the sound. Put the IR target in the milled slot at position A, and adjust the LED lens 7 in x and y to align the LED output to the cross-hairs. Adjust the lens in z in order to collimate the beam as well as possible.

b. Next disengage LASER 1 to bring the lower mirror in BS2 back up, directing the beam towards BS4. Again align the beam to the IR target. Now engage THRU TRANSMISSION with the output target out, and adjust BS4 lower mirror to direct the beam onto the IR target at C. Engage FIBER OR SOURCE and proceed to align to the IR target at D. It may be necessary to re-adjust the collimation by tweaking the z position of the LED lens 7. Next adjust mirror M1 to collect as much of the beam as possible, and direct it towards the target at position F. The 275 mm lens 11 should still be in place, roughly half way between M1 and M2. Finally, adjust M2 to direct the beam into the video camera. Leave the image of the LED on the right one third of the monitor, centered vertically.

4.1.3. Input Objective Lens.

a. Center the input objective lens 5 in x, y, and z over the range of travel of the respective motors. To do this, first push the appropriate button on the front panel to engage the corresponding motor. Then turn the front panel knob until the front panel display shows four dots, indicating that the motor has reached the end of its range of travel. Then press the ZERO button to zero the

display. Next, while holding the local button down, rotate the front panel knob in the opposite direction (from the previous motion) until the four dots vanish. Release the local button and continue turning the knob until the four dots appear again, indicating the limit of travel in the opposite direction. Take the reading on the front panel display and divide by two (if the display "tripped over" to 000, be sure to add 1000 to the number before division). Hold the local button down, and rotate the the knob in the opposite direction until the dots vanish. Then move the knob until the display shows the number that resulted from the division by two. Press ZERO to re-zero the display. This position is the center of travel in the appropriate axis. Repeat this procedure for the remaining two axes.

b. Place the lens cap (with white target and mark in center) on the lens. Position the lens in x, y, and z so that the center of the LED beam strikes the center of the lens cap. Note the reading on the front panel in x and y, which displays how many units away from the center of the lens travel the LED beam is.

c. If the reading in x or y is more than about 150 units, the brass U-shaped bracket in the opto-sensor may need to be adjusted to redefine the lens travel limits and therefore the lens travel zero. In order to do this, remove the bracket holder (x axis is underneath bench, y is above), and adjust the position either up or down slightly. Repeat steps a and b until the LED beam corresponds to the center of the x and y lens travel to within acceptable limits.

d. Redefine the zero lens position at the center of the LED beam by pressing the ZERO button on the front control panel for each input lens motor.

4.1.4. Input Fiber Chuck.

a. Remove the lens cap from lens 5. Make sure step 2d has been taken.

b. Prepare a length of fiber (1-2 meters) with cleaved ends. Place one end in the input fiber chuck, and place the other end of the fiber in a power meter (Si detector).

c. Loosen the set screws holding the vacuum chuck and adjust the vacuum chuck to maximize the power injected through the fiber, as detected by the power meter. To adjust horizontally, move the vacuum chuck horizontally. Make an effort to keep the chuck axis perpendicular to the lens. To adjust vertically, use the front panel control (input-y). To adjust longitudinally, push the fiber in and out for coarse adjustments, and use the front panel (input-z) for fine adjustments.

d. Tighten chuck screws so that the chuck is locked firmly in place.

4.1.5. Launch Spot.

a. Engage the BS4 lower mirror by pressing SOURCE. Replace lens 2 on the bench. Set launch spot into the beam by engaging LAUNCH SPOT. Move lens 2 along the slot (in z) to focus the spot on the monitor.

b. Disengage the launch spot. Replace lens 1 (in the adjustable mount) on the bench and move it along the slot to focus the LED on the monitor. Adjust the lens mount in x and y to center the LED image over its previous position on the right one third of the monitor, centered vertically.

c. Engage the launch spot again. Adjust the aperture position on the launch spot carriage in x and y to center the spot over the center of the LED image.

4.1.6. Output Objective Lens.

a. Engage the beamsplitter mirror in the top of BS4 by pressing FIBER LOAD. Loosen the mirror and adjust it until a (probably dim) reflected image of the input fiber end is positioned over the LED image (right one third, centered vertically). This squares the position of the light reflected onto the output objective lens.

b. Follow the procedure of Step 2 to center the output objective lens within its range of travel. Note however that because of the nature of the beamsplitter, in this case the LED beam will appear as a half-circle only. Be sure to redefine the zero lens position for each output lens motor.

c. Re-adjust the upper beamsplitter mirror of BS4 to direct the input fiber image onto the left third of the monitor, centered vertically (over the grease pencil marks). Tighten the mirror screws to lock it into place.

4.1.7. Output Fiber Chuck.

a. Place one end of the prepared fiber in the output chuck. Inject white light into the other end (this may be simply accomplished by placing the fiber end near the filament of an ordinary light bulb).

b. Press THRU TRANSMISSION to allow the white light through the fiber to reach the camera. Loosen the set screws holding the output vacuum chuck and adjust the chuck horizontally to put the output fiber image over the LED image in the right one third of the screen. Center the image vertically by adjusting the front panel control (output-y). To focus the image, push the fiber in and out for coarse adjustments, and use the front par el (output-z) for

fine adjustments.

c. Place the IR target at the position of lens 3 and check that fiber output is aligned with crosshairs. Then place IR target just after lens 11 and insure that beam is still aligned with crosshairs. If not, move the output fiber chuck angularly in x, and then reiterate steps b and c until the output fiber path lies squarely over the line between BS4 and BS5.

4.1.8. Output Target.

a. Replace lens 4 on the bench. Engage the output target. Move lens 4 along the slot (in z) to focus the image of the output target on the monitor.

b. Disengage the output target. Replace lens 3 (in the adjustable mount) on the bench and move it along the slot to focus the LED on the monitor. Adjust the lens mount in x and y to center the LED image over its previous position on the right one third of the monitor, centered vertically.

c. Engage the output target again. Position the aperture on the output target carriage in x and y over the LED image.

d. At this point the LED, output fiber, and output target should all be focussed on the same position on the right one-third of the screen, centered vertically. This position should be remarked with a grease pencil if necessary.

4.1.9. Lamp Path.

a. Engage LED on the front panel. Switch the lamp on, if it's not on already. Put the IR target at position F in the milled slot that leads from the monochromator output and BS3. Adjust lens 8 to focus the monochromator output on the IR target. Also adjust the positioning knob on top of the lamp to maximize the amount of light into the monochromator, and onto the IR target.

b. Engage the LAMP on the front panel. Engage the button below "LASER THREE" on the front panel. As before, BS2 will switch mirrors and the stepper motor driving the monochromator turret will attempt to turn the shaft. Put the IR target in the milled slot at position A. Adjust the mirror in BS3 to align the monochromator output to the crosshairs as well as possible. Engage LED again.

4.1.10. Ge Detector.

a. Engage SOURCE, Ge DET, and DETECTOR on the front panel control. With

the attenuator at 0, an image of the LED reflected from the surface of the Ge detector should be visible on the monitor. Adjust lens 10 (on the detector module) in x, y, and z to roughly center and focus the image within the large area of the detector.

b. Disengage the DETECTOR switch (upper beamsplitter mirror on BS5), and maximize the output of the Ge detector as seen on the lock-in amplifier.

c. Re-engage DETECTOR and be sure the image of the LED is not too near the edge of the Ge detector. (The most sensitive spot on the detector appears to be near the upper left edge.) Finally, disengage the DETECTOR switch.

4.1.11. InSb Detector.

a. In order to engage the InSb detector, the FOA-2000 System Software must have been loaded onto the HP computer. If the program is running (e.g. a menu is displayed on the HP screen), first press STOP on the keyboard. To connect the detector output to the lock-in amplifier, type the command

CALL F2000send("INSB")

b. Adjust lens 9 on the InSb detector module in x, y, and z to maximize the output of the detector as seen on the lock-in display. Large adjustments in x and y are not recommended.

5.0. How to get help.

In the event that the system does not appear to operate correctly, or if the HP computer returns an error message, the appropriate sequence of actions is as follows:

1. Review the section below entitled "Likely Problems" to see if the fix is indicated there.

2. If the computer indicates an FOA-2000 error message, check page 12-16 of the Photon Kinetics Installation manual for an explanation of the problem.

3. If the computer indicates an HP software problem, then check the "Error Message" appendix of the HP Language Reference manual for an explanation of the error.

If the above steps do not remedy the situation, then contact Russ May or Rick Claus at the Fiber & Electro-Optics Research Center, Virginia Tech, at (703) 231-7203. Replacement parts and knowledgeable insight into the correct operation of the original, unaltered FOA-2000 may be obtained by calling Customer Support at Photon Kinetics, Beaverton, OR, at (503) 644-1960. It should be made clear to Photon Kinetics that the instrument under discussion is Serial No. E4221, which was adapted for use with fluoride fiber by Virginia Tech.

5.1 FOA-2000 Error Messages:

Occasionally the HP computer will indicate an "FOA-2000 error" together with an error number. Most often this may occur when the computer will mistakenly try to drive a stepper motor beyond its permissible range. The meaning of the error number may be found on page 12-16 of the FOA-2000 Installation manual.

Some of the system software routines poll the instrument status of the EG&G lock-in amplifier. If an error is returned by the lock-in to the HP computer, the routine will indicate an error and report the HP basic error number. A description of the error and the associated number is found in the "Error Message" appendix in the back of the HP Basic Language Reference manual.

5.2 Likely Problems

A list of likely problems, their possible causes, and remedies follow:

Problem	Possible Cause and Remedy
Computer displays "Division by zero" error; or output graphs show measurements to be very noisy.	a. Preamp power supply not turned on. b. Lamp power supply not switched on. c. Lamp bulb burned out. d. Preamp battery charge low. e. The phase lock may have been lost on the phase-lock amplifier. This appears to happen after the GPIB bus has been cleared with a "CLEAR 7" command. To reset the phase of the amplifier, type "CALL CLEARUP" and Return. If the program has been halted, then type "CALL MENU" to access the main menu. f. Tried to read archived data in from a non–existent file.
FOA Error no. 97	If the FOA-2000 control panel is turned on, then the system software must be restarted in order to reinitialize the Z-80 µprocessor in the FOA-2000 control panel. In order to do this, stop the program execution (it may be necessary to hit the break key), and then type "RUN" and press the return key. It is not sufficient to "CALL MENU." The system software must be restarted. After restarting the software, the "Equipment Preset" routine should be run.
The HP computer seems to have halted or is "stuck" while trying to issue a command to the FOA-2000 unit or the lock- in amplifier.	The GPIB bus may have crashed when program execution was halted while the computer was issuing a command or waiting for a status byte on the bus. To remedy, first press the "STOP" key on the computer. Then type "CLEAR 7" and press the return key. Then type "CALL CLEARUP" and the return key. This will cause the phase to be reset on the lock-in amplifier, which is often lost when a "CLEAR 7" is executed. It may be possible to continue program execution by typing "CONTINUE", but more likely it will be necessary to "CALL MENU" and restart the test from the beginning.

Can't see the fiber end in "FIBER LOAD" mode.	a. Bad fiber end. Recleave. b. Fiber end off the screen. Put the FOA-2000 in "VIDEO OUT" mode, and peak the reading on the lock-in amp as the fiber is manually adjusted using the fiber movement controls on the FOA-2000 control panel. Then return the FOA-2000 to "FIBER OR SOURCE" mode.
During auto-alignment, the computer consistently returns messages indicating that the fiber end positions need to be adjusted.	a. The fiber end might not be perpendicular to the fiber axis. Check the end angle using a fiber inspection scope, or recleave the fiber. b. The fiber alignment motors may need to be recentered. See page 13-1 of the FOA-2000 installation manual for a procedure to recenter the motors.
Grinding sound from monochromator	In this case, the computer has lost track of actual position of the monochromator shaft, and is attempting to drive the shaft past its limits. The grinding sound results from the stepper motor slipping. To remedy, turn off the key switch on the FOA-2000 control panel immediately. Then turn on the front panel again, and type and execute "RUN" on the HP computer. Then run the "EQUIPMENT PRESET" subroutine from the main menu.

56    REM + Main Program "Mainprog"
58    REM + PURPOSE:
60    REM +  This is the main program that calls all other
62    REM +  test and utility modules. It sets up the required data
64    REM +  and calls the initialization routines that prepare the
66    REM +  FOA-2000 system for measurements. Then, it prints a menu
68    REM +  of options for the user to choose from. At present, the menu
70    REM +  contains options for running the test sequence defined by
72    REM +  the user's FIBERTEST module, setting the time and date,
74    REM +  inspecting the system set-up data, and archiving measurement
76    REM +  results. Other options can be added easily.
78    REM +

9350    !
9352  ! In the original FOA-2000, the monochromator only covers the range from
9354  ! 800 to 1600 nm.  For this range, only two cutoff filters were needed,
9356  ! one to cover 800 to 1000 nm, and another to cover 1000 to 1600 nm.  The
9358  ! value at which the filter was switched was denoted in the software as a
9360  ! parameter named Cutoff.  The NRL system requires five cutoff filters, so
9362  ! we need an array to pass the values of the wavelengths at which the
9364  ! cutoff filters should be switched.  For this we use an array called
9366  ! Filter(*), which is passed to this subroutine by the Sysdata COM block.
      ! This was used in the old software for an early version of the FOA-2000
```

```
9374   ! the filter values modified there.  Then we set a flag to tell
9376   ! the file that we are using a monochrometer with cutoff filters, which
9378   ! is necessary in order to set the Filter_flag to 2 (which in turn flags
9380   ! the program to determine which value of Filter(*) to use).
9382   !
9384   ! The cut-on wavelengths for the cutoff filters are as follows:
9386   !    Filter(1) =  500 nm
9388   !    Filter(2) =  900 nm
9390   !    Filter(3) = 1525 nm
9392   !    Filter(4) = 2175 nm
9394   !    Filter(5) = 3150 nm
9396   !
9398   ! If Filter_flag=2, we are using the monochromator with cutoff filters
9400   ! installed in SEVERAL positions of the filter wheel, so decide which
9402   ! one to use.  If Filter_flag=0, we are not using the cutoff filters.
