EXECUTIVE SUMMARY

This document provides reference material for personnel using the air traffic control (ATC) interface between the National Airspace System (NAS) and the Data Link Test Bed. This interface card can be used on any Versa Module Extended (VME) based computer system to provide an interface between that system and the NAS. It was originally designed to be part of the Data Link Test Analysis System (DATAS) in its role to provide interfaces to any part of the NAS components used for Data Link.

This document contains a detailed description of the hardware of the ATC Interface card. It includes schematics, Pal Source code, diagnostic descriptions, and should be sufficient for hardware personnel to become familiar with the operation of the card.

GENERAL DESCRIPTION

The Air Traffic Control (ATC) Interface card is a Versa Module Extended (VME) bus compatible module which provides an interface between the NAS (HOST or ARTS) system and the VAX-750. This card communicates with those systems via the synchronous modems of the LSSS. Intermediate processing of the data is provided by the 68020 processor of the VME system. This card can be used in the Data Link Test Analysis System (DATAS) or any other VME based 68020 system.

The ATC interface card has extensive "built in" diagnostic capability which can be controlled by the 68020. It has the ability to use either external or internally generated modem clocks (between 300 and 19,200 baud) for data processing. Configuration of the entire card is controlled via the 68020. Signals can be "looped back" for monitoring; sync detection logic, transmit parity generation logic and interrupts can be disabled. It also contains a mechanism for storing all incoming data (including the parity bits) if desired. The use of this capability makes it possible for two cards to reside in one VME chassis where one unit can be configured to monitor the performance of the other if desired.

The logic of the ATC Interface card is almost entirely in programmable logic and can be easily changed if desired.

Figure 1 is a block diagram of the ATC Interface card. Communication with the VME system is via A32/D08 standard protocol. The interface card is assigned a particular block of addresses for this purpose. It monitors the address lines as well as the address modifier lines and responds when one of the assigned addresses is accessed by the processor. Its transmit data is received from the processor and stored in "dual port" random access memory (RAM) so that both the card and processor can access the same locations. Control logic for configuration of the card is received in the same manner. When the processor desires to transmit a message to an external system, it loads the Transmit memory with the message and the control latches with the length of the message and issues a "start" command. When the card has completed the assigned transmission, it sends an interrupt request to the processor to indicate completion of the task.

The ATC Interface card receives its data from the external device (or internally if in the loop back mode), stores it in the Receive Memory and notifies the processor via an interrupt whenever a valid End of Message (EOM) is received or a parity error occurs. The card can also be configured to store all incoming data after a specified number of consecutive zeros occurs (controlled via 68020). If the receive sync detection logic is enabled, the data will be "overwritten" with the input data if a valid sync message (either 17 or 18 consecutive zeros followed by a 1) is detected. If no valid sync occurs (or sync detection is disabled) an

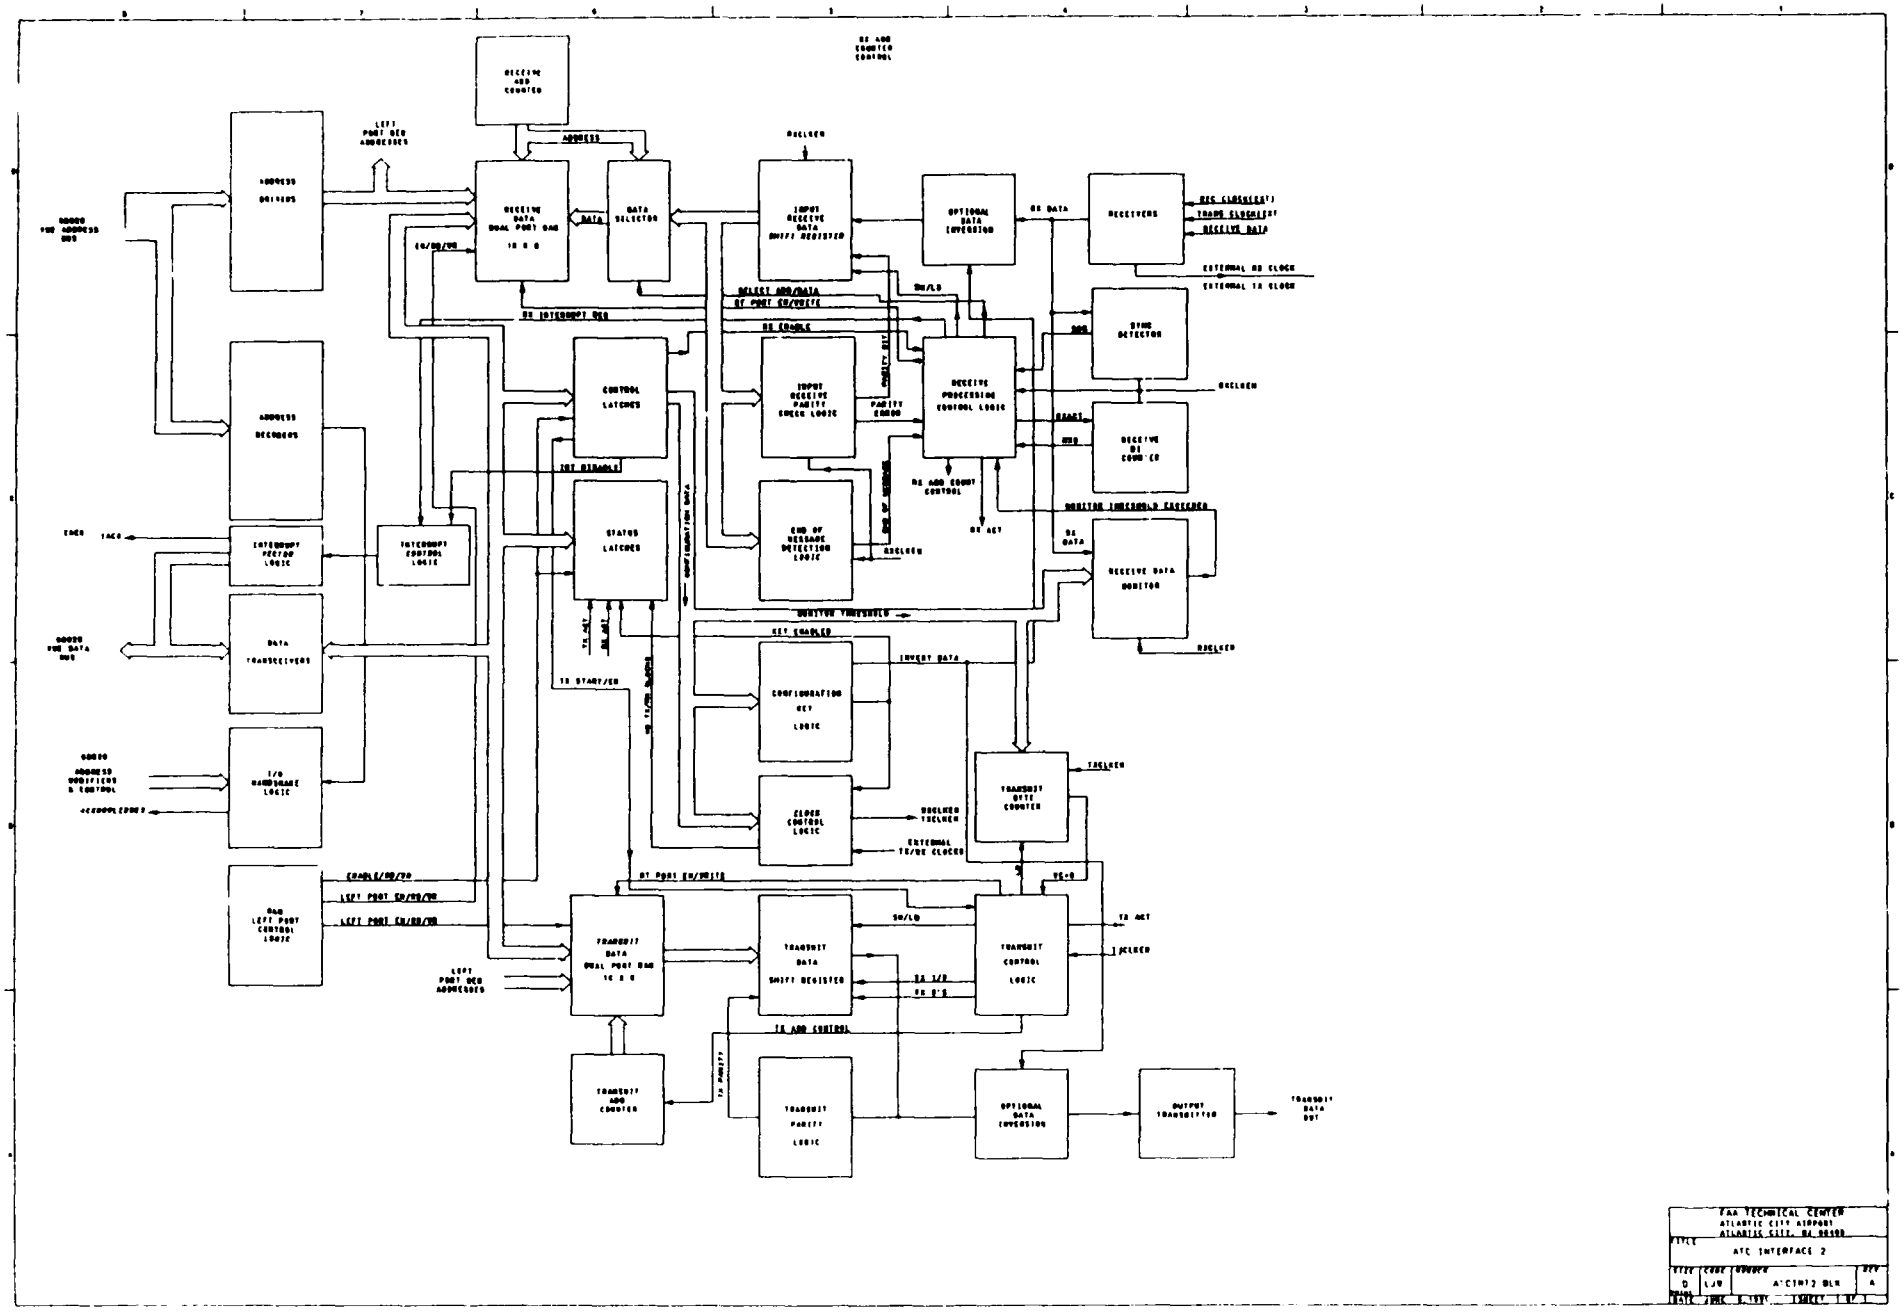

FIGURE 1. ATC INTERFACE BLOCK DIAGRAM

interrupt is issued to the processor when 128 bytes have been stored. The receive data are stored in memory blocks of 128 bytes. Each block is assigned a separate interrupt vector, so that the processor is apprised of the block which contains the end of the message when it receives the interrupt. These blocks are used in sequence so that the processor need not keep up in real time with the reading of the data.

HARDWARE CONTROL

All of the hardware controls are exercised via menu driven selections from the system console. When the system is initialized (the program is called **nas** and is in user directory **100.nas**), it comes up with a top level menu. This is the menu which is used by the system personnel when actually working with the NAS. There are two submenus for diagnostic purposes: (1) the Hardware Diagnostic menu which is accessed by entering L from the Top Level and (2) the Software Diagnostic menu which is accessed by entering G from the top level. Only the Hardware menu will be discussed here.

HARDWARE DIAGNOSTIC MENU (L).

The Hardware Diagnostic menu allows the following selections:

1 - **Display RX buffer** (a submenu allows selection of choice)
2 - **Display TX buffer**
3 - Not used
4 - Transmit 8 **byte test message** (ends with parity error)
5 - 1/**sec XMT test** (1 to 256 bytes)
6 - 1/**sec L/B test**

CARD CONFIGURATION MENU (J MENU).

This menu reads the **Hardware Status Control register** and interprets the contents so that the configuration of the hardware is easily seen. The status of the following parameters is given on the menu:

Interrupts	Enable/Disable
Loop Back	Enable/Disable
XMT data	Enable/Disable
RCV data	Enable/Disable
Invert data	Enable/Disable
RX sync	Enable/Disable
XMT Logic	Enable/Disable
# of Consecutive 0's	Value

It also reads the **Hardware Status Register** and reports the status of the following hardware parameters:

Status Register	Contents
TX Clock	Present/No TX clock
RX Clock	Present/No RX clock
Xmt Logic	Active/Inactive
RCV Logic	Active/Inactive

The J Menu also allows the selection of the configuration parameters from the following menu:

1 - Reset Card
2 - Enable Operation
3 - Disable Operation
4 - Set Baud Rate (300 to 19200 for internal clock)
5 - Enable Interrupts
6 - Disable Interrupts
7 - Enable Loop back
8 - Disable Loop Back
9 - Enable XMT data
A - Disable XMT data
B - Enable RCV data
C - Disable RCV data
D - Enable Invert data
E - Disable Invert Data

F - USE EXT XMT clock
G - UNUSE EXT XMT clock
H - USE EXT RCV clock
I - UNUSE EXT RCV clock
J - Enable RCV Sync Detection
K - Disable RCV Sync Detection
L - Set # consecutive sync 0's
M - Enable XMT Logic
N - Disable XMT Logic
R - Set XMT Test Conditions
S - Leo Test Mode Menu (hardware diagnostics)
T - George Test Mode Menu (software diagnostics)
U - Top Level Menu

MEMORY DIAGNOSTICS.

The memory diagnostics are run via a program called **nasmtest**. This program is menu driven and provides the following capabilities:

1. The ability to address any address within the system (not limited to those assigned to the ATC interface.

2. The ability to perform a "write - read - read" cycle on any address. Data are variable.

3. The ability to perform a constant "read" of any address. This is mainly for troubleshooting purposes.

4. The ability to perform a constant "write" of any address. This is also for troubleshooting purposes.

5. A function which verifies "write-read" data on one address. Data is variable but not selectable.

6. A function which verifies "write-read" data of 0 to 255 on a specified number of addresses.

7. A function which shifts a single 1 pattern to the left and verifies proper performance.

8. A function which shifts a single 0 pattern to the left and verifies proper performance.

9. The ability to "mask out" certain bits so that the processor does not check them. This function is used mainly to eliminate going to the screen with the errors as it slows down the prf of the functions considerably.

MEMORY MAP OF ATC2 INTERFACE

The memory of the ATC2 interface hardware will by organized as follows:

The memory of the ATC interface will be assigned to the addresses in the EF700000 block of system memory. It will be organized so that several interface cards can reside in the same unit, with the only difference being the addresses of each unit (one Pal difference). Assignments will be as follows:

```
EF700000-EF70FFFF   INTERFACE UNIT #1
EF710000-EF71FFFF   INTERFACE UNIT #2
EF720000-EF72FFFF   INTERFACE UNIT #3
EF730000-EF73FFFF   INTERFACE UNIT #4
```

The breakdown of memory allocation within each block is as follows:

```
EF700000  Hardware control Register
EF700001  Clock Contol Register
EF700002  Consecutive Zero Monitor Control
EF700003  No Longer Used
EF700004  Transmit Data Byte Count (8 lsbs)
EF700005  Software System Enable (1=enable, 0=disable)
EF700010  Hardware Status Word (Read Only)
EF700011
   TO
EF700FFF  NOT USED
EF701000
   TO
EF7013FF  Receive Data Memory
EF701400
   TO
EF701FFF  NOT USED
EF702000
   TO
EF7023FF  Transmit Data Memory
EF702400
   TO
EF70FFFF  NOT USED
```

All memory except for the Hardware Status word (EF700010) is **dual port** and can be written or read by the computer interface.

ADDRESS DECODING.

The ATC Interface card is set up as an A32 (32 address bits)/D08 (8 data bits) interface. It monitors the address modifier lines on the VME bus and responds to only address modifiers of 09, 08, 0D, and 0E which are valid only for A32/D08 systems. The two least significant bits of address are defined by the following truth table.

DS1	DS0	A01	LWORDLSB ADD
0	X	0	X0
0	X	1	X2
X	0	0	X1
X	0	1	X3

The address decode function is divided between several PALs on the interface card. ADEC.ABL (U13) decodes address bits 16 to 31 to break the decodes into 64k blocks. When the appropriate 64k block is accessed which matches that assigned to the particular interface card, it produces MAD1 to signify that fact. BDEC.ABL (U24) further breaks down the decode to either CONTROL, TRANSMIT MEMORY, or RECEIVE MEMORY. Its outputs are passed on to the final decode pal CDEC.ABL (U25) which produces the appropriate enables for the logic of the particular areas of the interface logic by using these inputs and the 8 Lsb's of the VME address. (The two Lsb's are produced by INBYT.ABL (U28) to decode the four signals which are used by the VME to address the two lowest address bytes (LWORD, DS0, DS1, and A01). In order to prevent right and left port simultaneous accesses to the same memory address, the right port (hardware side) is only enabled when an active transmit or receive cycle is in progress.

The acknowledge handshake logic for the VME bus is handled by PALs U30 (ACKTIM.ABL) and U31 (ACKLOG.ABL). These PALs use the data and address strobes from the VME bus along with the "write" control signals to produce the acknowledges required to satisfy the handshake protocol of the VME.

INTERRUPT PROCESSING.

All of the hardware interrupts to the 68020 are at system interrupt level 6. Figure 4 is a block diagram of that interrupt logic. There are eight different interrupt vectors. One is assigned to the transmit interrupt and the other seven are assigned to the receive data buffers. The buffer which contains the last valid receive data is used to generate the proper vector so that the processor can properly locate the latest data.

AINCONT.ABL (U17) controls the interrupt handshaking with the 68020. It receives the requests via INT0-2 from the priority PAL (IPRI.ABL). It accepts higher level interrupts until the end of state 1. It then freezes at that vector address until state 7 when it is reset. It furnishes the priority PAL with IAK which resets the interrupt request. The drawing of the state diagram is shown in figure 5.

IPRI.ABL (U18) stores interrupt requests from the system and passes them along to U17 according to priority (IRQ7 is the highest priority). Transmit interrupts (TINT) have priority over receive (RINT). The interrupt requests are active high and remain set

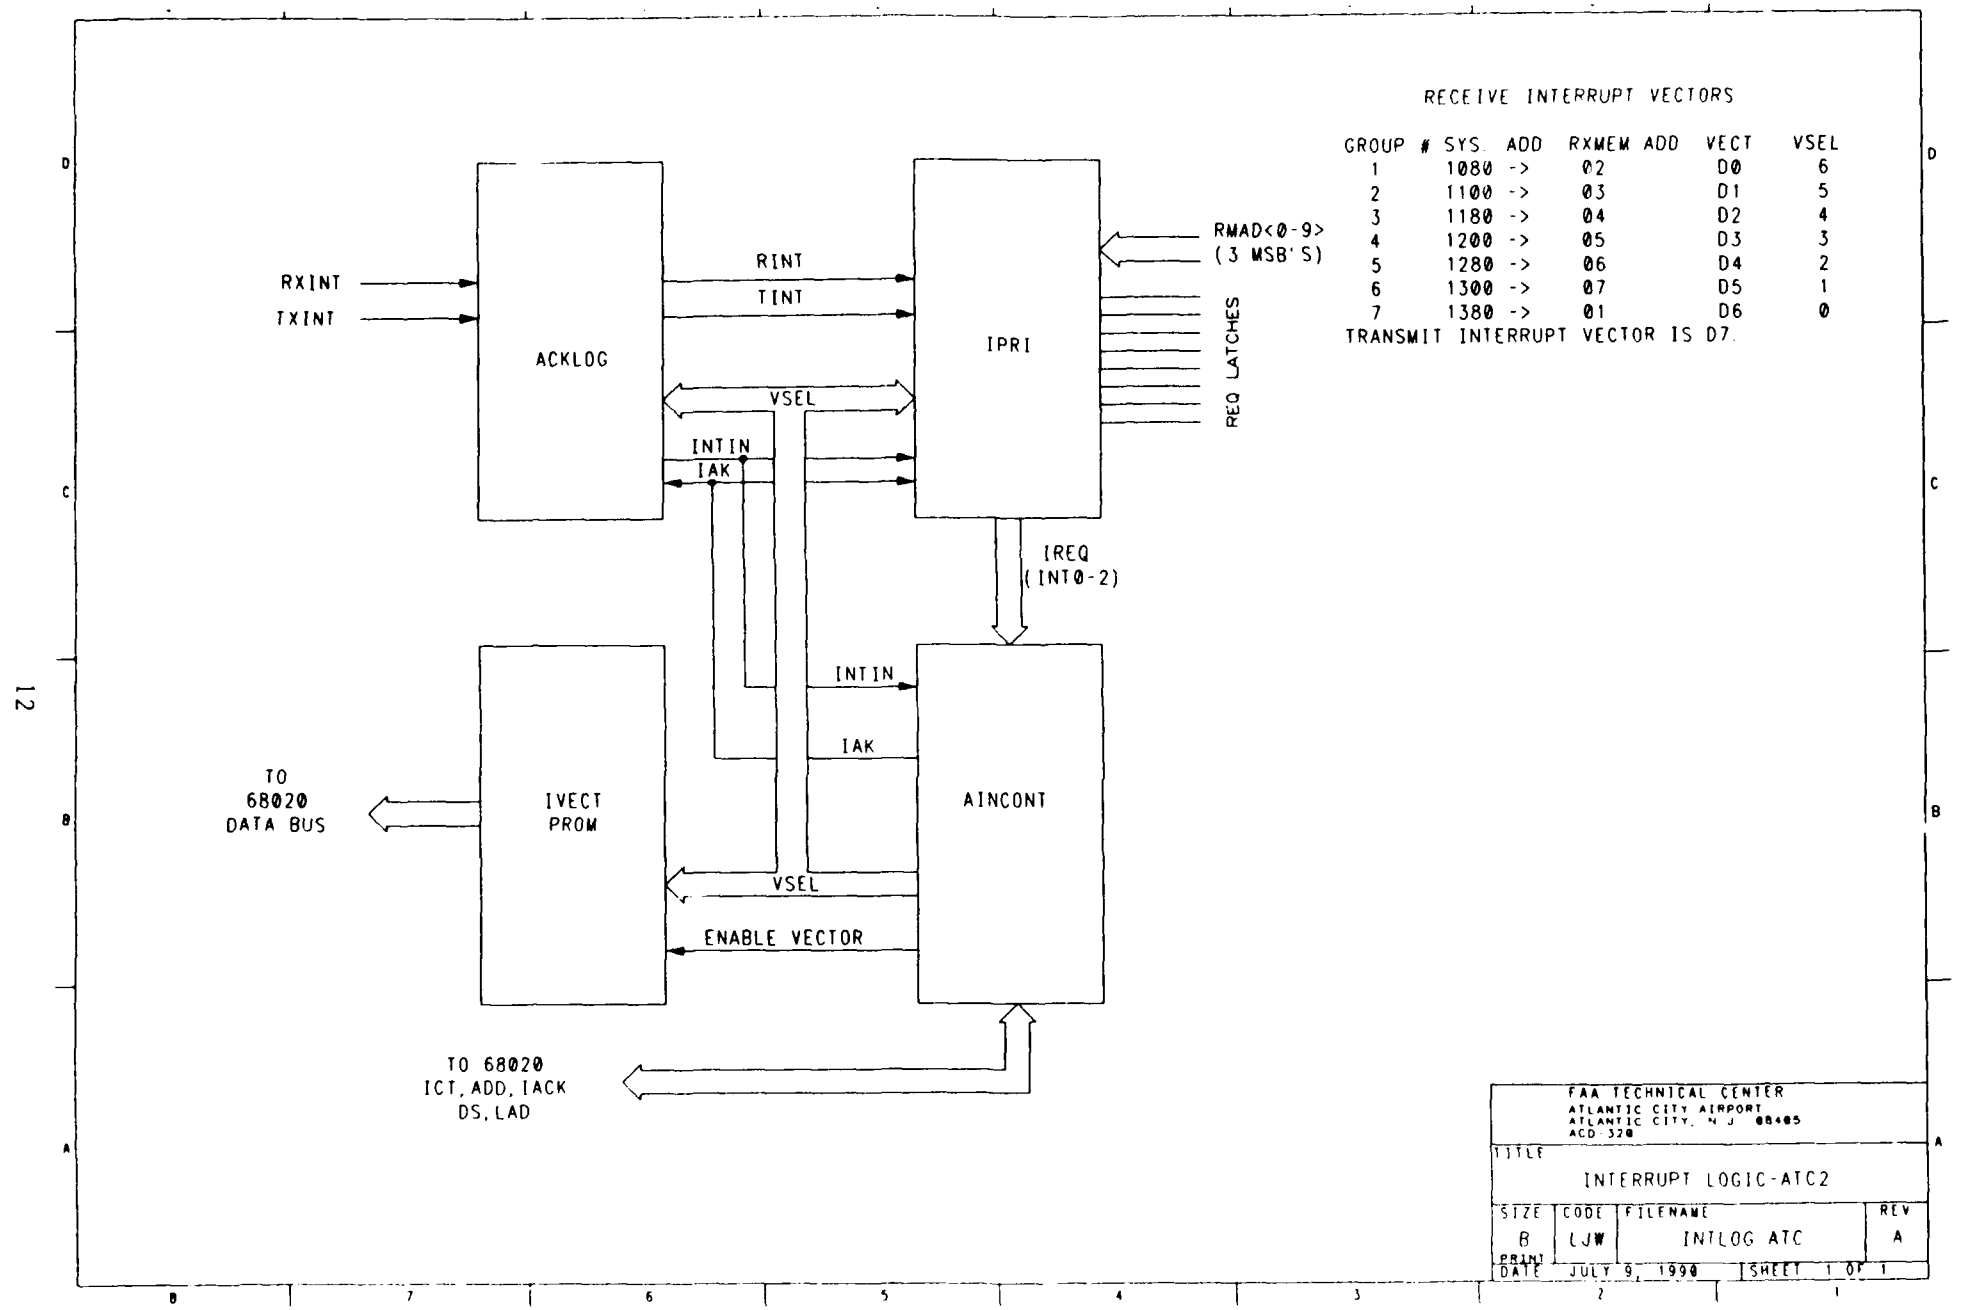

FIGURE 4. ATC INTERRUPT LOGIC

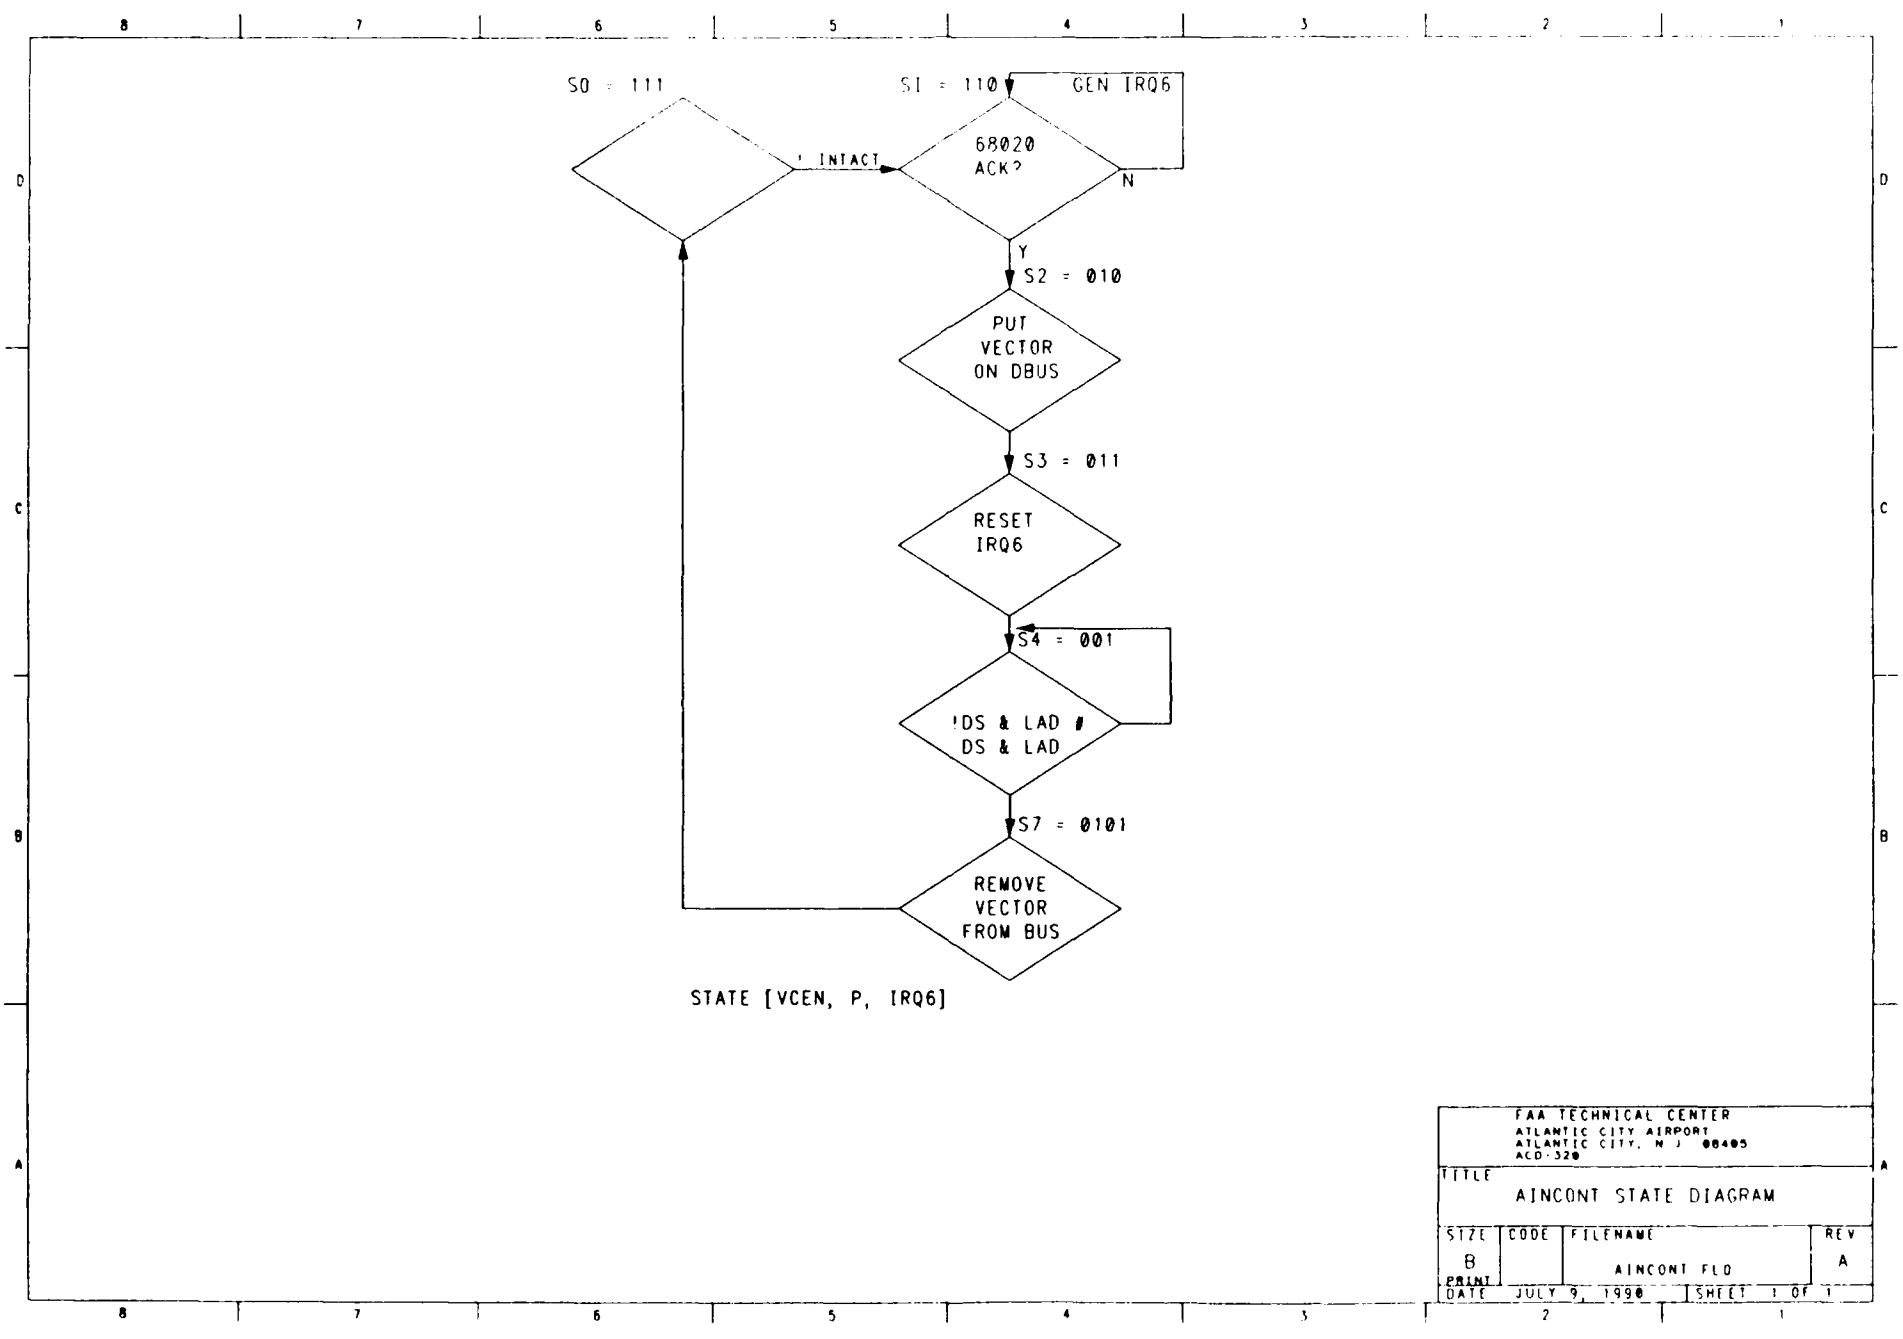

FIGURE 5. ATC INTERRUPT STATE DIAGRAM

until the interrupt is serviced. The vector request is an ACTIVE LOW three-bit field (IRQA,IRQB,IRQC). The outputs are also active low (INT2,INT1,INT0). All interrupts are cleared when a RESET is received. A separate vector is generated for each block of addresses of receive data.

The interrupt vectors for the various levels of interrupts are defined as follows:

Rec. Data Group 1	Vec.Prom Add.	Vector
1	006	D0
2	005	D1
3	004	D2
4	003	D3
5	002	D4
6	001	D5
7	000	D6

The vector for the transmit data interrupt is D7 and it is at address 007.

The requests for interrupts come from the transmit and receive data logic in the form of RXINT and TXINT. These signals are processed by the ACKLOG.ABL and passed on to the interrupt processing logic. TXINT is produced when the designated number of bytes have been transmitted by the hardware. In this manner, the computer is notified of the completion of the assigned task. The receive interrupt request (RXINT) comes to ACKLOG.ABL from the receive status logic (STATCON.ABL). See the description of the status logic for details.

INPUT CLOCK CONTROL.

The serial input clock control is handled by PAL U36B. This PAL is controlled by the following signals:

USEXTRX - Selects either the internally generated or external clock for use of receive logic.
USEXTTX - Selects either the internally generated or external clock for use of transmit logic.
LOOPBK - Uses either incoming RECDATA or output transmit data for input receive data.
INVDAT - Provides the option of inverting both transmit and receive data.

This module contains logic which effectively filters glitches on both transmit and receive clocks. The rise times of these signals can be several microseconds and the hysteresis provided by the line receivers is sometimes not sufficient to eliminate small glitches. Whenever the input clocks are high, a counter is enabled to count up to seven (where it remains until the input goes back low). The counter is reset every time the input clock goes low. Thus, if a

glitch occurs at the count of four or five, it merely restarts the counter. The external transmit logic is enabled by TXCKEN which occurs at the positive going edge of the input clock. The external receive logic is enabled by RXCKEN which occurs at the negative edge of the input clock. Both occur at a count of six of their respective counters. Either the external clocks or the internally generated clock (300 - 19200) can be selected by the input control signals.

TRANSMIT DATA PROCESSING

The transmit data processing logic is controlled via the Transmit Control logic of U55 and U56. This module is actually a state controller whose state diagram is shown in figure 6. If the processor desires to transmit a message, it first stores the transmit data in the Transmit Memory, U10. It stores the number of bytes to transfer in latches U5 and U20. U5 also contains the "transmit start" signal (TXSTART) which occurs on the transition of bit 0 from a 0 to a 1. This event sets TXACTIVE which enables the Transmit Control State controller to run. It moves one state at the Lead Edge of each Transmit Clock. State S1 starts the generation of the sync pattern. S2 enables the load of the byte count into the byte counter U53, U54. The transmit output continues to be all zeros until state S17 is reached, which generates a 1 for the sync message. S18 enables the loading of the shift register with the first byte of output data. S19 checks for a "word count=0" and since this is not the case, the controller goes to state S20 which enables the memory address counter to increment to the next byte. The next state, S21 enables the byte counter to decrement. The state controller then goes through states S22, S23, S24, and S25 while shifting out the data from the transmit shift register U57 via the transmit parity generator U58. At state S26 a check is made to see if the transmit parity generation logic is enabled (this requires a nine state loop - 8 data bits plus parity). If the logic is enabled, it goes to state S27 which loads the next byte into the shift register and transmits the parity bit out the serial transmit port. If the logic is disabled, it skips state S27 and goes to S19 to check for a word count of zero. The loop continues until a word count of zero condition is reached. At this time TXACTIVE is reset, a transmit interrupt request is issued, and the state controller goes to the IDLE state S0.

Appendix A is a file collected via a logic analyzer which shows two transmit sequences. The first is with the transmit logic enabled (pages A-1 to A-3) and the second is with the transmit logic disabled (pages A-4 to A-6). Both sets of data contain comments which flag significant events on any particular state.

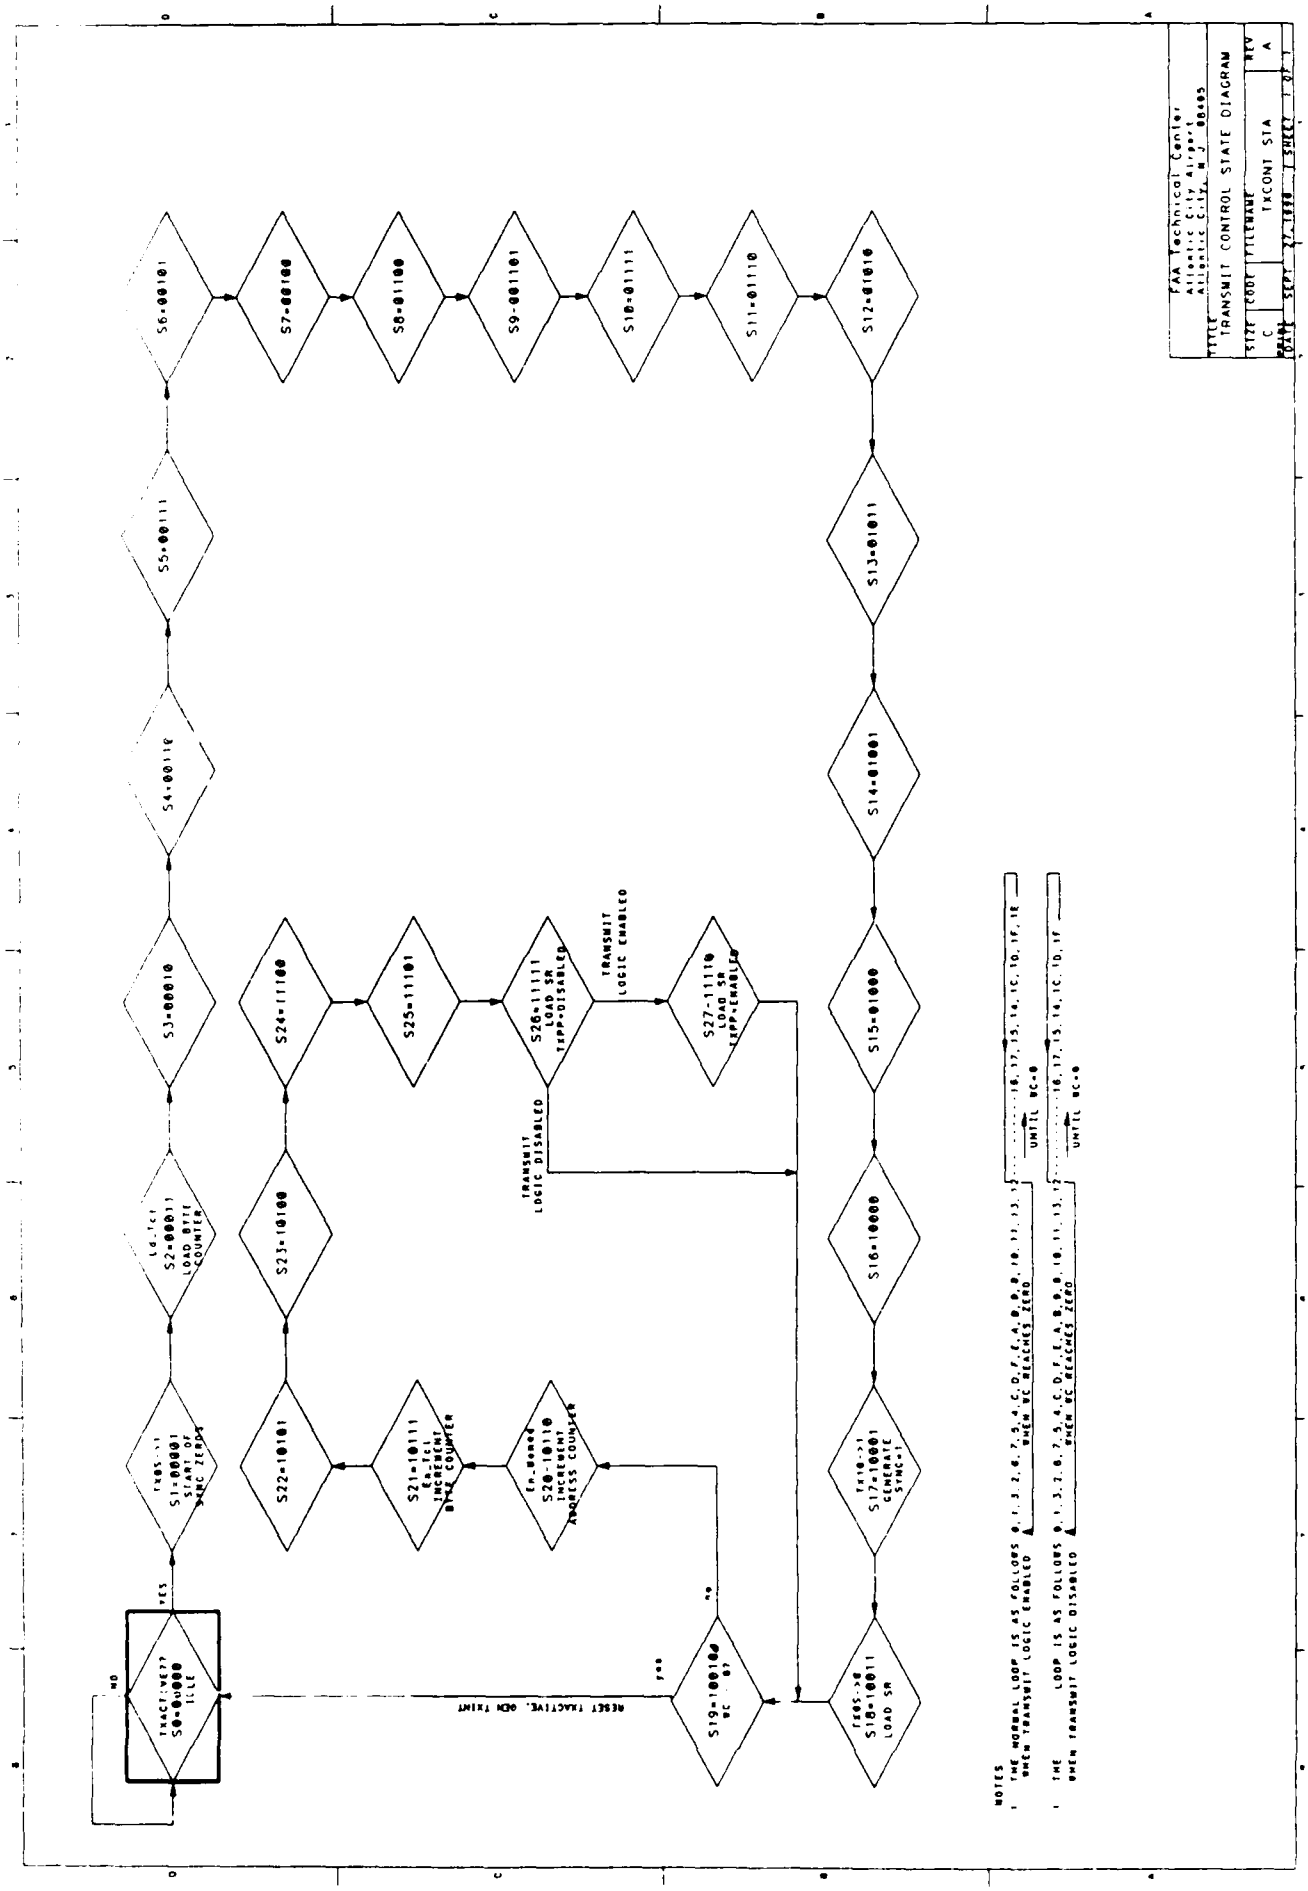

FIGURE 6. ATC TRANSMIT CONTROL STATE DIAGRAM

RECEIVE DATA PROCESSING

Many features are included for analysis of system operation when peculiarities occur. The normal sync pattern for the incoming data is either 17 or 18 zeros (depending on the level of the idle character when the sync pattern starts) followed by a 1. A common problem is the missing of a sync character because a 1 was picked up by the receive logic when a 0 was actually transmitted on the other end. The ATC interface contains logic to monitor the number of consecutive zeros prior to storage of data. When the threshold (controlled via the processor and address EF700002) is exceeded, all incoming data (including the parity bit) is stored in RAM so that it can be read by the processor. If an actual sync pattern is later detected prior to the storage of 128 bytes, the stored data is **over written** with the real message data. In this mode the parity bits are stripped off by the receive processing logic and only the message is stored.

Three sets of data are included as appendix B. They show receive logic state sequences for three different events.

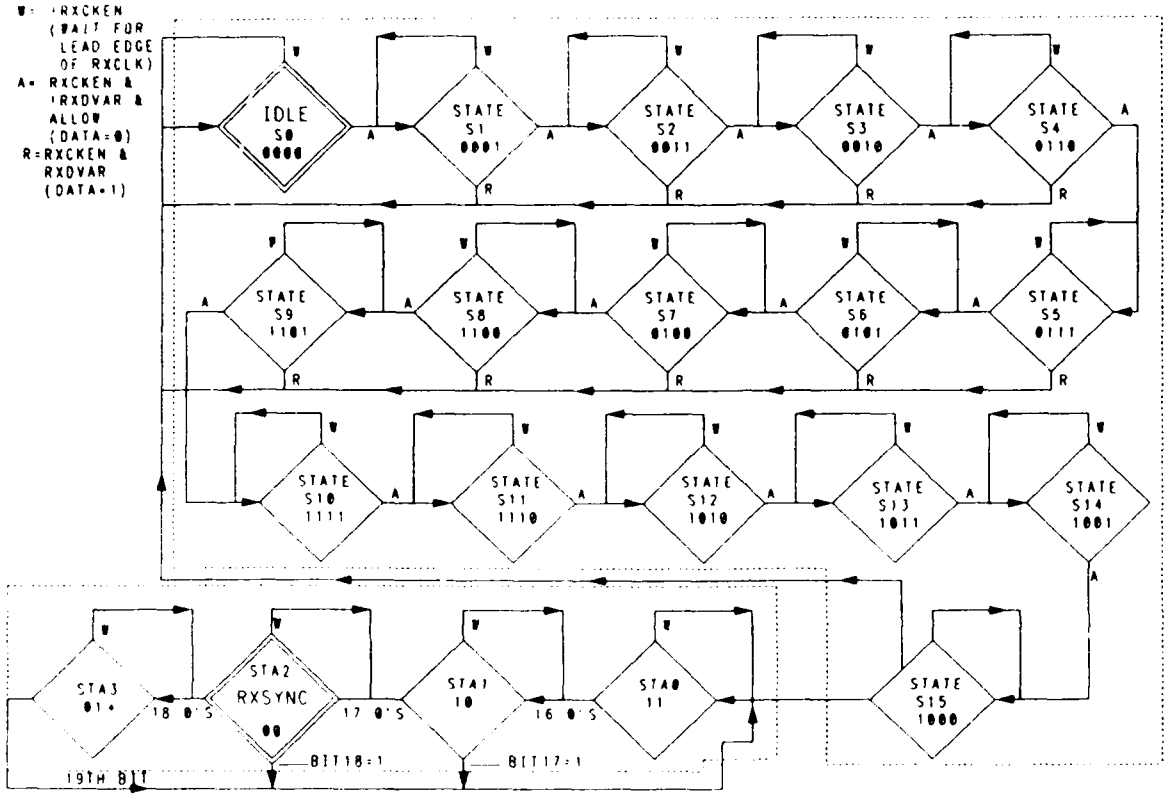
1. Pages B-1 to B-4 show the processing when the Receive Sync detection logic was **DISABLED** and a standard 8 byte message was received. Significant events are commented as the sequence is traced from sync occurrence and the exceeding of the MTE threshold until the end of the message occurs. This sequence illustrates the storage of all incoming data, including parity. The use of this data along with the state diagrams will make it easy to understand the receive logic.

2. Pages B-5 to B-7 show the same sequence as described above, but with Receive Sync Detection logic **ENABLED**. This shows the storage of only the real input data, with the parity bits stripped off by the hardware.

3. Pages B-8 to B-10 show the actual storage of data cycles. These sequences are actually performed by the Status Logic, which controls the storage of all Receive data. These sequences are in single 100 ns clock increments, unlike 1 and 2 above which were one clock sequence per Receive Clock (RXCK). These three sequences show a normal Memory storage cycle, a Status storage cycle, and a Reset cycle which occurs when sync is detected.

RECEIVE DATA SYNC DETECTION.

Sync detection is controlled by U42 (SYNDET.ABL). This logic searches for the sync pattern of either 17 or 18 zeros followed by a 1 to identify the start of a message. U42 is comprised of two state controllers which use RXCKEN and RXDVAR as the control inputs for the state controllers. Equations are given in SYNDET.ABL and the state diagram is shown on figure 7.



* STATE CONTROLLER
STA [RXSYNC,SIXT]

NOTES: 1 SYNDET ALSO PRODUCES 'ALLOW' AND 'RXACTIVE'
2 ALLOW IS SET WHENEVER THE DATA BIT = 1
3 RXACT.VE IS SET ON THE '1' FOLLOWING RXSYNC IF IT IS THE 18TH OR 19TH BIT AND REMAINS SET UNTIL RXEOM IS RECEIVED

FAA TECHNICAL CENTER ATLANTIC CITY AIRPORT ATLANTIC CITY, N.J. 08405 ACD-320

SIZE: B	CODE: [illegible]	FILENAME: [illegible]SYNDET STA	REV: A
PRINT DATE: JUNE 26, 1990		SHEET 1 OF 1	

FIGURE 7. ATC SYNC DETECTOR STATE DIAGRAM

The enable signal for the state controllers is ALLOW, which is activated any time a 1 is detected in the input data stream. It remains active until a string of 19 consecutive zeros disables the sync detection logic until another 1 is detected.

The first of the two state controllers in U42 (outputs QA,QB,QC and QD)detects 16 consecutive zeros. It is reset to state S0 when any input data bit is a 1. On the 16th zero, output SIXT goes low. On the 17th consecutive zero, RXSYNC is generated. If the 18th data bit is a 1, RXSYNC is terminated and RXACTIVE is generated. If the 18th data bit is a 0, the controller waits for the 19th bit. If the 19th bit is a 1, RXSYNC is terminated and RXACTIVE is generated (this timing is also shown on figure 1). If the data bit is another zero, ALLOW is disabled and the process must begin anew after another 1 has been received. All of the above cases are covered in the "test_vectors" portion of the PAL source code file SYNDET.ABL.

Receive data storage control is under the control of U43, BITCOUNT.ABL - This PAL contains the logic to control storage of receive data in memory. When the "consecutive zero threshold" is exceeded (MTE), incoming data are stored in RAM as it comes in (every eight bits). If sync is detected, the address counter is reset and data is stored every nine bits as parity is not stored in memory for real data.

This is accomplished in the following manner: A state controller which has 10 states (see figure 8) is in the IDLE state until MTE occurs. When this happens, the state controller goes around a loop as follows: S0(IDLE) jumps to S2-S3-S4-S5-S6-S7-S8-S9-S2-S3, etc. Data are written into RAM on S9. If sync occurs, the state controller goes to state S1 and also loops back to S1 instead of S2 making the loop equal to nine data bits. Data are still stored at state S9 by this PAL generating LDRX. The actual storage process is controlled by another PAL. This PAL also produces LACT which is a signal which lasts from the time MTE occurs until a real sync is detected (RXSYNC). If RXSYNC is detected before 128 bytes are stored, LACT is reset, the loop changes to nine bits, and the data previously written in RAM are written over with the actual message data. If no sync is detected, the storage of data ends after 128 bits and the status logic strobes the value of LACT to indicate to the computer that no valid start of message was detected, but the threshold was exceeded.

RECEIVE STATUS LOGIC.

The receive data are stored in RAM in blocks of 128 bytes. Each group has a 4-byte status word associated with it to identify some of its characteristics for the processor. The address assignments of these status blocks is shown below:

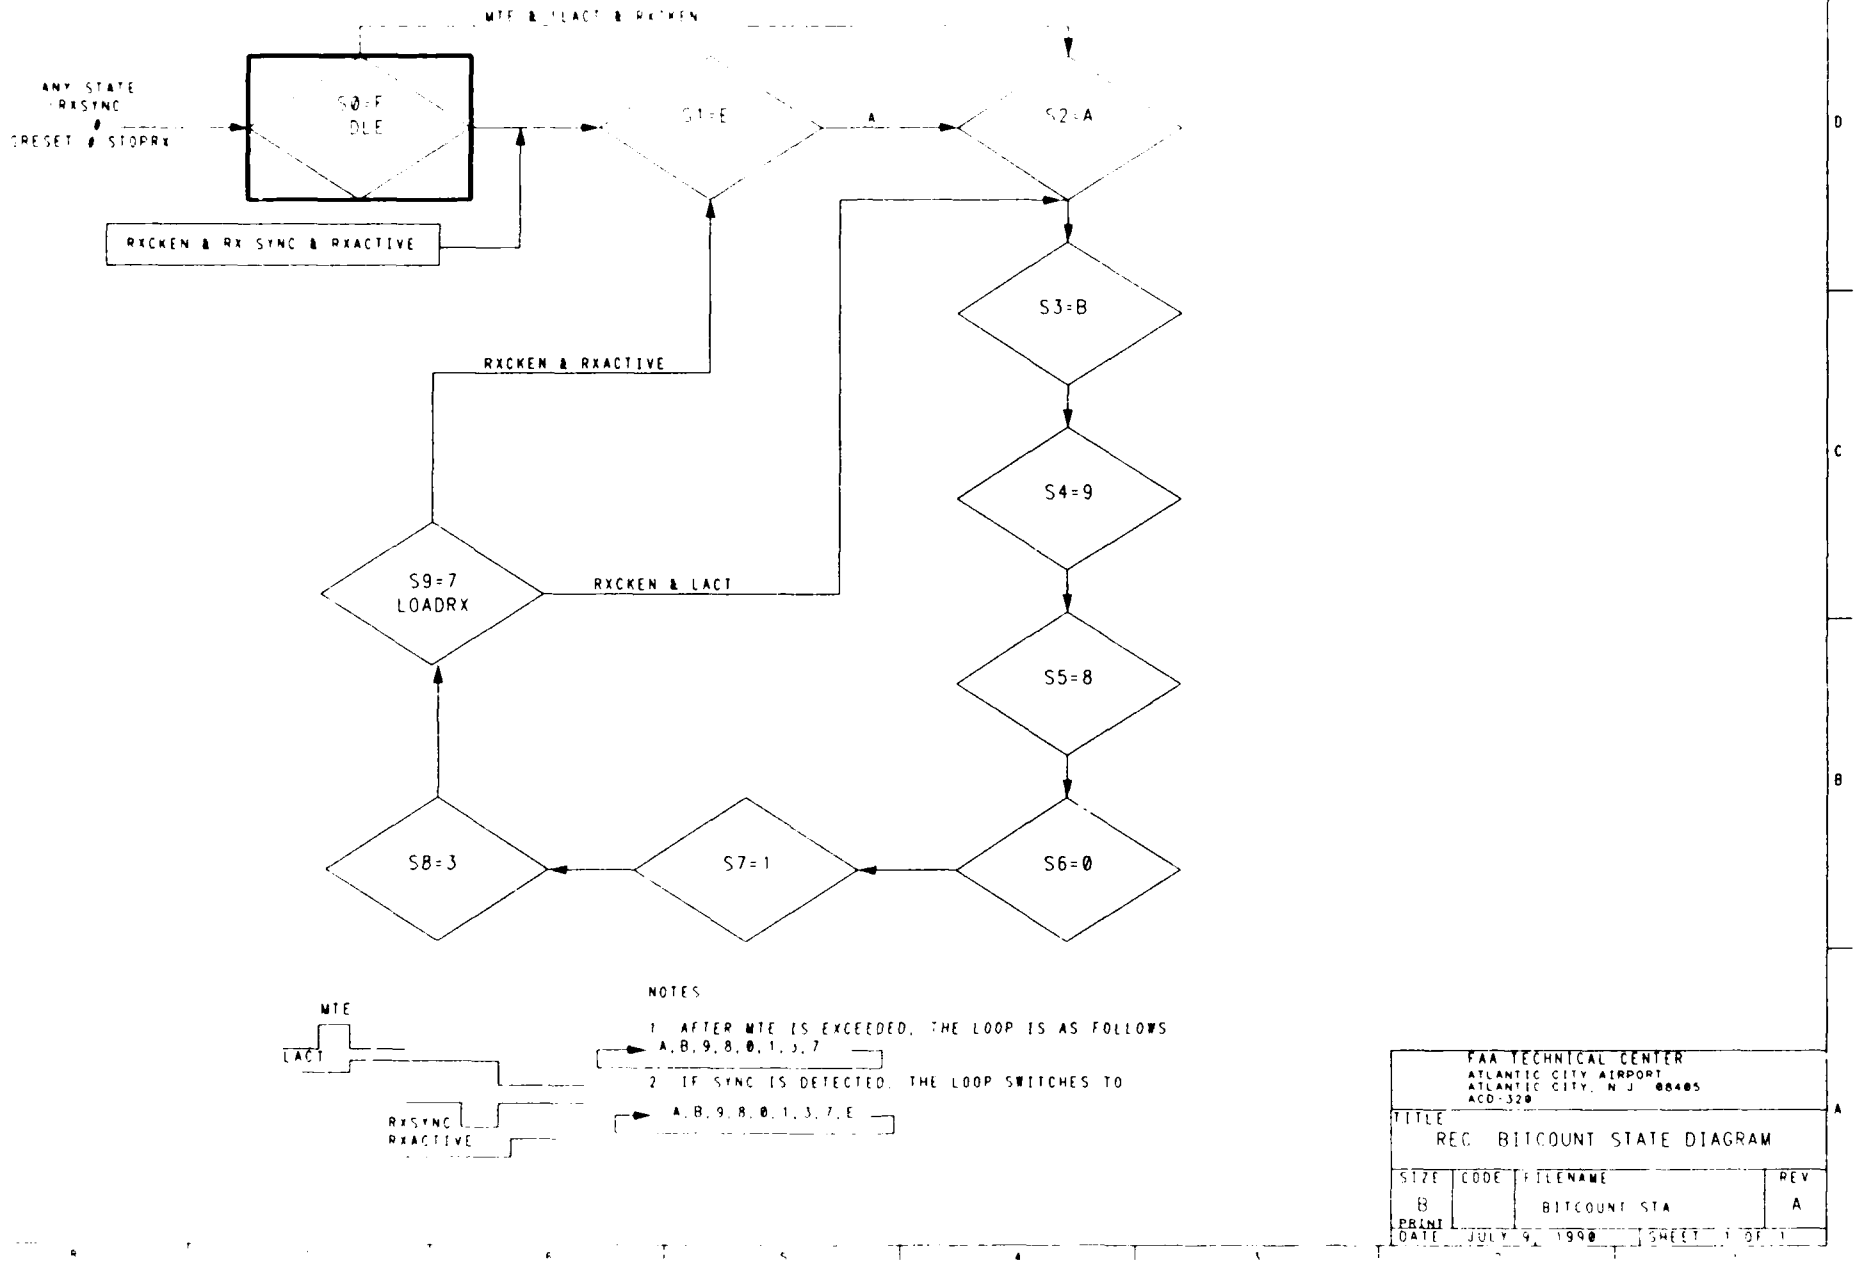

FIGURE 8. ATC BIT COUNTER STATE DIAGRAM

Block #	Data Address(start)	Status Address (start)
1	EF701080	EF701004
2	EF701100	EF701008
3	EF701180	EF70100C
4	EF701200	EF701010
5	EF701280	EF701014
6	EF701300	EF701018
7	EF701380	EF70101C

All data are actually stored in the receive data memory under the control of the status logic. The state diagram of this function is shown on figure 9. As indicated, this state diagram actually contains three separate loops. It is normally in state 0 (IDLE) awaiting a command to move to one of the other loops. It is preset to this state on **power up or reset** and is returned there upon leaving any of the other loops. The main control signal for the status logic is LDRX which comes from BITCOUNT.ABL during state 9 of its loop. The status logic first performs a **lead edge detection** of this signal since it lasts for the duration on one of the incoming receive data clocks. If no end of message (RXEOM) has been detected, the state controller goes to state 1. U47 then produces the write enable pulse, RXWR, to write the data into RAM. On the following clock, it goes to state 2 which results in En_Rmac which enables the address counter to increment to the next address. On the following clock, it returns to state 0 to await the next command. This loop will be the normal mode after the Monitor threshold has been exceeded until Sync has been detected.

When a receive sync pattern is detected, U42 produces **RXACTIVE**, which is sent to the status controller. It performs a "lead edge detection" of this signal which is used to send the state controller to state E. This is used to generate **Clr_Rmac** which is used to clear the memory address counter so that the data will be written over that stored previously after **MTE**. It remains in state E only for one clock period, after which it returns to state 0. Each nine bits thereafter, **LDRX** occurs and the loop is repeated to store all the incoming data in the Receive data memory. If **LDRX** is received after **RXEOM** and **RXACTIVE** have occurred, it signifies the end of the message and the status controller goes to the third loop to write the data and append the status data to the block. The sequence is as follows: At the lead edge of **LDRX** the state controller goes to state 3 which produces **RXWR** to write the last byte of data into the RAM. It then goes to state 4 which produces **Latlad** which is used to latch the address of the last byte into U51 and U52 (these data are to be included in the status block). On the following clock, it goes to state 5 which produces **Lo_Rmac** (which loads the memory address counter with the address for the status block for the particular group of data which has just been stored) and sets **STAT** to notify the logic that the Status portion of the receive cycle is in progress. **STAT** is used to disable the outputs of the input shift register U37 and to select the addresses of the status blocks in **RADCON.ABL** (the memory address counter

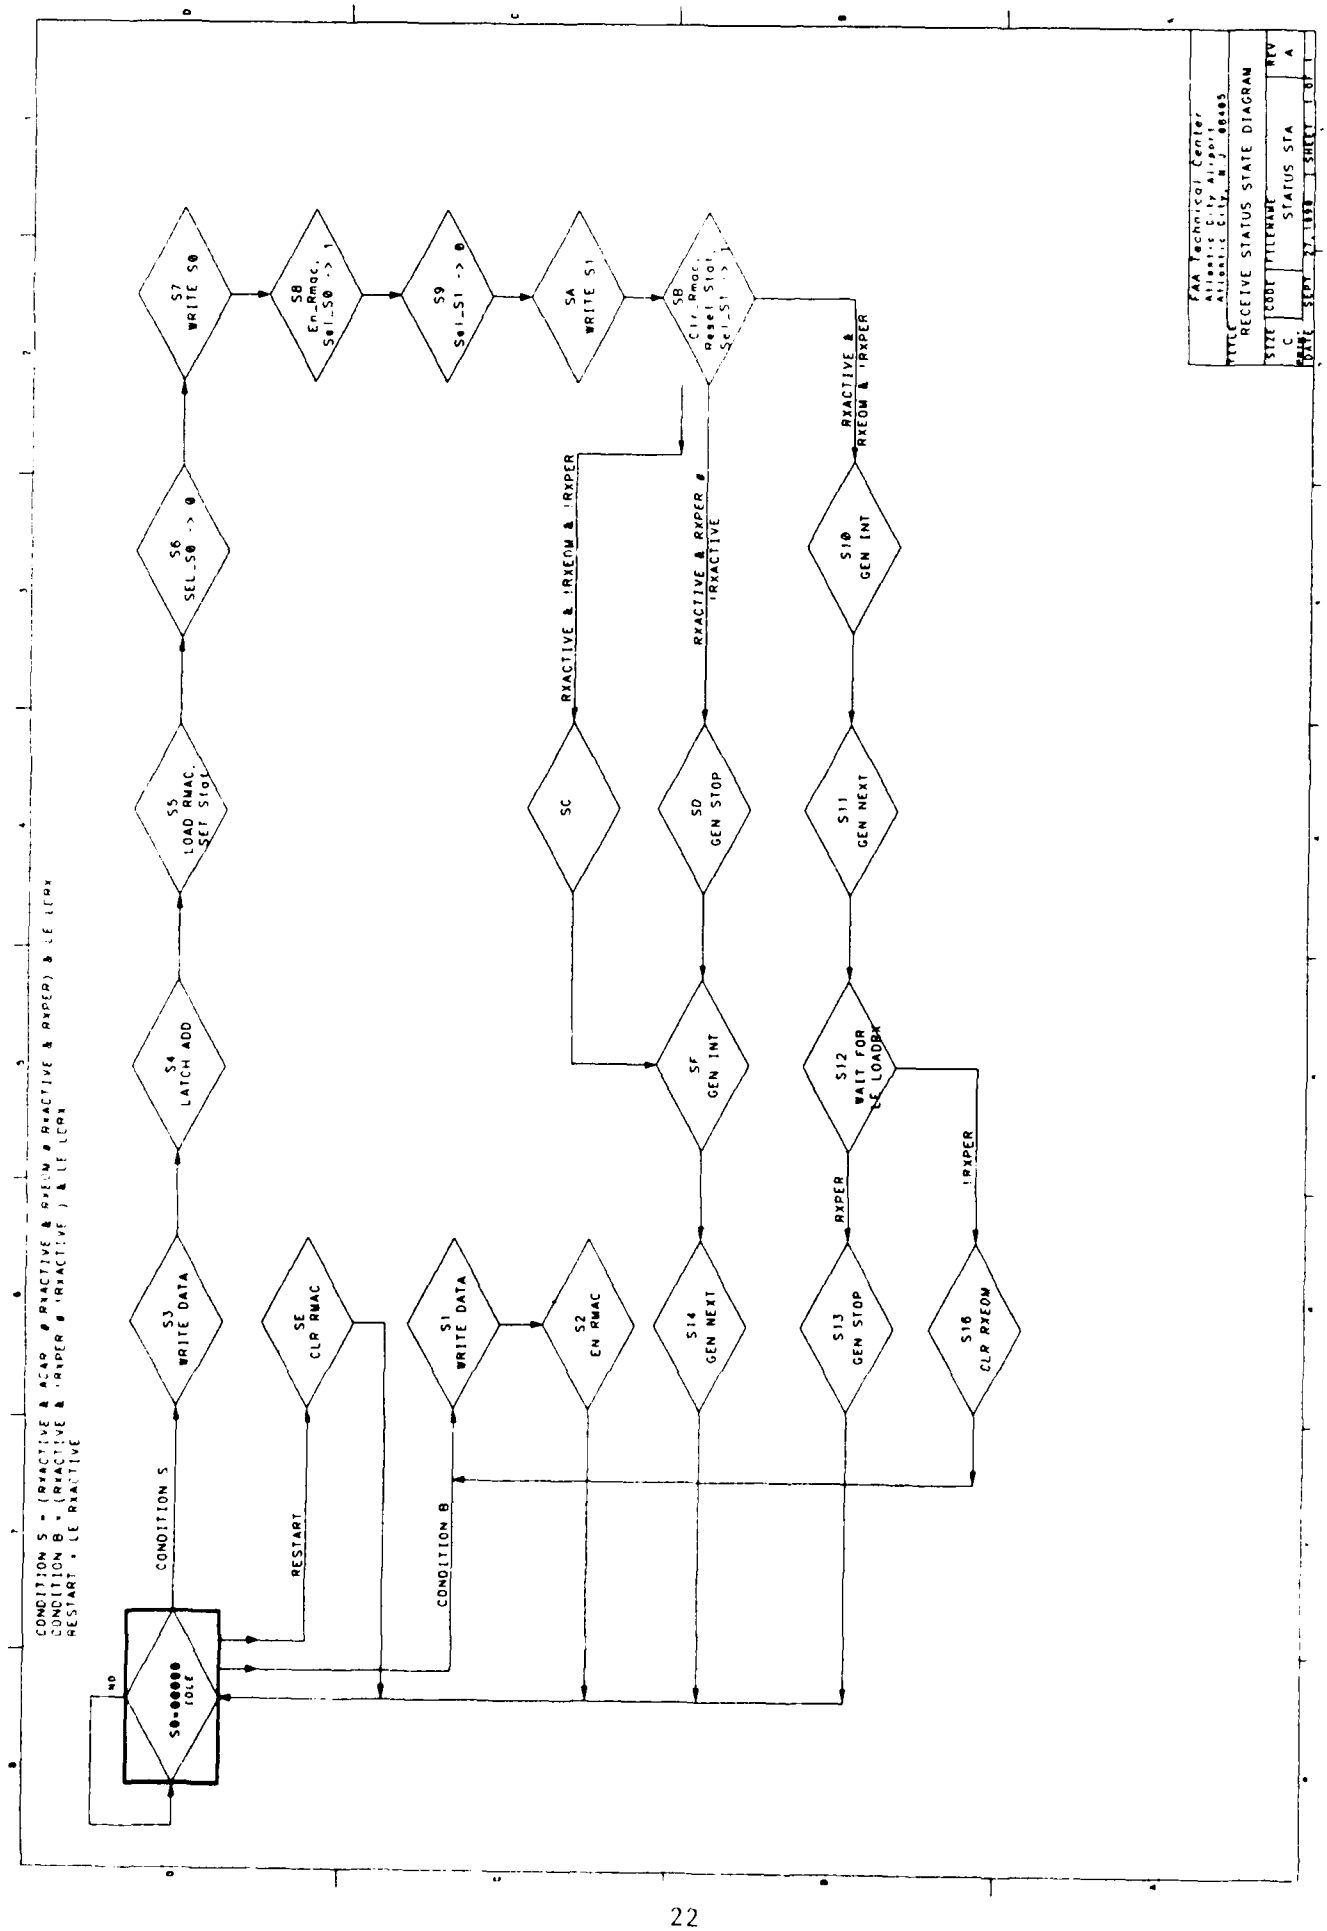

FIGURE 9. ATC RECEIVE STATUS STATE DIAGRAM

logic). The following clock takes the controller to state 6 which produces **Sel_S0** which is used to enable the contents of U52 to the Receive memory data bus (**RXDA<0-7>**). The contents of U52 were latched during state 4 and include the status of the following signals:

1. LACT - This signal is high from MTE to RXACTIVE and indicates to the processor that the data is a valid message (1) or input raw data (0).

2. ABORT - This notifies that processor that an ABORT message has been received. This consists of nine consecutive zeros.

3. HANDSHAKE BIT 7 - This bit is written to a zero by the processor each time it reads the status data and is written to a 1 each time a new status word is stored by the hardware. This bit is used to detect an out of sync condition between the hardware and software.

4. The two Msb's of the Last valid address.

The following clock takes the state controller to state 7 which produces **RXWR** to write the contents of U52 to memory. The following clock takes it to state 8 which produces **En_Rmac** to increment the address counter and reset **Sel_S0**. The following clock takes it to state 9 which produces **Sel_S1** to enable the contents of U51 to be placed on **RXDA<0-7>**. The following clock takes it to state A which produces another **RXWR** and writes the contents of U51 (the 8 Lsb's of the Last valid address) into memory. The following clock produces state B which produces **Clr_Rmac**, Resets **Stat** and sets **-Sel_S1** to a 1. On the following clock the logic takes one of three branches depending on the conditions. The normal exit loop for a valid message is shown in the sequence of appendix B, sheet B-9. This is for a message with a valid EOM and no parity error. If the **RXACTIVE** is a 1 and a parity error has occurred, the next state is SD, which generates **STOP** and then goes to SF on the following clock to generate the Receive interrupt. It then goes to S14 which generates **NEXT** to increment the address counter to the next block for the next message. The same loop is also followed if 128 bytes are stored after MTE without detecting a receive sync pattern. The only difference will be the fact that LACT will be a 1 to identify the block as entirely raw data after MTE was exceeded. If the state controller is at state SB with **RXACTIVE & !RXEOM & !RXPER** (the normal condition if a message exceeds 128 bytes), the state controller will go to state SC. From here it goes to S14 which generates **NEXT** to increment the address counter to the next block, but it skips the states which will generate an interrupt. An interrupt is generated only at the end of a sequence (a valid EOM or a parity error).

RECEIVE PARITY LOGIC.

The parity of incoming data is checked by RXPAR.ABL (U38). It monitors the output of the Input data shift register U37, and the input parity bit (RXPARIN) to see if the received parity matches that computed from the input data. If the expected and received parity bits are different and LDRX is a 1, RXPER is generated to signify a parity error has occurred. If this occurs, it will result in the generation of RXEOM by EOMDET.ABL (U44) and storage of input data will be aborted.

EOM DETECTION.

The EOM detection logic monitors the output of the receive data input shift register. The normal EOM character is B1. This logic is disabled on the character following the detection of LRCPREP, as the value of this byte can be anything and must not be confused with the normal EOM. A receive message is also terminated whenever a parity error is detected.

RECEIVE MEMORY ADDRESS CONTROL.

This function is not a straight forward counter because of the way in which the data are organized in memory. The function is performed in the module called RADCON.ABL which is comprised of U49 and U50. A simplified block diagram of the function is shown on figure 10. The function consists of two separate counters and a multiplexor. A 7-bit counter addresses the Lsb's and a 3-bit counter accesses the Msb's of the memory. When STAT is not active (when not in the status loop), the outputs of the counters are selected via the multiplexor. If STAT is active, the four Lsb's are selected and the remaining six are forced to zero. The four Lsb's were preset to the proper address as part of the status loop so that the status block can be associated with the particular block of 128 bytes stored in RAM. Normally, the three Msb's identify the 128 byte block, but if a message exceeds 128 bytes, a CAR from the 7-bit counter increments the Msb counter to the next block and message storage continues. The overflow will be flagged by the value of the "last valid address" in the status area of the message. **The status message will be in the area associated with the last block of data.**

APPENDIX A
TRANSMIT DATA SEQUENCES

APPENDIX A
TRANSMIT DATA OUTPUT SEQUENCES

This file is for the transmit logic operation. The message selected is the standard 8 byte message (0,1,2,3,4,5,6,B1).

THIS DATA SET IS A TRANSMIT CYCLE WITH TRANSMIT LOGIC ENABLED.
The logic analyzer is set up to store only if TXCKEN=1.
It is set to trigger on TXACTIVE.

When the transmit logic is ENABLED, the loop transmit control loop is as follows: (0,1,3,2,6,7,5,4,C,D,F,E,A,B,9,8,10,11,13,12,16,17,15,14,1C,1D,1F,1E,12,16,17,15,14 etc.) In this mode, the loop is 9 states long after the initial sequence.

THIS DATA SET IS A TRANSMIT CYCLE WITH TRANSMIT LOGIC DISABLED.
The logic analyzer is set up to store only if TXCKEN=1.
It is set to trigger on TXACTIVE.

When the transmit logic is DISABLED, the loop transmit control loop is as follows: (0,1,3,2,6,7,5,4,C,D,F,E,A,B,9,8,10,11,13,12,16,17,15,14,1C,1D,1F,12,16,17,15,14 etc.) In this mode, the loop is 8 states long after the initial sequence.

APPENDIX B
RECEIVE DATA SEQUENCES

APPENDIX B
RECEIVE DATA INPUT SEQUENCES

This file is collected to show the Monitor Threshold Logic operation (MTE). The input for all of these files is the standard 8 byte message ending in a"b1". The data is "0,1,2,3,4,5,6,b1". For this file, Receive Sync detection was disabled, the MTE threshold was "6" and the transmit logic was "enabled".

The output data in the loopback mode was 00180004050302416Odb15555555 to add 127.

The status data was "d1 7f 00", indicating the lack of a detected sync, a full 128 bytes of data in buffer No.1.

The logic analyzer was set to store data only if RXCK=1 OR STA=01.

This file is collected to show the Monitor Threshold Logic operation (MTE). The input for all of these files is the standard 8 byte message ending in a "b1". The data is "0,1,2,3,4,5,6,b1". For this file, Receive Sync detection was ENABLED, the MTE threshold was "6" and the transmit logic was "enabled".

The output data in the loopback mode was 00010203040506B1.

The status data was "82 87 00", indicating the good parity and 8 bytes of data in buffer No. 5.

The logic analyzer was set to store data only if RXCK=1 OR STA=01.

```
module DLCONT

This module will control the data bus latches for the
interface between the hardware and the 68020 and
controls the output of the address bus and other
miscellaneous functions. It also provides the multiplex
function required by the VME when swapping the data bit
position for even and odd bytes (bytes 0&2 are D8-D15 and
bytes 1&3 are D0-D7)

module AINCONT

This PAL controls the interrupt handshaking with the
68020. It receives the requests via INT0-2 from the
priority PAL. It accepts higher level interrupts until
the end of state 1. It then freezes at that vector address
until state 7 when it is reset. It furnishes the priority
PAL with IAK which resets the interrupt request.
The drawing of the state diagram is filename VINTER.FLO.

title INTERRUPT PRIORITY LOGIC -ATCINT- U18B
Leo J. Wapelhorst---FAA Tech Center-----7-7-90
   U18B device P22V10;

This Pal passes the interrupt requests on to the interrupt
control pal (aincont.abl). Transmit interrupts
(TINT) have priority over receive (RINT). The interrupt
requests are active high and remain set until the interrupt
is serviced. The vector request is an ACTIVE
LOW three bit field (IRQA,IRQB,IRQC). The outputs are also
active low (INT2,INT1,INT0). All interrupts are
cleared when a RESET is received. A separate vector is
generated for each block of addresses of receive data.

The following table shows the relationship between the
addresses and the vectors.

Mem group      Rx Mem Add     AD7-9   Int0-2   Pr Dat
  1        EF701080            02       02              D0(vector)
  2        EF701100            03       03              D1(vector)
  3        EF701180            04       04              D2(vector)

module INBYT

SRESET controls the logic of the ATC interface card. The
hardware is disabled until a write is made to address
EF700005. The hardware then remains enabled until a 'read'
to the same address which again resets all the hardware
until another write occurs.

module ACKLOG2

This module will generate the acknowledge signals required
to communicate with the 68020 system. This chip also
receives the interrupt requests from the transmit and
receive control logic and stores the fact that one in in
progress while it waits for the interrupt logic of U17 and
U18 to process the request. It resets the logic when an
IAK is received with the proper interrupt vector (VS0,1,2).

title RECEIVER BIT COUNTER  ATCINT-2 U43
Leo J. Wapelhorst---FAA Tech Center-----6-27-90

        U43 device P22V10;

This Pal contains the logic to control storage of receive
data in memory. When the consecutive zero threshold is
exceeded (MTE), incoming date is stored in Ram as it comes
in (every 8 bits). If sync is detected, the address
counter is reset and data is stored every 9 bits as parity
is not stored in memory for real data.

This is accomplished in the following manner: A state
controller is in the IDLE state until MTE occurs. When
this happens, the state controller goes around a loop as
follows:S2-S3-S4-S5-S6-S7-S8-S9-S2-S3 etc. Data is
written into Ram on S9. If sync occurs, the state
controller goes to state S1 and also loops back to S1
instead of S2 making the loop equal to nine clocks. Data
is still stored at state S9.

CLK,RXCKEN,RXSYNC,RXACTIVE,!RESET          pin 1,2,3,4,11;
MTE,STOPRX                                 pin 5,10;
LOADRX,LACT,RES                            pin 18,17,14;
QA,QB,QC,QD                                pin 20,21,22,23;

                                           reset,preset          node

title RECEIVE MEMORY ADDRESS CONTROL LOGIC -- ATCINT U49,50
Leo J. Wapelhorst---FAA Tech Center-----7-5-90
   U49,U50 device E0600;

This module contains the memory address control for the
receive data memory. It consists of a 7 bit counter for
the Lsb's and a 3 bit counter for the Msb's. The Msb
counter incrementers on a carry from the Lsb or NEXT from the
status control logic. When the STATUS signal occurs, the
Lsb's are loaded to the value corresponding to the status
word for the data group which is stored. The 2 Lsb's of
the 7 bit counter  and all three Msb's are loaded to 0
so that the status is written in to the base address of the
memory. When status is over the address lines are again
set to equal the counter value until incremented by the
status control logic.

title RECEIVE MEMORY ADDRESS COUNTER  -- ATCINT U53
Leo J. Wapelhorst---FAA Tech Center-----6-9-90
   U53,U54 device P22V10;

This module contains the Transmit Memory address counter.
It is a 9 bit counter which is preset with the # of words
to be transmitted. It produces an output when it reaches
zero.

title EXTERNAL CLOCK MONITOR LOGIC  -- ATCINT U60
Leo J. Wapelhorst---FAA Tech Center-----6-22-90
   U60 device P22V10;

Thia module checks for the presence of External Transmit
and receive clocks. This is done in the following manner.
Each occurrence of the internally generated ICLK causes a
1 to be shifted down a shift register. Each external
clock resets the shift register. If the 1 ever reaches
the third stage of the shift register, the output is high
signalling the absence of external clocks. This output is
written into the hardware status latch so that this fact
is accessible to the computer.

title TRANSMIT MEMORY ADDRESS COUNTER  -- ATCINT U61
Leo J. Wapelhorst---FAA Tech Center-----6-19-90
   U61 device P22V10;

This module contains the Transmit Memory address counter.
It is a 9 bit counter which is preset with the # of words
to be transmitted. It produces an output when it reaches
zero.
