PREFACE

This document was written to serve as an addendum to Master's Thesis project AFIT/GNE/ENP/91M-6, "High Altitude Neutral Particle Transport Using the Monte Carlo Simulation Code MCNP With Variable Density Atmosphere". The research and development for this thesis was provided by Captain David L. Monti, USAF. Assistance was provided by Lieutenant Commander Kirk A. Mathews, USN. This document was written to provide understanding and assistance to users who plan to implement additional modifications to MCNP.

This effort was part of an ongoing AFIT research project to improve accuracy, decrease run time, and improve overall Monte Carlo transport methods at AFIT. There were two primary goals of this thesis project. The first was to develop an accurate model describing the variation of air density with altitude and to incorporate it into a generalized version of the Monte Carlo code MCNP. The second goal was to perform radiation transport simulations using a point isotropic neutron-photon source and study the effects over long ranges.

This work was sponsored by the Air Force Weapons Laboratory; this AFIT technical report is intended to serve as a formal addendum to the actual thesis project. A primary goal in this report is to provide the sponsor and all future users of the modified MCNP code with detailed information regarding the additions and modifications made to MCNP, version 3B. We hope it provides the necessary documentation to assist in future work in this area.

ABSTRACT

MCNP version 3B was modified to incorporate a continuously variable density atmosphere. This was accomplished by representing the variation of air density as a function of altitude with a series of continuous piecewise exponential curves up to a maximum altitude of 1000 km. User-written subroutines and functions were written which incorporated these piecewise functions. These subroutines and functions were subsequently incorporated into a production version of MCNP. Several MCNP subroutines and files were modified in support of these modifications. This report discusses detailed information regarding the theoretical development of the variable density model, the user-written subroutines and functions, the modifications to MCNP subroutines and files, and other relevant information.

1 Introduction

MCNP version 3B [1] was modified to incorporate a continuously variable density atmosphere as part of a Master's Thesis project. This addendum is part of Master's Thesis AFIT/GNE/ENP/91M-6 [2], still unpublished at this writing. There were several reasons for incorporating these modifications. These include: 1) improving the accuracy of computed Monte Carlo density-dependent radiation transport results within the atmosphere, 2) decreasing the overall computer run time, 3) increasing the dimensions of the problem geometry, and 4) lessening the user overhead in preparing the input files. A full discussion on this topic can be found in Master's Thesis AFIT/GNE/ENP/91M-6 by David L. Monti.

There are several areas requiring further work on the modified MCNP code, some of which were discussed in Section VIII of AFIT/GNE/ENP/91M-6. This addendum was written to assist future users in performing additions and/or modifications to the modified MCNP version 3B code at the Air Force Institute of Technology (AFIT).

1.1 Background

The purpose of the thesis project was to perform Monte Carlo simulations of neutral particle transport with primary and secondary photon production as it applies to a point isotropic source within a variable density atmosphere. Specifically, the goal was to increase the accuracy of neutral particle transport calculations within the atmosphere by accurately representing the variability of air density with altitude. In previous studies of Monte Carlo radiation transport within the atmosphere, many discrete spatial cells were used to represent the change in air density as a function of altitude. This was accomplished by using a series of constant density regions, usually with a constant scale height factor. This proliferation of cells proved to be costly in terms of computer run time, especially for large dimension problems.

During this study, analytic representations for air density and mass integral which modelled the variation of air density with altitude were developed. The generalized Monte Carlo code MCNP, version 3B, was modified using the newly developed atmospheric model. The work included the development of user-written subroutines and functions as well as modification of MCNP subroutines and files.

1.2 Approach to Problem

The approach to the problem of developing a variable density atmosphere was based on a two-phase approach: 1) develop

analytic expressions to represent both the variation of air density with altitude and cumulative mass-integral with altitude, and 2) implement these analytic functions into MCNP via user-written subroutines and functions. It was also necessary to perform auxiliary modifications to MCNP files and subroutines in support of the variable density model.

2 Project Goals

The overall objectives of the thesis project were as follows:

1. Develop a working Monte Carlo simulation code (MCNP) that incorporates a continuously variable air density capability;
2. Improve the accuracy of density-dependent transport results over previous results;
3. Decrease computer run time relative to the unmodified Monte Carlo code, MCNP;
4. Increase the capability to run very large dimension problems;
5. Study the radiation effects from a high altitude burst over long ranges.

The overall objectives of this report are as follows:

1. Provide detailed information on the atmospheric density model;
2. Provide detailed information on the user-written subroutines and functions incorporated into MCNP;
3. Provide detailed information on MCNP files and subroutines modified in support of the variable density atmosphere.

3 Sequence of Presentation

Section 4 presents the relevant MCNP program flow. Section 5 provides the theoretical discussion behind the variable density representation of the atmosphere. Section 6 presents a detailed discussion of the user-written subroutines and functions integrated into MCNP as part of the modifications. Section 7 provides a detailed discussion of the affected MCNP subroutines. Section 8 presents some miscellaneous information concerning the MCNP code. Appendix A contains listings of the user-written subroutines and functions integrated into MCNP. Appendix B contains listings of the MCNP files and subroutines that were modified.

4 MCNP Program Flow

This section describes the relevant portions of MCNP program flow. Topics discussed include the program flow of Subroutines HSTORY and TRANSM, where most of the particle transport takes place.

4.1 Transport Program Flow

Particle transport in MCNP is controlled via the main transport overlay MCRUN. MCRUN calls subroutine TRNSPT to start particle histories via subroutine HSTORY.

4.1.1 Subroutine HSTORY

Subroutine HSTORY begins the particle history by starting a particle from the source via subroutine STARTP. All source parameters such as initial direction, weight, and energy are determined. Initial source parameters are next checked against user-supplied weight cut-offs and energy cut-offs and some summary information is incremented. Subroutine TALLY is called to score tally contributions during a particle history. If point detectors or ring detectors are being used, then subroutine TALLYD is called from TALLY to score contributions to detectors. If DXTRAN spheres are being used, then DXTRAN is called to score DXTRAN sphere contributions. The weight window variance reduction game is played if requested, and energy splitting or Russian roulette is performed if required.

Back in subroutine HSTORY, particle transport continues by calling TRACK to determine the intersection of the particle trajectory with each bounding surface of the cell. The distances to the nearest cell boundary, DLS, time cut-off, DTC, and DXTRAN sphere, DXL, are calculated. Cross sections for the cell are determined via subroutines ACETOT for neutrons and PHOTOT for photons. A macroscopic cross section, GPL, is calculated and then modified by the exponential transform in subroutine EXTRAN, if necessary. The distance to next collision, PMF, is determined by a random number sampling of a logarithmic distribution. Up to this point, no modifications were made to subroutine HSTORY.

The track length in the cell is determined by taking the minimum of the distance to collision, PMF, the distance to time cut-off, DTC, the distance to the nearest bounding surface, DLS, and the distance to a DXTRAN sphere, DXL. The particle will undergo a collision only if the distance to collision, PMF, is less than the distance to a surface crossing, DLS. Subroutine TALLY is called to increment any cell tallies if necessary and some summary information is incremented. The particle's position is also updated. The

energies and directions of the particles exiting a collision site are handled in subroutines ACECAS and ACEOS.

4.1.2 Subroutine TRANSM

Subroutine TRANSM is called from TALLYD to calculate the total transmission to the detector. Prior to calculating the transmission, subroutine DDEET is called to calculate the distance, DD, to the detector and TRACK is called to calculate the distance to the nearest intersecting surface, DLS.

Cross sections for the cell are determined via subroutines ACETOT for neutrons and PHOTOT for photons. Once the microscopic cross section in the cell has been determined, it is multiplied by the atom density in the cell to obtain the macroscopic cross section. The track length in the cell, D, is determined by taking the minimum of the distance to the nearest bounding surface, DLS, and the distance to the detector, DD. The number of mean free paths to the detector or nearest bounding surface, AMFP, is determined using the values of the macroscopic cross section in the cell, PLE, and the minimum distance to the detector or nearest bounding surface, D. Then the locations of the new cell and particle position are updated.

5 Theoretical Discussion of the Variable Density Atmosphere

This section presents a detailed theoretical discussion of the variable density atmosphere incorporated into MCNP, version 3B. This served as a basis for the development of user-written subroutines and functions which were subsequently incorporated into MCNP. Topics discussed include: definition of a reference density and calculation of important atmospheric transport parameters.

5.1 Reference Density

Modelling the variable density atmosphere involved defining a reference air density. In the unmodified version, MCNP computes density-dependent parameters using a discrete cell density defined in the input file. In the modified version, the variation of air density is continuous, and a constant density spatial mesh in the vertical direction is no longer needed, except for splitting/Russian roulette. Therefore, in the modified version of MCNP, the air density in each cell is redefined to be the mass density at sea-level, 1.225×10^{-3} g/cm³, regardless of the values read from the input file. All subsequent calculations of density-dependent parameters will now be calculated based on a sea-level homogeneous atmosphere. At this point, prior to computing the distance to collision or the transmission to the detector or nearest intersecting boundary, the MCNP calculations are intercepted.

The aforementioned parameters are then corrected for a variable density atmosphere.

Prior to running the MCRUN overlay, the main overlay IMCN is run to read the input file to obtain the necessary parameters used in defining the problem. Subroutine NEXTIT is called to process items from the input file, i.e., to store such parameters as material density and cell descriptions. Subroutine NEXTIT was modified for the purpose of redefining the density in each cell to be the density at sea-level.

5.2 Transport Parameters

In Monte Carlo transport calculations, there are two principle parameters that involve determining the optical path length between two points in space: 1) the sampled distance to collision and 2) the number of mean free paths to a detector or nearest intersecting boundary. Both parameters are closely related and depend strongly on the atmospheric density. Details of the calculation of each of these two important transport parameters is presented below.

5.2.1 Distance To Collision

The distance to collision, PMF, computed in HSTORY, is based on the microscopic cross section in the cell and the atom density in the cell, which was redefined in NEXTIT to be the air density at sea-level. This is given by

$$PLE - TOTM \cdot DEN(CELL) \quad (1)$$

where

PLE = macroscopic cross section in current cell [cm^{-1}]
TOTM = microscopic cross section in current cell for
either a neutron or photon reaction [barns/atom]
DEN(CELL) = atom density in current cell [atoms/barn-cm]

Since the distance to collision is a probability based on density, it is necessary to correct this value for a variable density atmosphere. Subroutine EQDIST, called from HSTORY, was written to calculate the corrected distance to collision based on values input from HSTORY, i.e., current particle altitude, z-direction cosine, and distance to collision based on a sea-level homogeneous atmosphere. Calculation of the required quantities used to determine the corrected distance to collision are explained below. See Figure 3, Section III, AFIT/GNE/ENP/91M-6, "Mass-Integral Scaling (MIS)" for the general coordinate geometry used in this analysis. The variable names referenced in the discussion below are the

variable names used in the non-MCNP (user-supplied) subroutines or functions.

The unmodified version of MCNP computes distances in units of distance, centimeters. However, the variable density atmospheric model computes distances in units of mass range, g/cm². Therefore, before correction for a variable density atmosphere can be made, it was first necessary to transform the MCNP-computed distance to collision, PMF (EDST in subroutine EQDIST), from units of centimeters to an equivalent mass range in units of g/cm² for a sea-level homogeneous atmosphere. This equivalent distance was then corrected for a variable density atmosphere using the MCNP modifications.

The mass-integral along the particle path in a homogeneous sea-level atmosphere is calculated using the following equation

$$MIPDH = 1.225 \times 10^{(-3)} EDIST \quad (2)$$

where

MIPDH = equivalent mass range along particle path in a sea-level homogeneous atmosphere [g/cm²]
 EDIST = distance to collision in a sea-level homogeneous atmosphere [cm]

This calculation is performed in function DMI.

The cumulative mass-integral, MICA, at the current particle altitude, Z₀, can be computed using Equation (3) below once the scale height region has been determined. This calculation is performed in function MASI.

$$MICA = MI(z_1) + \rho(z_1) S_1 \left[1 - \exp\left(-\frac{(z_0 - z_1)}{S_1}\right) \right] \quad (3)$$

where

MICA = mass-integral at current particle altitude [g/cm²]
 MI(z₁) = mass-integral at base altitude of ith region [g/cm²]
 ρ(z₁) = density at base altitude of ith region [g/cm³]
 z₀ = current particle altitude [cm]
 z₁ = base altitude of ith region [cm]

S_i = mass-integral scale height factor of i^{th} region
[cm]

$z_i \leq z_0 \leq z_{i+1}$

Though the collision altitude, ZC , is still unknown, the values of $MIPDH$, $MICA$, and the z -direction cosine, W_0 , can be used to determine the required cumulative mass-integral, $MICP$, at the collision altitude, ZC . $MICP$ is computed based on the known mass range to collision, $MIPDH$. This calculation is performed by calling function MIZ .

$$MICP = MICA + MIPDH * W_0 \quad (4)$$

where

$MICP$ = required mass-integral at collision altitude
[g/cm²]

$MICA$ = mass-integral at current particle altitude
[g/cm²]

$MIPDH$ = mass-integral along particle path to collision
in a sea-level homogeneous atmosphere [g/cm²]

W_0 = z -direction cosine

At this point, a check is made to compare the computed cumulative mass-integral at the collision altitude, $MICP$, with the mass-integral at infinity, $MIINF$, defined to be 1035.635131402448 g/cm², the cumulative mass-integral at the 990 km altitude limit. If $MICP$ is greater than $MIINF$, then Subroutine $EQDIST$ is exited and PMF is set to $HUGE$, a very large number used by $MCNP$, effectively eliminating any collisions along the current particle track. If $MICP$ is less than or equal to $MIINF$, then the collision altitude, ZC , is determined using the following expression

$$ZC = z_i - S_i \ln \left[1 + \frac{(MI(z_i) - MI(ZC))}{(\rho(z_i) S_i)} \right] \quad (5)$$

For cases where the z -direction cosine, W_0 , becomes very small (nearly co-altitude relative to the current particle position), the change in density is very small along the particle path. Therefore, the average density between the current altitude and the collision altitude is used. In this case, the difference between the current altitude and collision altitude is ≤ 10 meters. The air densities are calculated by calling function $DNTY$.

Finally, the distance to collision, PMF ($EDST$ in Subroutine

EQDIST), corrected for a variable density atmosphere, can be computed by calling function EQUIVDST. Function EQUIVDST accepts as inputs the collision altitude, ZC, the current particle altitude, Z0, the z-direction cosine, W0, the mass-integral along the particle direction in a homogeneous sea-level atmosphere, MIPDH, and the densities (calculated only if W0 is small). For cases where W0 is not small, the corrected distance to collision is given by Equation (6) below

$$EDST = \frac{(ZC - Z0)}{W0} \quad (6)$$

where

EDST = distance to collision corrected for a variable density atmosphere [cm]

For cases where W0 is small, the density is nearly constant along the particle path, hence the corrected distance to collision is given by

$$EDST = \frac{MIPDH}{[(DENCA + DENCP) / 2]} \quad (7)$$

where

DENCA = air density at current particle altitude [g/cm³]
DENCP = air density at collision altitude [g/cm³]

5.2.2 Mean Free Paths To Detector or Boundary

Contributions to a detector are made at every source or collision point by creating and transporting a pseudoparticle directly to the detector. The total transmission to the detector depends on several factors: 1) the exponential attenuation through the medium, 2) a probability density function for scatter toward the detector, 3) spherical divergence, which accounts for the solid angle effect, and 4) the particle weight.

The only one of the aforementioned parameters that depends on atmospheric density is the exponential attenuation term. The attenuation term represents the total attenuation of the radiation by the atmosphere along the particle path over a given number of mean free paths. The attenuation along the particle path to a detector is given by the following relation

$$A = \exp(-AMFP)$$

(8)

where

A = attenuation along the particle path

AMFP = number of mean free paths to the detector or
nearest intersecting boundary

At this point, MCNP computes the distance to the detector, DD, using subroutine DDEDET. MCNP next determines the minimum of the distances to the detector or the nearest intersecting boundary. MCNP now computes the macroscopic cross section in the cell, PLE, for a sea-level homogeneous atmosphere using Equation (1). It is necessary to correct the macroscopic cross section in the cell, PLE, for a variable density atmosphere using subroutine EQDIST. A flag is set prior to calling EQDIST in subroutine TRANSM to indicate the origin of the calling statement, either subroutine HSTORY or subroutine TRANSM. The value of the flag, either 0 or 1, will determine the specific calculations that are performed.

Prior to calling EQDIST, the reciprocal of the macroscopic cross section, XMFP = 1/PLE, is computed to give the mean free path in a sea-level homogeneous atmosphere (recall that MCNP first calculates all density-dependent parameters based on sea-level density in each cell). EQDIST is then called from subroutine TRANSM with the mean free path, XMFP, the current altitude, ZZZ, the z-direction cosine, WWW, the calculation flag, NINP, and the track length in the cell, D, as inputs.

In subroutine EQDIST, it is first necessary to transform the MCNP-computed minimum distance to the detector or nearest intersecting boundary, D, from units of centimeters to an equivalent mass range in units of g/cm² in a sea-level homogeneous atmosphere. This equivalent mass range is then used to correct the macroscopic cross section, PLE, for a variable density atmosphere.

In subroutine EQDIST, the altitude of the detector or nearest intersecting bounding surface is determined using the following equation

$$ZD = ZO + W0 \cdot DTD$$

(9)

where

ZD = altitude of detector or intersecting boundary [cm]
ZO = current particle altitude [cm]
WO = z-direction cosine
DTD = distance to detector or intersecting boundary [cm]

The mass-integral along the particle path in a homogeneous atmosphere, MIPDH, is next calculated using Equation (2). Function DMI performs this calculation.

Next, the cumulative mass-integral at the current particle altitude, MICA, and the cumulative mass-integral at the detector or intersecting boundary altitude, MIDA, is computed using Equation (3). This calculation is performed in function KASI.

The mass-integral along the particle path in a variable density atmosphere, MIPD, can now be determined using the following relation (for WO not too small)

$$MIPD = \frac{(MIDA - MICA)}{WO} \quad (10)$$

where

MIPD = mass-integral along the particle path in a variable density atmosphere [g/cm²]

For cases where the z-direction cosine, WO, becomes very small (nearly co-altitude relative to the current particle position), the average density between the current altitude and the collision altitude is used. In this case, the difference between the current altitude and collision altitude is ≤ 10 meters. The air densities are calculated by calling function DNTY. For small values of the z-direction cosine, WO, MIPD is computed using the following relation

$$MIPD = DTD * \left[\frac{(DENCA + DENCP)}{2} \right] \quad (11)$$

where

DTD = minimum distance to the detector or nearest intersecting boundary [cm]
DENCA = air density at current particle altitude [g/cm³]
DENCP = air density at collision altitude [g/cm³]

Recall that the minimum of the distances to the detector and nearest intersecting boundary, D , was first transformed into an equivalent mass range, $MIPDH$. The corrected mass range in a variable density atmosphere, $MIPD$, was then computed. It is now possible to correct the mean free path to the detector or nearest intersecting boundary, $EDST$, for a variable density atmosphere. This can be calculated using

$$EDST = \frac{(EDST * MIPDH)}{MIPD} \quad (12)$$

where

$EDST$ [LHS] = corrected mean free path [cm]
 $EDST$ [RHS] = uncorrected mean free path [cm]
 $MIPDH$ = mass range along particle path in a sea-level homogeneous atmosphere [g/cm^2]
 $MIPD$ = mass integral along particle path in a variable density atmosphere [g/cm^2]

Back in $TRANSM$, the corrected macroscopic cross section in the cell, PLE , is found by taking the reciprocal of the corrected mean free path, $EDST$ (defined as $XMFP$ in $MCNP$), where $EDST$ is given by Equation (12). Finally, the cumulative total number of mean free paths to the detector or nearest boundary over all cells traversed by the particle trajectory, is found from the following equation

$$AMFP = AMFP + PLE * D \quad (13)$$

where

$AMFP$ [LHS] = cumulative total number of mean free paths to the detector or nearest boundary along the particle path
 $AMFP$ [RHS] = number of mean free paths along the particle path in the current cell

$AMFP$ here is equal to $PLE * D$.

6 User-Written Subroutines and Functions

This section describes in detail the implementation of the variable density model developed in Section 5. This was accomplished by developing various user-written subroutines and functions and later integrating them into $MCNP$. The variables referenced in the discussion below refer to the variable names used in the user-written subroutines or

functions as opposed to the variable names used in the MCNP subroutines.

6.1 Data Blocks

There was only one data block defined as part of the MCNP modifications and is described below.

6.1.1 Data Block ATINIT

ATINIT is a user-defined data block which initializes the arrays containing parameters which define the variable density atmospheric model. The arrays are stored in a user-defined common block /ATCOM/. Common block /ATCOM/ is defined in the file CM.inc.

There are 5 arrays contained in data block ATINIT. The arrays SHFM and SHFD contain scale height factors [cm] for both mass-integral [g/cm^2] and density [g/cm^3] data, respectively. The array ZI contains the base altitude [cm] for each scale height region. The array DENI contains the reference density [g/cm^3] at each base altitude. The array AMII contains the cumulative mass-integral [g/cm^2] at each base altitude.

6.2 Functions

There were 6 user-written functions incorporated into the MCNP code. The function of each of these is explained below.

6.2.1 Function DNTY

This function calculates a density, DNTY [g/cm^3], given an input altitude, Z [cm]. Function DNTY is called from subroutine EQDIST. In order to compute a density based on the variable density atmospheric model, the array ZI containing base altitudes for each scale height region, the array DENI containing densities at each base altitude, and the array SHFD containing density scale height factors for the scale height regions are required. Function DNTY first determines the correct scale height region based on the input altitude, Z, by searching the base altitude array, ZI. The array indexing variable, k, is used to index the DENI and SHFD arrays to obtain the corresponding density and scale height factor for that scale height region. Function DNTY then computes the density at Z using the correct atmospheric model parameters.

6.2.2 Function MASI

This function calculates a mass-integral, MASI [g/cm^2], given an input altitude, Z [cm]. The computed mass-integral repre-

sents the cumulative mass-integral from ground level up to the input altitude, Z . Function MASI is called from subroutine EQDIST. In order to compute the cumulative mass-integral based on the variable density atmospheric model, the array ZI containing base altitudes for each scale height region, the array DENI containing densities at each base altitude, the array SHFM containing density scale height factors for the scale height regions, and the array AMII containing the cumulative mass-integrals for the base altitudes are required. Function MASI first determines the correct scale height region based on the input altitude, Z , by searching the base altitude array, ZI. The array indexing variable, k , is used to index the DENI, SHFM, and AMII arrays to obtain the corresponding density, scale height factor, and cumulative mass-integral for that scale height region. Function MASI then computes the density at Z using the correct atmospheric model parameters.

6.2.3 Function ZMAS

This function calculates an altitude, ZMAS [cm], given an input mass-integral, MI [g/cm^2]. The computed altitude represents the altitude necessary to achieve the given cumulative mass-integral. Function ZMAS is called from subroutine EQDIST. In order to compute the required altitude based on the variable density atmospheric model, the array ZI containing base altitudes for each scale height region, the array DENI containing densities at each base altitude, the array SHFM containing mass-integral scale height factors for the scale height regions, and the array AMII containing the cumulative mass-integrals for the base altitudes are required. Function ZMAS first determines the correct scale height region based on the input mass-integral, MI, by searching the array, AMII. The AMII array contains the cumulative mass-integral for the base altitudes of the scale height regions. The array indexing variable, k , is used to index the DENI, SHFM, and ZI arrays to obtain the corresponding density, scale height factor, and base altitude for that scale height region. Function ZMAS then computes the altitude using the correct atmospheric model parameters.

6.2.4 Function DMI

This function calculates a mass-integral, DMI [g/cm^2], between two points in a sea-level homogeneous atmosphere. The required input value is: 1) the distance to collision or mean free path to the boundary or detector [cm]. Function DMI is called from subroutine EQDIST. Function DMI computes the mass range along the particle path of known range in a sea-level homogeneous atmosphere. The mass density at sea-level is given by the U.S. Standard Atmosphere, 1976 [3], to be $1.225 \times 10^{-3} \text{ g}/\text{cm}^3$.

6.2.5 Function MIZ

This function calculates a mass-integral, MIZ [g/cm²], at the new particle altitude in a variable density atmosphere. The new particle altitude is not yet explicitly known. The required input values are: 1) the mass-integral at the current particle altitude, MIP [g/cm²], 2) the mass range along the particle path in a sea-level homogeneous atmosphere, DMI [g/cm²], and 3) the z-direction cosine, W. The z-direction cosine represents the cosine of the angle between the polar axis, Z, and the horizontal axis, Y. Function MIZ is called from subroutine EQDIST. Function MIZ computes the mass-integral required at the new particle altitude based on previously computed mass-integral values and the current z-direction cosine. The new particle altitude is computed subsequently.

6.2.6 Function EQUIVDST

This function calculates an equivalent distance to collision, EQUIVDST [cm], along the particle path which gives the same mass-integral as computed in a sea-level homogeneous atmosphere. The required input values are: 1) the current particle altitude, Z [cm], 2) the new particle altitude, ZN [cm], 3) the z-direction cosine, W, 4) the density at the current particle altitude, DCA [g/cm³], 5) the density at the new particle altitude, DCP [g/cm³], and 6) the mass range along the particle path in a sea-level homogeneous atmosphere, MIPD [g/cm²]. Function EQUIVDST is called from subroutine EQDIST. If the difference between the new altitude and the current altitude is less than 1000 cm (10 meters), then W is very small and the density changes very little along the particle path. In this case, the average of the densities at the new altitude and the current altitude are used in computing the new equivalent distance to collision, EQUIVDST. If the difference between the new altitude and the current altitude is greater or equal to 1000 cm (10 meters), then the difference in the altitudes divided by the direction cosine is used to compute EQUIVDST.

6.3 Subroutines

There was only one subroutine written to support the modifications built into MCNP. This subroutine used all the functions described above. This subroutine is described below.

6.3.1 Subroutine EQDIST

This subroutine is used to calculate one of two transport parameters, depending on the calling subroutine within MCNP. If the input value is the sampled distance to collision, PMF

[cm], from subroutine HSTORY, then subroutine EQDIST returns an equivalent distance to collision corrected for a variable density atmosphere, EDST [cm]. If the input value is the calculated mean free path, XMFP [cm], to the detector or nearest intersecting boundary from subroutine TRANSM, then subroutine EQDIST returns an equivalent mean free path corrected for a variable density atmosphere. If subroutine EQDIST is called from subroutine HSTORY, then the input values are: 1) the distance to collision, EDST [cm], 2) the current particle altitude, ZC [cm], 3) the z-direction cosine, WO, 4) the flag NINP. The flag NINP has either the value 0 or 1, indicating which calculations are to be performed. NINP has the value 0 if the calling subroutine is HSTORY, and hence the corrected distance to collision is required. NINP has the value 1 if the calling subroutine is TRANSM, and hence the corrected mean free path to the detector or nearest intersecting boundary is required.

Before any specific calculations are performed, subroutine EQDIST first defines the mass-integral at infinity, MIINF, to be 1035.635131402448 g/cm². This represents the cumulative mass-integral at the upper altitude of the atmospheric model, 990 km. Transport calculations are not performed above this altitude limit.

Next, the optimum array search parameters are determined based on the current particle location and direction. Either the upper half, the lower half or the entire array is searched. This decreases the table look-up time versus searching the entire array every time. The array search parameters are passed as input values to the six user-written functions described previously.

At this point, a test is performed to check the value of the flag NINP. Recall that a value of 0 indicates the calling subroutine is HSTORY, in which case the first set of calculations are performed. These calculations are primarily a set of calling statements to one or more of the user-written functions. Each subsequent line of code is well documented as to its function, and thus will not be repeated here. The theory behind each calculation is described in Section 5 of this addendum, and details of the functions performing these calculations are described above under the heading "Functions". It is important to note that before the new collision altitude, ZC [cm], is computed, a test is performed to ensure that the mass-integral required at the collision altitude, MICP, is within both the upper (MIINF) and lower (0.0 g/cm²) limits of the atmospheric model.

If this test is successful, the calculations continue. The new corrected distance to collision, EDST, is computed and returned to subroutine HSTORY. In subroutine HSTORY, PMF is

defined to be EDST. If the test fails, then the new corrected distance to collision, EDST [cm], is returned with the value -1. In subroutine HSTORY, EDST, with a value of -1, is defined as the variable PMF, and then PMF is set equal to HUGE, a very large number in MCNP. The particle is thus assumed to exit the problem, effectively eliminating any further particle interactions along the path.

If the flag has the value 1, then subroutine EQDIST is called from subroutine TRANSM. First, the detector altitude or altitude of the nearest intersecting boundary with the particle path is computed. The given input values of the direction cosine, WO, and the minimum distance to either the detector or the nearest intersecting boundary, DTD, are used. Each subsequent line of code is well documented as to its function, and thus will not be repeated here. The theory behind each calculation is described in Section 5 of this addendum, and details of the functions performing these calculations are described above under the heading "Functions". It is important to note that before any additional calculations are performed, a test is performed to ensure that the detector or boundary crossing altitude, ZD, is within both the upper (990 km) and lower (0.0 km) limits of the atmospheric model. If this test is successful, then calculations continue. If this test fails, then an error message is printed to the output listing. Calculations continue until a new, corrected mean free path, EDST [cm], is computed. EDST is based on the given input mean free path, EDST [cm], the mass range along the path in a sea-level homogeneous atmosphere, MIPDH [g/cm²], and the mass range in a variable density atmosphere, MIPD [g/cm²]. EDST is returned to subroutine TRANSM and defined to be XMFP, the variable used in subroutine TRANSM.

7 Modified MCNP Subroutines and Files

This section describes in detail the auxiliary modifications performed on various MCNP subroutines and files. The variables referenced in the discussion below refer to the variable names used in the MCNP subroutines or files as opposed to the variable names used in the user-written subroutines or functions.

7.1 Include Files

There were two include files that were modified, and these are discussed below.

7.1.1 Comdeck CM.inc

This include file serves as the main common block declaration file for all overlays used in MCNP. The following modifica-

tions to CM.inc were made:

1. line 2: the five arrays containing parameters for the atmospheric density model are dimensioned as double precision arrays.
2. line 37: common block /ATCOM/ is defined and contains the necessary arrays that store the various parameters defining the variable density atmospheric model.

7.1.2 Comdeck ZC.inc

This include file serves as an auxiliary comdeck file to comdeck CM.inc and defines processor-dependent constants and parameters and also dimensions general constants and I/O unit numbers. The following modifications to ZC.inc were made:

1. line 6: message defined to inform user that the variable density version of MCNP is being used.
2. line 7: error statement called from subroutine EQDIST.
3. line 25: two variables, NR1 and NR2, are defined and used to dimension the parameter arrays for the atmospheric model. NR1 is the number of atmospheric regions and NR2 is the number of scale height factors.

7.2 Subroutines

There were four subroutines that were modified, and these are discussed below.

7.2.1 Subroutine IMCN

This subroutine serves as the main overlay subroutine, and controls the input and sorting of the problem data. The following modifications to the IMCN overlay were made:

1. line 6: character BLNK defined and used in printing messages.
2. lines 112 thru 118: message printed to both the terminal and output listing informing the user that the variable density version of MCNP is being run.

7.2.2 Subroutine NEXTIT

This subroutine controls the processing of input items.

1. lines 34 thru 40: density in all cells redefined to be 1.225×10^{-3} g/cm³, the mass density of air at sea-level, regardless of input value.

7.2.3 Subroutine HSTORY

This subroutine performs the main transport calculations including the distance to collision, PMF. Starting on line 61, cross sections [barns/atom] for the cell are determined via subroutines ACETOT for neutrons and PHOTOT for photons. On line 75, a macroscopic cross section, QPL [cm^{-1}], is calculated. In the variable density version of MCNP, it is not recommended that the exponential transform be used until a full study is made of the effects to the macroscopic cross section. The mean free path, GS [cm] is next computed on line 81 by taking the reciprocal of the macroscopic cross section, QPL. Up to this point, no modifications had been made to subroutine HSTORY. The following modifications were made to subroutine HSTORY:

1. line 92: random sampling of the logarithmic distribution function slightly modified. The original calculation was as follows

$$qzridg\text{-}RANG() \quad (14)$$

$$PMF\text{-}\text{--}LOG(qzridg) * GS \quad (15)$$

The above calculations were modified as follows

$$qzridg\text{-}RANG() \quad (16)$$

$$qzridg1\text{-}\text{--}LOG(qzridg) \quad (17)$$

$$PMF\text{-}qzridg1 * GS \quad (18)$$

where

GS = mean free path [cm] based on the macroscopic cross section, QPL

PMF = distance to next collision [cm]

The purpose of this modification was to enable the recalculation of the mean free path, GS, and the macroscopic cross section, QPL. These values then serve as the effective values corrected for a variable density atmosphere. It is possible that these quantities are used elsewhere within MCNP, affecting quantities not directly related to transport quantities. A full investigation of this was not made due to

time constraints.

At this point, transport calculations were interrupted in order to correct the above quantities for a variable density atmosphere.

1. line 104: the flag NINP set equal to 0 indicating the calling subroutine is HSTORY.
2. line 105: subroutine EQDIST called to calculate the distance to next collision, PMF, corrected for a variable density atmosphere.
3. line 108: if PMF is returned with the value -1, then PMF is set equal to HUGE, a very large number used by MCNP. This effectively transports the particle out of the problem with no further collisions.
4. lines 111 thru 113: effective values of the mean free path, GS, the macroscopic cross section, GPL, and the macroscopic cross section, PLE, are recalculated. Since the exponential transform is not used in the variable density version of MCNP, there is no difference between GPL and PLE.

Transport calculations continue from this point with no further modifications.

7.2.4 Subroutine TRANSM

This subroutine calculates the transmission to the detector or nearest intersecting boundary when point detectors or ring detectors are used. Prior to calculating the transmission, subroutine DDEET is called to calculate the distance, DD, to the detector. On line 24, subroutine TRACK is called to calculate the distance to the nearest intersecting surface, DLS.

Cross sections for the cell are determined via subroutines ACETOT for neutrons and PHOTOT for photons on lines 30 and 31. Once the microscopic cross section [barns/atom] in the cell has been determined, it is multiplied by the atom density [atoms/barn-cm] in the cell to obtain the macroscopic cross section [cm^{-1}] on line 32. On line 34, the track length in the cell, D, is determined by taking the minimum of the distance to the nearest bounding surface, DLS, and the distance to the detector, DD.

Normally, the number of mean free paths to the detector or nearest intersecting boundary is computed by multiplying the track length in the cell, D, with the macroscopic cross section, PLE. At this point, normal calculations are interrupted in order to compute a new macroscopic cross section in

the cell corrected for a variable density atmosphere. The following modifications were made to subroutine TRANSM:

1. line 44: the flag NINP set equal to 1, indicating the calling subroutine is TRANSM;
2. line 45: the mean free path, XMFP [cm] is calculated by taking the reciprocal of the macroscopic cross section, PLE [cm^{-1}];
3. line 46: subroutine EQDIST is called in order to calculate a corrected mean free path, XMFP;
4. line 48: a new macroscopic cross section is determined by taking the reciprocal of the mean free path, XMFP, returned from subroutine EQDIST;
5. line 51: the corrected number of mean free paths along the track length to the detector or nearest intersecting boundary is computed using the corrected macroscopic cross section, PLE.

Calculations continue with no further modifications.

The number of mean free paths to the detector or nearest bounding surface, AMFP, is determined using the values of the macroscopic cross section in the cell, PLE, and the minimum distance to the detector or nearest bounding surface, D. The locations of the new cell and particle position are then updated.

8 Miscellaneous Information

This section presents some miscellaneous information which might be useful to future users of the modified MCNP code at AFIT. Topics discussed include: 1) the nature of the source spectra used, 2) the location of the MCNP files, and 3) comments concerning the applicability of the modified MCNP code.

8.1 Neutron-Photon Source

There were two source spectra provided with the SMAUG-II code [4]. The spectra included 37 neutron energy groups ranging from thermal energies to a maximum of 14.2 MeV and 21 photon groups ranging from 10^{-2} MeV to a maximum of 14 MeV. The neutron and photon spectrum energies and corresponding energy bin probabilities are listed in Appendix F in thesis AFIT-GNE/ENP/91M-6. The default spectra provided with the SMAUG-II code were used in the MCNP simulations to facilitate the comparisons between SMAUG-II and MCNP. Each Monte Carlo simulation was repeated three times so primary neutrons,

primary photons, and secondary photons could be generated. The source spectra were not classified, but rather generic, unclassified spectra provided with the computer code SMAUG-II.

8.2 Location of MCNP files

There are now two versions of the MCNP code version 3B at AFIT: 1) the unmodified version of MCNP and 2) the modified version of MCNP incorporating a variable density atmosphere. The location of the unmodified MCNP files and the executable program can be found on the ELXSI (GALAXY) computer at AFIT, i.e., under the following directory

/src/mcnp/Working

The location of the modified MCNP files and the executable program can be found under the following directory

/src/mcnp/Working1

The location of the cross section libraries can be found under

/src/mcnp/XCLib

Copies of both the unmodified and modified versions of MCNP were transferred to the TRITON SUN system at AFIT, in LCDR Kirk Mathews office (AFIT/ENP) under the /dculp and /dmonti directories, respectively. Once the capability to run MCNP on TRITON has been added, either MCNP version can be run. Copies of the cross section libraries were also transferred to TRITON.

The file transfer sequence to copy individual files from GALAXY to TRITON are given below

- login to userid on GALAXY
- go to directory containing applicable files
- ftp triton
- userid
- password
- cd to target directory on triton
- mput (multiple files) or put (1 file) filename
- close
- quit

If a large number of files needs to be transferred to TRITON, use the following sequence of commands

- login to userid on GALAXY
- go to directory containing applicable files

- ar r archive name *.* (archives all files in directory)
- repeat ftp sequence above to transfer the archive file to triton.

Once the archive file has been transferred, perform the following commands to retrieve the archived files

- logon to userid on triton
- go to applicable directory
- ar x archive name *.* (extracts all archived files)

8.3 Comments

8.3.1 Exponential Transform

Although modifications to incorporate a variable density atmosphere to MCNP were very successful, further work is required to investigate the effects of the exponential transform (not used thus far) on the macroscopic cross section. The exponential transform can be invoked in the HSTORY subroutine from the input file (see MCNP user's manual). Since discrete cells, for the purpose of representing the variation of air density with altitude, were not required, all transport density-dependent parameters within MCNP were first calculated based on sea-level air density. The parameters were then corrected for a variable density atmosphere. The full effects of invoking the exponential transform, which involves path length stretching, requires investigation before this feature can be used with confidence.

8.3.2 Other Density-Dependent Features

There are other density-dependent features used by MCNP which may require modification. These include: 1) fission heating, 2) dose-response relationships, 3) cell energy deposition, and 4) track mean free path. Fission heating (if this were somehow invoked in the atmosphere), cell energy deposition, and dose calculations all involve knowing either the air density and the density of some other material (if applicable) within the atmosphere. Modifications would be required to enable the user to use the variable density version of MCNP with more than one material. The track mean free path is printed to the output listing upon program completion. It is computed based on the average mean free path along all particle tracks within a cell. Again, fewer discrete cells are used in the modified MCNP code, and thus the track mean free path within a cell becomes meaningless. This will not affect final results; the track mean free path is used only as diagnostic information.

C  ATMOSPHERE.
C
C  VARIABLES USED IN THIS FUNCTION:
C
C      MIP - MASS INTEGRAL AT CURRENT PARTICLE ALTITUDE
C           IN A VARIABLE DENSITY ATMOSPHERE
C      DMI - MASS INTEGRAL ALONG PARTICLE DIRECTION IN A
C           HOMOGENEOUS SEA-LEVEL ATMOSPHERE
C      W   - Z-DIRECTION COSINE RELATIVE TO THE POLAR
C           ANGLE
C      MIZ - MASS INTEGRAL AT NEW ALTITUDE IN A
C           VARIABLE DENSITY ATMOSPHERE
*
*
C      DOUBLE PRECISION MIP,DMI,W,MIZ
C
C  CALCULATE MASS INTEGRAL AT NEW ALTITUDE.
C      MIZ = W*DMI + MIP
C      END
```

BLOCK DATA ATINIT

```
*
*
C  THIS DATA BLOCK IS USED TO SUPPORT THE VARIABLE
C  DENSITY ATMOSPHERIC MODEL.  INITIALIZE COMMON /ATMCOM/
C  WITH VALUES OF ATMOSPHERIC PARAMETERS.
*
*
C      include 'CM.inc'
*
*
C      SHFM - ARRAY CONTAINING MASS INTEGRAL SCALE HEIGHT
C           FACTORS
C      SHFD - ARRAY CONTAINING DENSITY SCALE HEIGHT FACTORS
C      ZI   - ARRAY CONTAINING BASE ALTITUDE OF VERTICAL
C           REGIONS
C      DENI - ARRAY CONTAINING DENSITY AT ZI
C      AMII - ARRAY CONTAINING MASS INTEGRAL AT ZI
*

13. ABSTRACT (Maximum 200 words) MCNP version 3B was modified to incorporate a continuously variable density atmosphere. This was accomplished by representing the variation of air density as a function of altitude with a series of continuous piecewise exponential curves up to a maximum altitude of 1000 km. User-written subroutines and functions were written which incorporated these piecewise functions. These subroutines and functions were subsequently incorporated into a production version of MCNP. Several MCNP subroutines and files were modified in support of these modifications. This report discusses detailed information regarding the theoretical development of the variable density model, the user-written subroutines and functions, the modifications to MCNP subroutines and files, and other relevant information.
