Abstract

In 1989 a DURIP grant for scientific equipment was awarded to the Department of Physics of the Michigan Technological University with Professor S. A. Marshall to be principal investigator. This grant, in the amount of \$135,000, was administered through the Office of Naval Research with Dr. Gabriel Roy the grant monitor. Its purpose was to modernize and up grade scientific equipment used by research oriented universities having DoD contracts. In addition, the funds for this grant were to be used to further the efforts of the Office of Naval Research contract No. N00014-89-J-1955 issued by the . The purpose of this contract was to establish a noninvasive experimental methodology for determining, (a) density, (b) velocity, and (c) vorticity of a flowing medium using the methods of electron paramagnetic resonance imaging. To develop this methodology, specialized equipment was purchased for the purpose of constructing a pulsed or time domain electron paramagnetic resonance spectrometer. Such a spectrometer is now in partial operation and work has begun on an up dated version. A total of \$144,533 has been expended on equipment for this spectrometer and its associated signal processing equipment. The excess \$9,533 supplied was made up by funds taken from the Office of Naval Research contract No. N00014-89-J-1966.

Discussion

The purpose of this research effort is to establish a methodology for determining certain dynamical parameters of a compressible fluid in motion. It is supported by the Office of Naval Research under contract No. N00014-89-J-1956. These dynamical flow parameters are: (a) density, (b) velocity, and (c) vorticity. It is intended that these three parameters be determined at sufficient number of fluid volume cells, voxels, to provide useful information on flow dynamics. These voxels are to be taken at points in planes perpendicular to the flow axis, tomes, with the tomes distributed contiguously along the flow direction. The widths of the tomes are to be determined by demands on the grain details of the flow characteristics.

At the present, one result of our experiments on the imaging of molecular oxygen under static fluid conditions is that a high quality image of gaseous molecular oxygen having a slice thickness of 0.1 millimeter or 100 micrometers can be obtained. However the cost in data accumulation time and computer image data processing time is of the order of eight or so hours, which is considerable. If image quality and cellular resolution requirements are relaxed we estimate that tome thickness and resolutions of the order of 1.0 millimeter can be achieved in a matter of a few hours. It should be mentioned that these preliminary results on spatial resolution and data accumulation time estimates are based upon our former use of frequency domain spectroscopy or CW spectroscopy.

The matter of spatial resolution is based upon the quality of gradient magnetic field coil design and coil performance. As of this report, our gradient magnetic field coils were designed for our former frequency domain spectrometer. More sophisticated gradient magnetic field coils are in the process of being designed and constructed. These new or smart coils would be used

along with our new time domain spectrometer. Smart gradient magnetic field coils are designed to produce highly uniform gradient magnetic fields over a significant region of the specimen volume and close to zero magnetic field over the same volume, that is, in much the same manner as a Helmholtz coil do but with greater efficiency.

Frequency domain spectroscopy generally requires data accumulation times of the order of several minutes for each back projection and as many as 180 to 360 back projections for per tome. Typically, our most efficient data taking procedures have taken as long as eight hours per tome with azimuthal angle increments of one to two degrees of arc. The principal bottleneck in this process of data accumulation is (a) that of reorienting the magnetic field direction so as to provide azimuthal angle increments and (b) that of scanning through the frequency or magnetic field domain of a resonance absorption line.

Many of these difficulties can be avoided through the use of time domain spectroscopy. Using this technique, spectral data can be obtained from either the Free Induction Decay signal, FID , or from the electron spin echo signal of an electron spin system. There is still a more compelling reason for going over to time domain spectroscopy and thereby abandoning frequency domain spectroscopy. The reason is that the ultimate goal of this project is to establish a methodology for determining flow parameters, these being, density, velocity, and vorticity. Frequency domain spectroscopy is basically a d.c. type measurement which necessarily means that time dependent phenomena are averaged out to yield time averages. As a consequence, although fluid density can be determined, neither the velocity nor vorticity can be determined by this technique. However, these two latter flow parameters can in principle be determined by electron spin echo spectroscopy. The details of how velocity and vorticity can be determined for a fluid in motion have been developed in a previous report submitted to O.N.R. contract

No. N00014-89-J-1966 .

Figure 1 is a schematic diagram of the electron spin echo spectrometer. The figure does not include a diagram of the gradient magnetic field coils required for the production of some images nor of the pulsed gradient field coils required to develop gradient magnetic fields required for determining flow field velocities and vorticities.

A replica of an electron spin echo taken at 77 K of the EPR signal generated by the free radical molecule ion CO_3^{3-} produced in gamma-irradiated single crystal calcium carbonate is presented in Figure 2a. This system was chosen because of the ease of producing the free induction decay signal as well as the electron spin echo signal. At this temperature, the CO_3^{3-} molecule ion has a resonance absorption line width which is of the order of 15 milligauss, its frequency equivalent being 45 kilo-Hertz. Figure 2a is a photograph of the electron spin echo signal taken from a digital oscilloscope. It provides a record of most of the temporal parameters used to produce the echo signal. In Figure 2b, the signal information captured by the digitizer is transferred to a desk-top computer. A graphics program then produces an x-y tracing of the signal captured by the digital oscilloscope.

Further work on the time domain electron spin echo spectrometer is currently in progress and will continue along the lines of producing a more flexible and versatile spectrometer tailored to the task of magnetic resonance imaging and capturing image information required to produce such three dimensional flow information as fluid density, and such stream distribution information as velocity and vorticity.

The principal investigator of this contract is deeply grateful to the Department of Defense and the Office of Naval Research for making this DURIP equipment grant possible. In particular, special thanks are directed to Dr. Gabriel Roy of the Office of Naval Research for having demonstrated confidence in the overall mission of the project and by complementing the

project's equipment allowance with this grant.

Further development involving the use of equipment procured by this DURIP grant for the purpose of establishing a noninvasive methodology for producing density, velocity, and vorticity information on the stream field of a fluid will be presented in a future progress report to be delivered to the Office of Naval Research for the parent O.N.R. contract No. N00014-89-J-1966 .

On the following pages an account is given of the expenditures committed to this O.N.R. contract by the DURIP funds.
