Abstract

Digital archiving of bioacoustic data provides both curatorial and scientific benefits. To realize these benefits, key system requirements must be satisfied. This report discusses these requirements, and describes the software tools developed by the WHOI bioacoustic laboratory to maintain and utilize an archive of digitized biological sounds. These tools are written in standard C code, and are designed to run on PC-compatible microcomputers. Both the usage and structure of these programs are described in relation to the SOUND database of marine animal sounds. These tools include software for analog-to-digital conversion, text header maintenance, data verification and interactive spectrographic review. Source code listings are supplied.

1 Introduction

Historically, bioacoustics laboratories have maintained libraries of field recordings and prints of spectrographic analyses. Well-organized catalogs for such collections permit routine retrieval of tapes or spectrograms in the inventory. With computer systems, digital technologies can be incrementally added to these collections. A more comprehensive review of potential digital applications suggests that fundamental reorganizations of bioacoustic programs are appropriate.

Bioacoustic studies are increasingly concerned with objective, quantitative analysis of sounds. Such results can be difficult to obtain using spectrographic prints. Many research topics require analysis of thousands of sounds; this would be virtually impossible without dramatic changes in techniques.

Many laboratories are now confronting the difficulty of maintaining or accurately reproducing aging analog tapes in their archives. With analog recording technologies, gradual degradation of the data cannot be avoided. Aging magnetic tape media and tape duplication introduce artifacts and corrupt the original recordings.

Digital technologies provide an immediate solution to the archiving problem. Entire tapes can be converted to digital format and stored on a variety of media. Although no medium is eternal, some optical storage technologies are more stable than magnetic tape. In addition, direct digital copies can be made with extremely low error rates, and such errors can be detected and removed.

Important benefits can be realized even if the entire inventory cannot be digitized. Sound sequences can be digitized and stored as they are analyzed

in the course of research. Re-analysis can proceed with the digitized copy. This minimizes the handling of analog tapes, reducing the risk of damage and degradation from repeated usage. Also, it should be much easier to retrieve an existing series of digitized sounds than to locate the tapes and queue the sounds for re-analysis. Digitized sound sequences also provide "voucher specimens" of the exact acoustic data used to reach scientific conclusions.

The accumulation of digitized sound sequences can provide new opportunities, by increasing the scope of research. For example, digitized sequences produced in the course of studying individual or species-specific repertoires can be combined later to examine the structure and function of these sounds in broader systematic or geographic contexts. To realize these opportunities, a laboratory must coordinate computer resources and solve a variety of data management problems. The value of thousands of digitized sounds is dramatically increased by a flexible means of organizing, selecting, and retrieving them based on associated biological and environmental data (e. g. species, geographic location, season, social context, individual identity, sex and age). We have achieved this capability with the SOUND databases and associated software tools (Watkins, Fristrup and Daher 1991). This report describes the philosophy and implementation of our developing a tool set for bioacoustic research.

2 System Overview

Our basic resource is a large analog tape library accumulated over more than 40 years. The reorganization of these recordings began with the development of a database to improve access to the materials. Each tape is now described in an entry in the SOUND database (Watkins, Fristrup and Daher 1991), which includes the geographic location, time, date, species present, social context, behavioral observations, and other relevant information. SOUND is currently maintained with INMAGIC software (Cambridge, MA). The structure of SOUND makes it a convenient starting point for new research projects. Database queries based on specific research needs can provide an immediate assessment of the available resources, as well as easing their retrieval. We can evaluate the research potential of our library for particular historical periods, geographic regions, phylogenetic groups, types of sounds, etc.

Given the capacity to select tapes of interest, the next need is a means of converting the acoustic data into digital form suitable for computer data processing. Two distinct applications can be identified. An investigator may need to browse tapes to extract particular sounds of interest. This requires a system that is continuously digitizing, and that can be interrupted by the operator to save the most recent portion of the signal. Alternatively, an investigator may wish to convert entire tape recordings into digital form. This latter application requires software that manages the rapid transfer of digital data from an analog-to-digital converter to a large mass storage device.

Before digitized acoustic data are accumulated and software tools are

developed, standard file formats need to be defined. The file format should incorporate a text field containing enough information to ensure proper identification even if external references are lost. The name and storage location of a file can be used to identify sound cuts, but the embedded information is more secure. Digitized sound sequences – or sound cuts – are of little use without a convenient means of searching for and retrieving data of interest. A second database is an obvious means of organizing sound cut information, and it can be closely related to the database catalog of tapes. Our sound cut database is called SOUNDNC (Watkins, Fristrup and Daher 1991).

Other requirements for maintaining collections of digital sound cuts are screening the acoustic data for errors in digitizing, cross-checking the text data embedded in each sound cut file against that file's record in the sound cut database, and automatic routines that manage the transfer of validated data to archival mass storage. These are tedious and time-consuming operations; efficient and reliable methods are critical.

A program for reviewing stored sound cuts and manipulating the data for further analysis is required. This should provide visual and aural presentations of the sounds as well as the ability to make simple measurements of signal features. Additionally, the program should be capable of exporting all or portions of a sound cut in convenient file formats for other analyses.

A coordinated system that meets all of these needs is described below. Each function, along with the structure and operation of the relevant software tools, is discussed.

3 Digital File Format

It is important that a bioacoustic collection standardize the format of their digitized sound files. To assure compatibility, we have adopted a header and file format based on the capabilities of a standard commercial analyzer, the Kay Elemetrics 5500 Digital Signal Processor (Pine Brook, N. J.). Their "5500" (KAY) format is used. It has a header of 512 bytes; the data follow in the form of 16 bit binary integers stored in 2's complement, low byte, high byte format.

The header is a mix of binary and ASCII data. The binary data, written by the Kay digitizing equipment, record sampling rate, number of bits of precision, and size of the sound cut. The text field is used for storage of arbitrary notes and information. In the header, we record a portion of the record from the SOUNDNC database that describes the data to unambiguously identify the source of the material and the digitizing process.

In the following description of the KAY file header, the bytes in the header are numbered from 1 to 512. Not all fields are listed.

25-26: ASCII '1' '2' -- number of bits/sample.

27- : ASCII, null-terminated string -- number of samples in the file.

65-71: ASCII, "5500SD" -- Kay 5500 "trademark".

121-122: binary integer -- exponent (base 10) for sample rate.

123-124: binary integer -- mantissa for sample rate.

151-512: ASCII text: we insert SOUNDNC record information

File names code the identity of the sound cut. The first two characters are the last two digits of the year the recording was made. The next three

characters are a tape number within the year; tapes are usually numbered sequentially as they are cataloged. The last three characters are the number of the digitized sound cut. Because more than 999 cuts may be extracted from a single tape, we use a 36-base numbering system for the cut number. This provides over 40000 unique cut names per tape. The digits are 0 – 9, followed by A – Z. Thus, the cut after 00Z is 010. The remainder of the file name (the MS-DOS file “type”) is .KAY. Thus, 8721101A.KAY is the 46th cut (#01A) from the 211th tape recorded in 1987. The first eight characters of the name also provide the unique identifier for the corresponding database record in SOUNDNC.

4 Analog-to-Digital Conversion

We satisfy the digitizing requirements of our research with two modes of analog-to-digital conversion. In the interactive mode, data are collected continuously into a ring buffer of random access memory (RAM), with the oldest data being overwritten by fresh samples as they are acquired. This cycling is interrupted by the operator when a signal of interest is complete, and the contents of the ring buffer (the digitized signal) are saved on a mass-storage device as a data file. In practice, we use real-time sound spectrographic processors for interactive data collection: the combination of aural and visual review of taped material promotes more effective signal review and identification. In addition, the interactive mode typically supports higher sampling rates because the data are stored in system RAM, which has much faster storage times. About a minute of sound can be stored at the highest sampling rates in our systems.

In the batch mode, an extended portion of a recording is continuously digitized into a large file, usually on a hard disk. These long data files are subsequently edited or processed automatically to extract signals of interest. Batch digitizing permits larger volumes of data to be acquired with reduced operator involvement. We routinely digitize tens of minutes of continuous sounds at a sampling rate of 80 kHz. Automatic techniques for detecting and characterizing signals are planned to further expand our data processing capacity (Frstrup and Watkins 1992, K. Christian pers. comm., J. Buck pers. comm.).

The Kay Elemetrics 5500 Digital Signal Processor (Pine Brook, N. J.) is a commercial interactive sound spectrograph used for displaying, selecting,

and digitizing sound cuts. The Kay can sample and display one or two channels. Its ring buffer has 8 megabytes of memory, which represents 51.2 seconds of data for a single channel at the highest sampling rate available (81960 Hz). Optional hardware and software permit portions of the data buffer to be downloaded into an ISA bus computer running MS-DOS. The file management software supplied by Kay places binary information (sample rate, sample precision (bits), data length) in a header that precedes the data. The operator can choose to insert notes into this header prior to downloading the signal data.

VOICE is a sound spectrograph developed at the Woods Hole Oceanographic Institution (Martin, Catipovic, Fristrup and Tyack 1990). VOICE consists of an ISA bus microcomputer running MS-DOS, augmented by analog interface and signal processing boards. Its ring buffer is limited to 320 kilobytes of memory, and the maximum sampling rate for gap-free data is about 30 kHz. At the maximum rate, the buffer holds the most recent five seconds of signal. Any portion of the ring buffer can be saved as a signal file. At present, VOICE does not support placing text in the header, but this function is supplied by other utilities described in Section 5.

CSTRM is a batch digitizing program that runs on an AT-compatible microcomputer augmented with analog interface hardware. At present, it is configured to work with the Canetics PC-DMA12 analog interface board. Key features of the PC-DMA12 are DMA circuitry for both A/D and D/A, 100 kHz maximum sampling rate, anti-alias filtering and programmable input amplifiers. CSTRM streams data to hard disk in the KAY format at sampling rates up to 83 kHz.

4.1 CSTRM: A Batch Digitizing System

By: Kurt Fristrup

System requirements: MS-DOS, ISA bus, Canetics PC-DMA12, or an equivalent A/D board (with modifications to the code), a hard disk system (fast and large capacity preferable).

Usage: `cstrm <dest> <# 64kbyte blocks> <sample rate in Hz>`

Before executing CSTRM, the operator should use a utility that eliminates disk fragmentation. This will minimize seek time required by the hard disk, and permit maximum throughput. The operator also must ensure that there is enough room for the samples requested. At present, CSTRM does not verify that enough disk space is available. We have found it convenient to dedicate a physical disk or logical partition for streamed data and move the data to another storage location after each session to clear the partition for subsequent use.

The command line arguments are the disk/directory destination (a standard DOS path description), the number of 64 kilobyte blocks (32 kilosamples), and the sample rate in Hz. We have digitized up to 190 megabytes of continuous sounds with CSTRM.

Code Description.

CSTRM utilizes subroutines adapted from those supplied by Canetics with their PC-DMA12 analog interface board. We extensively modified the function managing continuous acquisition and transfer to disk. This program is compiled using the COMPACT model of memory management (NEAR code branches, FAR data pointers) to specify memory allocation

functions that use far pointers. This is the only program we have developed that does not use the SMALL model (NEAR code branches and data pointers).

The first statement in `main()` calls `memreq()` to obtain a full 64kb page of memory, to serve as the buffer for the DMA data transfers. This function allocates 128kb of memory, and returns a pointer to the first byte (offset=0x0000) on the full page of memory embedded in this block. This is a bit wasteful of memory, but it does not limit the program's function.

The block of conditionals involving `argc` and `argv[ ]` access and test the command line arguments. The assignment statements referencing `sets` → initialize a data structure used by the routines controlling the analog interface board (AIB). The call to `init_board()` initializes control parameters in the AIB, and `kill_timer()` disables the AIB's timer device. This ensures that the board is quiescent prior to initiating data acquisition.

The subroutine `kfrdfile.cont()` performs the data acquisition. The initial section of the subroutine initializes several pointers that monitor DMA status, shift the data to 5500 format, and transfer the data to disk. The skeletal 5500 header is created and written before data acquisition is initiated.

The general strategy involves dedicating a 64 kilobyte page of memory as a DMA memory buffer, and setting the DMA controller to cyclically transfer data into this page. Thus, the DMA controller resets itself automatically when a full page of data has been acquired, and resumes transferring at the beginning of the page. The program follows the DMA controller's progress, transferring segments of data to disk when they are complete. When the page is divided into two segments, this strategy simplifies to a ping-pong

buffer system. We use 8 segments at present, which leaves 7/8ths of the buffer available to buffer data acquisition against transient delays during disk writes.

The logic of the acquisition/write loop is relatively simple. The high byte of the DMA pointer register is polled repeatedly, and all of the new data (up to the DMA pointer) are shifted right four bits to translate from Canetics integer format (most significant 12 bits used) to 5500 integer format (least significant 12 bits used). If the DMA pointer has passed the end of the current data segment, then these data are written to disk, and the pointers marking the current segment are updated to the next segment in the buffer. The last segment in the buffer is treated differently, because the DMA pointer register rolls back to zero when it increments past the last byte on the page. This mandates a slightly different test to determine when the last segment is full. This code also updates the page count variable, and terminates sampling when the page count equals the requested sample size.

Program termination is signalled by a brief sequence of audible tones generated by the computer's speaker. The program also prints a reminder that the DOS clock may need to be reset, as the timer tick interrupt is disabled during data acquisition.

A slightly faster, multichannel version of this program (CSCRM) has also been developed for acoustic localization. This version does not produce a KAY formatted file: data are streamed to disk in the native format of the (Canetics) PC-DMA12. This uses the most significant 12 bits of a 16 bit word to store each sample, while the KAY format uses the least significant 12 bits.

For multichannel recordings, the analog interface board interleaves data from the different channels into a single file. Accordingly, an additional program (DUMSPLIT) was developed to demultiplex the multichannel information in the composite file and to produce separate Kay files for each channel. In addition to separating the data, DUMSPLIT shifts the sampled values 4 bits to the right to convert from Canetics to Kay sample format.

5 Text Header Maintenance

The text portion of the file header identifies the source of the data and specifies the digitizing settings. This information should be complete enough to replicate the sound cut by re-digitizing the original recording. Headers need to be added to files made with digitizing instruments that do not place text into the header when digitized sounds are saved. Furthermore, changes in database structure or digitizing procedures may require altering the format of the text already in place for a large number of files. Therefore, a program that permits interactive modification of individual headers is needed, along with a second program that processes large groups of headers automatically.

HEADEDIT provides the interactive, file-by-file review and replacement of the header's text. MASSEDIT updates the headers of many files automatically, using the information from a formatted text file that can be imported to, or exported from, the SOUNDNC database (Watkins, Fristrup and Daher 1991, pp. 31-32).

5.1 HEADEDIT: Interactive Header Manipulation

By: Kurt Fristrup

System requirements: MS-DOS

Usage: `headedit <filename>`

HEADEDIT reads the header on the file, and displays three binary fields (sample rate, number of samples, number of bits per sample) and all of the text information. If the two letter codes for fields used in the text database

are recognized in the header, then the text is formatted to display each field separately. Otherwise, the text is displayed unformatted. If the information is correct, the file may be left unchanged.

If the text portion of the header is to be changed, type [Ctrl-n]. A prompt appears for the new text, which may be typed or "pasted" in using a program such as SIDEKICK PLUS (Borland International, Scotts Valley, CA.). When the text is complete, an [Esc] terminates the entry. HEADEDIT ignores more than the first 362 characters entered into the header.

The new header can then be accepted [Ctrl-y], retyped [Ctrl-n], or you can exit the program leaving the header unchanged [Esc]. Our use of Ctrl-y and Ctrl-n for yes or no stems from problems with pasting text using SIDEKICK PLUS: when we attempted to paste too much text into the header, a surplus character was sometimes interpreted as a reply to the prompt. If you type [Ctrl-y], the new header is inserted in the data file, and the program exits. If you type [Ctrl-n], the program cycles back and you are prompted for a new header. [Esc] aborts the program without changing the data file.

Code Description.

HEADEDIT opens the file named in the command line, and reads the first 512 bytes into a buffer. Integer pointers extract the mantissa and exponent of the sampling rate from binary fields in the header. The number of bits per sample and the number of data samples are stored as ASCII text and are extracted using character pointers. The text portion of the header (starting at byte 150) is searched for each of the two letter codes used in the SOUND database (e.g. RN). A pointer is assigned to reference each code

found in the header. If the RN (Record Number) field code is not found, the text is displayed verbatim. Otherwise, each field associated with a two letter code is displayed on a new line.

The input section takes text (from the keyboard or a text block from SIDEKICK PLUS) and places it into the header buffer. The character combination that marks the end of a line (carriage return, line feed) is translated to an underscore. This method marks the end of each line, yet allows most software packages to treat the text information as one continuous string.

The program terminates by saving the new header information, [Ctrl-y] or retaining the old header, [ESC].

5.2 MASSEDIT: Batch Substitution of File Headers

By: Kurt Frstrup

System requirements: MS-DOS

Usage: `massedit <textfilename> <disk:path\>`

With text and data stored in distinct locations, and many researchers contributing to the database, verifying the correspondence of text and data is a significant concern. Additionally, the format and contents of the text database may evolve with time, such that the information in the header becomes out of date. To address these concerns, we use the same text file to update both SOUND C and the sound cut headers; alternatively, we update the sound cut headers using a text file written from SOUND C. Thus, MASSEDIT accepts the SOUND C formatted text records and inserts portions of each record into the corresponding sound cut file.

To prepare for MASSEDIT, a text file must be created with the particular format expected by the SOUND C database program. In this format, fields within a record begin on a new line, starting with a two letter code that identifies the name of the field. Records are separated by a dollar sign symbol (\$) placed on a line by itself.

The first command line argument to MASSEDIT is the SOUND C text file name. The second, optional argument allows the operator to specify the storage location of the KAY files. If no location is specified, the default directory is used. As the program executes, screen messages indicate flawed text records or failure to locate a sound cut file corresponding to a text record.

Code Description.

MASSEDIT begins by retrieving the text file name from the command line argument list, and opens the file to prepare for reading records. MASSEDIT reads the text for a single record into a buffer (stopping on encountering an end of record dollar sign (\$)). The buffer is then searched for the letters RN (Record Number), and the eight character number is read. If the RN field is not successfully retrieved, an error is reported, and the first fifty characters of the record are displayed. The program proceeds to the next record without taking further action.

The eight character RN code, with the letters ".KAY" appended, corresponds to the name of the digital sound cut file referred to by the record. MASSEDIT prepends the `disk:path` information to the file name, and attempts to open the file. If MASSEDIT doesn't find, or cannot open the file, an error is reported. This flags the presence of a text record for which

no sound cut was found (perhaps from accidental erasure of the sound cut).

If the file is found, MASSEDIT inserts as much of the SOUND C text as the header will accommodate (362 characters). End of line characters are translated into underscore characters, to avoid a conflict in the KAY file management software. If the record contains fewer than 362 characters, the remainder of the text buffer is filled with spaces.

The program terminates when the last record has been read and it reaches the end of the text file.

6 Data Verification

Duplication of text and data files can involve large numbers of files and enormous volumes of data. Often, these files may exist on different machines, perhaps even machines that use different operating systems. To verify that all copies are identical, we have devised an automatic procedure based on two public domain utilities: CRC and DIF. Versions of these programs are available for many different machines. This procedure can be applied to any subset of the database, and on different machines in widely separated locations. We present here the sequence of instructions that is appropriate on MS-DOS machines; a similar sequence exists for most other machines.

```
for %c in (*.kay) do crc %c >> dirname.crc
```

```
sort <dirname.crc >dirname.srt
```

now copy the .srt files to a common machine, and execute

```
dif dirname1.srt dirname2.srt
```

The initial CRC command generates a single line in DIRNAME.CRC for each filename that satisfies the wildcard specification. In addition to the name and size of the file, a 32 bit CRC value (a common error checking code) is generated for each file. The sort command ensures that all file entries are in alphabetical order, and the DIF command will identify and print differences between the sorted files. This will find file omissions as well as virtually all forms of file corruption.

MASSEDIT will identify text records that have no corresponding sound cut file, and update the headers of all files that do match. It does not

detect sound cut files without a corresponding text record. It also does not check the validity of the digital data. To address these needs we developed KAYCHECK.

KAYCHECK scans the data to ensure that the signal was not clipped during digitizing. KAYCHECK also verifies the presence of a SOUND formatted text field, and checks some of the text values for consistency with the binary data in the header. KAYCHECK provides these checks on every KAY file in a specified directory, and it generates three MS-DOS batch files to assist in subsequent diagnosis of flawed files transfer of validated files, and removal of archival files from the working mass storage. On exiting, KAYCHECK displays the total number of files processed and the number of files with flaws. The batch files automate tedious, time-consuming tasks, and remove the possibility of faulty copy or delete operations due to errors in manually issuing these commands.

6.1 KAYCHECK: Header and Data Verification

By: Kurt Fristrup

System requirements: MS-DOS.

Usage: `kaycheck <diskdirectory> [c]`

The logical structure of KAYCHECK is relatively simple. Text output files (KCOPY.BAT, KDELETE.BAT, KDIAGNOS.BAT) are opened to receive commands for copying files that passed and diagnosing files that have faults.

Each KAY file (located by Turbo C's findnext() function) is opened and the header is loaded into a buffer. The record number (RN) code is compared with the file name. The sample rate (SR) field is compared with the binary

coded sample rate. The cut size (CS) field is compared with the quotient of the binary coded data length divided by the binary sample rate. If any of these comparisons detect an inconsistency, an error message is displayed on screen and a line is added to the KDIAGNOS file that will run HEADEDIT on this sound cut file to diagnose the problem.

The data in the file are screened for signal clipping that might have occurred during digitizing. At present, clipping is indicated when a binary data value falls below 1 or above 4094 (the maximum A/D sample number). If no evidence for clipping is found, the minimum and maximum sample values are checked to ensure that a sufficient fraction of the sampling dynamic range is used. If less than one-eighth of the dynamic range is used, an underflow message is reported, suggesting that the signal should be redigitized. In either case, a call to SIG (refer below) is inserted into the KDIAGNOS file, and a message is displayed on screen.

If all tests are passed, KAYCHECK creates an entry in the KCOPY batch file that will copy the data file to a new drive and directory and perform a binary file comparison of the copy with the original. KAYCHECK also places an entry in the KDELETE file to assist in the safe recovery of hard disk space after copying.

Code Description.

KAYCHECK begins by forming the wildcard file name using the first command line argument (`drive:directory`) and appending ".KAY". The three batch files (KCOPY, KDELETE, KDIAGNOS) are also opened and assigned to FILE variables. The Turbo C `findfirst()` function is used to locate the first file matching the wild card. These steps complete the

preparation for the principal program loop which follows.

The first statements in the loop increment the file count variable, open the KAY file and determine its length. The header material - the first 512 bytes - are read into a character array. The header material is checked for consistency by the function `headbad()`, which returns a non-zero code if an error is found. The non-zero code causes an appropriate screen message to be displayed and an entry is added to the KDIAGNOS batch file to run HEADEDIT on the KAY file.

If no header errors are found, the data are scanned (`datscan()`) for clipping or underflow (insufficient gain during digitizing). These errors are also indicated by a non-zero code value returned by `datscan()`; an appropriate screen message is displayed and a SIG entry is added to KDIAGNOS.

A counter is used to keep track of the number of files with problems, and when the program terminates, the total number of files scanned and the number with problems are reported.

7 Sound Cut Review

To review stored sound cut files, a flexible tool for browsing, editing and exporting digital acoustic data is required. In addition to providing a graphic representation of the signal, this program provides elementary signal measurement functions and the capability to edit and export acoustic data. The most challenging aspect of developing this utility has been the wide range of signal durations and amplitudes that it must handle. The graphic display should provide a reasonable presentation regardless of the particular structure of the signal.

We have developed a utility that can be used as an independent program (SIG) or in conjunction with the text database (R_SIG, a TSR "pop-up"). R_SIG allows immediate display and manipulation of the digitized signals from within the SOUND_C database program by swapping it out of memory and loading SIG into memory. Both versions provide reasonable spectrographic displays with the default settings, and can work with files of any size. Selected portions of signals can be expanded for more detailed display, or exported to ASCII or MATLAB (The Math Works) formatted files for additional analysis. With appropriate hardware, selected portions of the signal can also be played back for aural review.

7.1 SIG and R_SIG: Sonagram and Waveform Display Utilities

By: Kurt Fristrup and Terrance Howald

System Requirements: MS-DOS, ISA bus, numeric coprocessor, EGA or VGA video graphics system, Canetics PC-DMA12, or (with modifications

to the code) an equivalent D/A board with DMA capability, amplifier and speakers.

Usage: sig filename.KAY [dr] [aa] [e/v]

Usage: tsrint

 r_sig <drive:path\ >

 R_SIG is subsequently invoked by hitting Alt-Esc.

SIG is a program that produces spectrogram and waveform displays of acoustic data files. Additionally, portions of the data can be selected for more detailed display or exported into ASCII, MATLAB, or KAY format files. R_SIG is a terminate-stay-resident (TSR) program designed to work with the SOUND C database. When R_SIG is loaded, any file whose record is being reviewed in SOUND C can be displayed with SIG at the touch of a key. R_SIG loads a small (10 Kbytes) keyboard monitor into the main memory. When a hot-key sequence is detected, R_SIG saves the SOUND C environment to extended memory or hard disk and loads SIG into memory. The KAY file name is taken from the SOUND C screen by R_SIG, prepended with drive:path , and passed to SIG. When SIG is exited, R_SIG restores the SOUND C environment.

SIG can process long sequences (we have used it on 80 Mb of continuous data). When SIG is invoked, the screen clears and the program begins scanning the data to obtain scaling parameters for the waveform and spectral displays. Just prior to the actual display of the signal spectrogram, time and frequency lines are drawn, forming a grid on the screen. These labelled lines provide a convenient means of interpreting the spectrograph during the drawing of the display, which can take a minute or more for long files.

The grid is erased as the signal spectrogram is drawn. Cursors are used to pick out time and frequency information once the spectrogram display is complete.

The completed waveform and spectrogram displays include basic information regarding the data file. The top line contains the name of the file, the number of samples, the minimum and the maximum A/D conversion numbers, the sample frequency, the dynamic range, analysis attenuator values (the latter two scale the conversion of spectral power to color values) and the FFT size. At this stage, the commands tabled below can be used to position cursors or alter the display parameters. Four cursors are available to bracket features in the waveform and spectrogram display. These provide a means of scaling the image and measuring time or frequency intervals. They can also be used to focus on particular sound sequences by restricting the range of data displayed. This "zoom" function is implemented as a stack with five levels, so successive commands can be used to pick out local details and subsequently return to the more general display.

Other commands include toggling the spectrogram display on/off, toggling noise compensation on/off, adjusting dynamic range and analysis attenuator, saving a section of the data to a new file, listening to the data between the time cursors, changing the FFT size, and exiting the program. The format of an exported data file from SIG is determined by the extension specified for the name (.TEX, .MAT, or other). TEX files are saved in ASCII, MAT files are saved in MATLAB (MathWorks) format, and any other extension results in a KAY format.

COMMANDS FOR SIG

left, right arrow	move a time cursor left, right.
up, down arrow	move a frequency cursor up, down.
ctrl left, right arrow	move a time cursor 5x speed.
Home <keypad>	toggle front/back cursors.
PgDn <keypad>	zoom in to new display bound.
PgUp <keypad>	pop back to previous display bounds.
Alt-P	listen to data between time cursors.
Alt-F1	multiply playback rate by two.
Alt-F2	divide playback rate by two.
Ctrl PrtSc	export data between the cursors
Esc	exit the program!
Alt-F	toggle spectrogram display!
Alt-N	toggle noise compensation!
Alt-D	restore default parameters!
Alt-F5	multiply fft size by two!
Alt-F6	divide fft size by two!
Insert <keypad>	increase dynamic range by 3db!
Delete <keypad>	decrease dynamic range by 3db!
Ctrl-PageUp	increase analysis attenuator by 1db!
Ctrl-PageDn	decrease analysis attenuator by 1db!

! -- these commands are effective during screen draw

Code Description.

The code for SIG is split into several files, which are loosely organized by function. The core subroutines are in COMSIG.C, including `main()`. All routines related to FFT processing are in FFTFUNCS.C. All simple routines related to screen display are in PLOTUTLS.C. WHTIMIO.C contains a few input/output routines related to data access and error reporting. NDRAWVLN.C and DRAWHLN.C are graphics subroutines that utilize inline assembly code to maximize line drawing speed. NDRAWVLN.C is roughly ten times faster than the Turbo C library function.

`Main()` copies the first command line argument (the KAY file name) into a global string variable `filename`, sets global video constants and spectrogram scaling parameters, and passes control to `pstest()`. This structure reflects our adaptation of the previous generation TSR support routines from South Mountain Software (South Orange, N. J.). This required that for the program to be activated as a TSR, it had to be a subroutine. In that version, there was no `main()` in COMSIG.C, and the TSR subroutine used `pstest()`.

`Pstest()` switches the video screen to graphics mode, opens the KAY file to read the data, and initializes global variables in the FFTFUNCS.C file using functions provided for that purpose. The header is loaded and the sample rate is decoded from two integer fields. Next, `pstest()` calls `getscale()`, which selectively scans the file and determines appropriate scaling factors for the waveform and spectrogram displays.

`Getscale()` does not always read every data value in the file. Exceedingly long files are sampled at regular intervals, and the scaling factors are

estimated from these samples. `Getscale()` also estimates the background noise spectrum for the sound cut. The sampled data blocks are ranked by acoustic intensity, and those that fall between the fifth and tenth percentiles are used to form an average noise power spectrum. This spectrum can be used to adjust the spectrogram display such that the background noise is "whitened".

After scaling factors are determined, the screen display commences. `Lineplot()` performs the waveform and spectrogram display. If a keystroke is sensed while `lineplot()` is executing, the routine aborts and returns the keystroke code. This permits the adjustment of the scaling factors without having to wait for the screen display to complete.

When the graphics picture is complete, a brief header and footer are written to summarize the salient characteristics of the sound cut. Then, the program waits for a keystroke that would further adjust the scaling parameters, activate time or frequency cursors, zoom in on a selected portion of signal, or export a portion of the signal.

Any keystrokes that change the screen display (changing dynamic range or analysis attenuator, modifying FFT size, etc.) cause `getcurses()` to exit and pass control back to the principal program loop. The exit code is used to indicate which function has been requested. After the proper parameters have been changed, program control cycles back to `lineplot()`.

The organization of the graphics display is constrained by the specifications of the EGA and VGA graphics standards. There are 640 vertical lines in the display, so the portion of the file being displayed is divided into 640 equal segments. If there are fewer than 640 segments of 256 samples

each in the file (163840 samples), the envelope display is completed (no samples skipped during min/max search), and the spectrogram is based on a 256 sample segment. Because the spectrogram buffer includes more data than each waveform segment, the spectrogram will tend to lead the waveform display. In an extreme display of one sample per vertical line, features will appear in the spectrogram display nearly one-half screen ahead of the waveform display.

If there are more than 163840 samples in the file, data will be skipped in computing the waveform and spectrogram displays. The spectrogram display becomes the average of several subsegments within the data spanned by one vertical line, and the waveform is the range of sample values observed in those subsegments.

When noise compensation is enabled, the color scaling on screen is related to the noise floor for each frequency bin, but when this is disabled, all frequency bins are scaled using the same standard. The noise floor is established by averaging 64 power spectra formed from segments that fall between the fifth to tenth percentiles in observed rms values. In practice, noise compensation tends to bring out weak signals at higher frequencies.

The dynamic range parameter adjusts the range of values spanned by the fifteen colors used in the display. The analysis attenuator parameter determines the range of values placed in the same color bin as the loudest signal found. In a linear relationship between intensity (in dB) and color value, the dynamic range sets the slope of that relationship, and the analysis attenuator determines the offset.

The playback feature of SIG utilizes the D/A capabilities of the Canet-

ics PC-DMA12 board, or an equivalent analog interface system. The initial playback rate is set equal to the sample rate. The user may increase or decrease the playback rate from a minimum of 640 Hz up to a maximum of 81920 Hz. D/A playback is initiated by entering [Alt-P] to call the function `start_dac()`. Parameters passed to `start_dac()` are the first and last data points, the sampling rate, and a scaling factor for the sampling rate. This sound playback routine executes in a manner similar to CSTRM, with the exception that `start_dac()` performs D/A conversions instead of A/D conversions. `Start_dac()` was developed from routines distributed by Canetics (Pasadena, CA) with their PC-DMA12 analog interface board.

`Start_dac()` allocates a 64kb page of memory by calling `memreq()` and sets the data pointer to the first data point. The program then determines the number of samples, the user selected playback rate (sample rate times the scaling factor), and the number of 64kb pages to be converted. Next, the routine initializes the AIB and executes `wtfile_cont()` which controls the D/A process.

`Wtfile_cont()` examines the amount of sound data to be analyzed. If this amount is less than 65535 (64kb), then the data are read from the hard disk to memory, converted from the KAY integer format to the Canetics integer format, and sent via DMA to the AIB in 16kb blocks. If the last 16kb block is not complete, the remaining portion of the block is filled with the value of the last data point. The PC-DMA12 operation is halted after execution of the last block.

If the amount of data to be converted is greater than 64kb, then the first 64kb of the data is loaded into memory, and the conversion process is started.

After the memory pointer passes the first 16kb, the old data is overwritten by the next 16kb of data in the sound sequence. This process of sending a block to the AIB and then filling that block with new data continues until less than 16kb of remain. The last block is handled as described above, and the function terminates

The code for R_SIG consists of one file. Many of the functions used in `main()` are adapted from those provided by South Mountain Software (Pasadena, CA). The first code in `main()` checks to see if the switch "rel" is included in the command line. If the switch is included, the program attempts to remove R_SIG from memory. The program reports successful removal or failure to find R_SIG in memory. If the switch is not present, the program checks to see if R_SIG is already loaded or if a path to the data files is included in the command line. If there are no problems with the command line, `swap_tsr()` decides where to temporarily store the SOUND_C data. Then `init_tsr()` loads a small kernel of 10kb into the main memory.

This kernel monitors the keyboard for a hot-key sequence. When the key sequence [Alt-Esc] is detected, `run_sig()` is executed. This routine gets the name of the KAY file being examined in SOUND_C from the video memory and prepends "SIG" at the beginning of the string and ".KAY" at the end of the string. SOUND_C is then swapped out of memory and SIG filename.KAY is executed. Once SIG is exited, SOUND_C is swapped back into memory and the user can continue from the point where the hot-key sequence was entered.

8 Conclusions

The system that has been developed for curating and analyzing marine animal sounds from our SOUND databases has evolved over several years. These software tools have satisfied our needs remarkably well, and we anticipate that they could be useful to others for similar signal database management. Their functions are summarized as follows:

- Maintenance of a database catalog of field recording resources and their contents.
- Integration of resources for interactive and batch conversion of field recordings to digital form suitable for computer data processing.
- Adoption of a standard file format for digitized sound sequences that includes a text field for identification.
- Maintenance of a database catalog of the digital sound sequences and their contents.
- Creation and revision of text information attached to sound data files.
- Verification of the presence and consistency of text information in sound data files.
- Validation of the sound sequence data (no clipping, sufficient dynamic range).
- Coordination of means for finalizing the animal sound data, copying validated sound files, diagnosing flawed files, and removing files from working mass storage once they have been archived.

- Utilization of tools for reviewing sound data files, making simple measurements, and exporting all or portions of files in convenient formats for additional analysis.

The WHOI marine animal SOUND database system was developed before commercial database programs were available to store and manipulate arbitrary binary data in concert with text. Several programs now offer this capability, including the capacity to develop custom routines for displaying and manipulating the binary data. These programs would remove the necessity of coordinating a database catalog with separate archives of digitized sound sequences. However, they would not offer equivalent latitude in analytical procedures. A critical factor in evaluating such databases is the flexibility allowed for custom programming and the ease of developing such analytical routines.

The evolution of research requirements emphasizes the need for flexibility. The SOUND database was designed to encourage selection and retrieval of data files based on biological criteria. Our recent work has focussed on automatic characterization of marine animal sounds (Fristrup and Watkins 1992) requiring analysis and comparison of sounds from many species. This could have been accomplished by performing separate select and copy operations for data associated with each species, with distinct disk directories dedicated to each set of data. However, it was much easier to process all relevant sounds without prior sorting. We subsequently linked all of the numeric results to their respective SOUND entries, and used database queries to sort and summarize the results.

We discovered that INMAGIC software currently used by the SOUND databases was not flexible enough to conveniently support this kind of linkage between text information (which remains unchanged) and varying amounts of numeric information. Relational database programs (such as PARADOX, Borland International, Scotts Valley, CA) supply this flexibility by providing linkage between separate tables of information. The SOUND data was translated, therefore, into a PARADOX table that carried the biological information. The analytical results were tabulated separately, with a file name and the related numerical values constituting an entry. The SOUND record identifier and the file name field in the numerical tables provided the means of linking the tables. Categorical summaries were obtained by performing queries based on the SOUND information, and reporting linked numerical data specified by PARADOX.

It is not possible to foresee future research requirements, but extensive retooling can be avoided by sufficient scientific insight and effective data management. The time invested in acquiring and annotating the digital bioacoustic data will be well spent if the resulting system facilitates established protocols and fosters innovative research.

Acknowledgements

These software tools for acoustic database management have evolved to meet the needs of the bioacoustic research community at WHOI. Many key features were inspired by thoughtful suggestions from our colleagues. We particularly thank Peter Tyack and Laela Sayigh for their contributions, and Lisa Taylor for help with the manuscript.

The main source of funding for the marine animal SOUND database system has been the Office of Naval Research through a series of contracts and grants, including N00014-91-J-1445 from the Ocean Acoustics Program. Supplemental support for specific enhancements of the marine animal sound data have been provided by NOARL (Stennis Space Center, MI), and ORINCON/DARPA (NOSC, San Diego). Funding for particular analytic assessments of sound characters has been through TRICCSMA (NUSC, Newport) from NAVSEA, Contract Number N00140-90-D-1979.

9 Appendix: Source Code Listings

These listings represent “working code”; they are not necessarily free from bugs or structured in the most logical fashion. Continued development and modification are anticipated. Most of the code for these programs was developed using Turbo C++ (Borland International, Scotts Valley, CA); the exceptions are the 87FFT library (Microway, Kingston, MA) and some video graphics functions that were coded in assembly to increase screen drawing rates. We used standard C code to enhance portability (object-oriented extensions were not used). Compiler switches were set – for efficiency – to generate 80286 code, use a numeric coprocessor, and maximize register and jump optimizations.

/* This routine initializes the timer device on the PC-DMA, setting it up to generate trigger pulses spaced (spaces) microseconds apart. Note that the A/D's timer is operated in a different mode from that of the D/A. The D/A's timer is a straight divide by n counter producing triggering pulses every n microseconds. The A/D's timer, on the other hand, is triggered by the D/A's timer and functions as a programmable delay. It is used to produce a triggering pulse n microseconds after the D/A timer produces a pulse. This was intended to allow Input and Output conversions interleaved at a rate determined by the D/A's timer, and spaced (D/A to A/D period) by the A/D's timer. In order to use the A/D alone the programmer sets up the timers for interleaving but sets the D/A to be triggered by software control, effectively disabling it as far as the timers are concerned.

```

*/

REPORT DOCUMENTATION PAGE	1. REPORT NO. WHOI-92-11	2.	3. Recipient's Accession No.
4. Title and Subtitle Software Tools for Acoustic Database Management		5. Report Date January 1992	
		6.	
7. Author(s) Kurt M. Fristrup, Mary Ann Daher, Terrance J. Howald and William A. Watkins		8. Performing Organization Rept. No. WHOI-92-11	
9. Performing Organization Name and Address Woods Hole Oceanographic Institution Woods Hole, Massachusetts 02543		10. Project/Task/Work Unit No.	
		11. Contract(C) or Grant(G) No. (C) N00014-88-K-0273 (G)	
12. Sponsoring Organization Name and Address Office of Naval Research		13. Type of Report & Period Covered Technical Report	
		14.	
15. Supplementary Notes This report should be cited as: Woods Hole Oceanog. Inst. Tech. Rept., WHOI-92-11.			
16. Abstract (Limit: 200 words) Digital archiving of bioacoustic data provides both curatorial and scientific benefits. To realize these benefits, key system requirements must be satisfied. This report discusses these requirements, and describes the software tools developed by the WHOI bioacoustic laboratory to maintain and utilize an archive of digitized biological sounds. These tools are written in standard C code, and are designed to run on PC-compatible microcomputers. Both the usage and structure of these programs are described in relation to the SOUND database of marine animal sounds. These tools include software for analog-to-digital conversion, text header maintenance, data verification and interactive spectrographic review. Source code listings are supplied.			
17. Document Analysis a. Descriptors marine animal sounds database management digital animal sound cuts b. Identifiers/Open-Ended Terms c. COSATI Field/Group
