**AN ANALYSIS OF USSPACECOM'S SPACE SURVEILLANCE NETWORK
SENSOR TASKING METHODOLOGY**

THESIS

**Presented to the Faculty of the School of Engineering
of the Air Force Institute of Technology**

Air University

**In Partial Fulfillment of the
Requirements for the Degree of
Master of Science in Space Operations**

Jeff Mark Berger, B.S. Joseph Bruce Moles, B.S., M.S. David George Wilsey, B.S.

Captain, USAF

Captain, USA

Captain, USAF

December 1992

Approved for public release; distribution unlimited

THESIS APPROVAL

STUDENTS: Captain Jeff M. Berger, USAF
Captain Joseph B. Moles, USA
Captain David G. Wilsey, USAF

CLASS: GSO-92D

THESIS TITLE: An Analysis of USSPACECOM's Space Surveillance Network Sensor Tasking Methodology

DEFENSE DATE: November 24, 1992

COMMITTEE: NAME/DEPARTMENT

SIGNATURE

Advisor: Thomas S. Kelso, Lt Col, USAF
Asst Professor of Space Operations
Dept of Operational Sciences
School of Engineering

Thomas Sean Kelso

Co-Advisor: William E. Wiesel, Jr.
Professor of Astronautical Engineering
Dept of Aeronautics and Astronautics
School of Engineering

William E. Wiesel, Jr.

Acknowledgments

In performing this research, we have received help from many sources. We would like to thank our research advisor, LtCol Thomas S. Kelso for his continued patience and exhaustive assistance throughout our work. We would also like to thank our co-advisor, Dr. William E. Wiesel, for his help in the technical aspects of our research. Thanks are also due to Capt Gregory Bishop of the 1st Command and Control Squadron for information on NORAD operations provided during numerous telephone and personal interviews. Finally, CPT Moles would like to thank his wife Mary for her patience and support during the months of this research effort.

Jeff Mark Berger

Joseph Bruce Moles

David George Wilsey

 I. INTRODUCTION	 1-1
1.1 Background	1-1
1.2 Problem	1-2
1.3 Research Objective	1-2
1.4 Scope of Research	1-2
1.4.1 Analysis of the SSN.	1-3
1.4.2 Analysis of Earth Satellite Population.	1-3
1.4.3 Truth Model Development.	1-4
1.4.4 Differential Corrector Development.	1-4
1.4.5 Statistical Analysis.	1-4
1.5 Limitations of Research	1-4
 II. LITERATURE REVIEW	 2-1
2.1 Introduction	2-1
2.2 SSN Sensor Types and Characteristics	2-1
2.2.1 Radar Sensors.	2-1
2.2.2 Optical Sensors.	2-5
2.3 Space Surveillance Network Composition	2-6

	Page
2.3.1 Dedicated Sensors.	2-6
2.3.2 Collateral Sensors.	2-7
2.3.3 Contributing Sensors.	2-8
2.4 Space Surveillance Network Coverage and Limitations	2-10
2.5 Space Surveillance Network Sensor Accuracies	2-10
2.5.1 Radar Sensor Error.	2-10
2.5.2 Propagation Effects.	2-16
2.5.3 Optical Sensor Error.	2-20
2.5.4 Sensor Bias and Sigma.	2-23
2.6 Orbit Classifications	2-27
2.6.1 Informal Classes.	2-27
2.6.2 Gabbard Classes.	2-27
2.7 Sensor Tasking Methodology	2-31
2.7.1 Tasking Categories and Suffixes.	2-32
2.7.2 Near-Earth Sensor Tasking.	2-34
2.7.3 Deep-Space Sensor Tasking.	2-36
2.8 SSN Sensor Observation Processing Methodology	2-38
2.9 Observation Processing and Orbital Element Correction . . .	2-39
2.9.1 SSC Observation Processing.	2-39
2.9.2 Differential Correction: Batch and Sequential.	2-42
2.10 Summary of Past SSN Assessments	2-45
2.10.1 Space Surveillance Program Architecture Report. . .	2-45
2.10.2 Final Report of the Surveillance Command and Control Study.	2-46
III. THEORETICAL BACKGROUND	3-1
3.1 Element/Covariance Propagation	3-1
3.1.1 The State Solution.	3-1

	Page
3.1.2 The State-Transition Matrix.	3-7
3.2 Differential Correction	3-9
3.2.1 Least Squares Estimation.	3-9
3.2.2 Bayes Estimation Algorithm.	3-13
3.3 Numerical Calculation of the Observation Matrix.	3-14
3.4 Variance Reduction Techniques	3-15
3.4.1 Common Random Numbers (CRNs).	3-15
3.4.2 Antithetic Variates (AVs).	3-15
IV. METHODOLOGY	4-1
4.1 Analysis of Earth Satellite Population	4-1
4.1.1 Satellite Composition Analysis.	4-1
4.1.2 Perturbations Analysis.	4-2
4.1.3 Classification Scheme Development.	4-3
4.1.4 Representative Satellite Selection.	4-3
4.2 SGP Program Library	4-4
4.3 Truth Model	4-5
4.3.1 Model Development.	4-5
4.3.2 Model Execution.	4-7
4.3.3 Model Verification.	4-10
4.4 Differential Corrector	4-11
4.4.1 Model Development.	4-11
4.4.2 Model Execution.	4-19
4.4.3 Model Verification.	4-21
4.5 Statistical Analysis.	4-22
4.5.1 Observation Rate/Update Interval Selection.	4-22
4.5.2 Monte Carlo Analysis.	4-22
4.5.3 Variance Reduction.	4-24
4.5.4 Data Analysis.	4-25

	Page
V. ANALYSIS OF EARTH SATELLITE POPULATION	5-1
5.1 Satellite Composition Analysis	5-1
5.2 Perturbations Analysis	5-13
5.3 Classification Scheme Development	5-20
5.4 Representative Satellite Selection	5-25
5.5 Data Discrepancies	5-26
VI. ANALYSIS OF DIFFERENTIAL CORRECTOR MODEL	6-1
6.1 Analysis of Individual Satellite VMAGT Data.	6-1
6.1.1 Class 1-1-1 (NORAD Catalog Number 15141). . . .	6-2
6.1.2 Class 1-1-2 (NORAD Catalog Number 15259). . . .	6-3
6.1.3 Class 1-3-2 (NORAD Catalog Number 14199). . . .	6-4
6.1.4 Class 2-1-3 (NORAD Catalog Number 10293). . . .	6-5
6.1.5 Class 2-1-4 (NORAD Catalog Number 10393). . . .	6-5
6.1.6 Class 2-2-3 (NORAD Catalog Number 19859). . . .	6-6
6.1.7 Class 3 1 1 (NORAD Catalog Number 01996). . . .	6-7
6.1.8 Class 3 1 2 (NORAD Catalog Number 14443). . . .	6-8
6.1.9 Class 3 1 3 (NORAD Catalog Number 19643). . . .	6-9
6.1.10 Class 3 1 4 (NORAD Catalog Number 17429). . . .	6-9
6.1.11 Class 4 1 1 (NORAD Catalog Number 20355). . . .	6-10
6.1.12 Class 4 1 2 (NORAD Catalog Number 15584). . . .	6-11
6.2 Tuning the Differential Corrector	6-12
6.3 Differential Correction Model Performance	6-18
VII. CONCLUSIONS AND RECOMMENDATIONS	7-1
7.1 Conclusions	7-1
7.2 Follow-On Research Recommendations	7-2

Abstract

This study provides the basis for the development of a cost/benefit assessment model to determine the effects of alterations to the Space Surveillance Network (SSN) on orbital element (OE) set accuracy. It provides a review of current methods used by NORAD and the SSN to gather and process observations, an alternative to the current Gabbard classification method, and the development of a model to determine the effects of observation rate and correction interval on OE set accuracy. The proposed classification scheme is based on satellite J_2 perturbations. Specifically, classes were established based on mean motion, eccentricity, and inclination since J_2 perturbation effects are functions of only these elements. Model development began by creating representative sensor observations using a highly accurate orbital propagation model. These observations were compared to predicted observations generated using the NORAD Simplified General Perturbation (SGP4) model and differentially corrected using a Bayes, sequential estimation, algorithm. A 10-run Monte Carlo analysis was performed using this model on 12 satellites using 16 different observation rate/correction interval combinations. An ANOVA and confidence interval analysis of the results show that this model does demonstrate the differences in steady state position error based on varying observation rate and correction interval.

AN ANALYSIS OF USSPACECOM'S SPACE SURVEILLANCE NETWORK SENSOR TASKING METHODOLOGY

I. INTRODUCTION

I.1 Background

Following the launch of Sputnik I on 4 October 1957, the United States realized that it needed the capability to track and identify objects in earth orbit (7:12-10). Shortly thereafter, development began on a system of sensors to perform that mission. Today, it is the responsibility of the United States Space Command (USSPACECOM) Space Surveillance Center (SSC), at Cheyenne Mountain Air Force Base (CMAFB) in Colorado, to detect, track, identify, and catalog all objects in earth orbit (26:1) (23:39). To perform these tasks, the SSC requires accurate positional data on all of the objects in orbit. This data is provided by the 25 worldwide sensors of the Space Surveillance Network (SSN).

The sensors of the SSN continuously track approximately 6,000 man-made objects in earth orbit and gather metric (positional) data on them. The sensors send these observations (approximately 40,000 observations a day) to the SSC. The SSC uses this data to classify and identify all detected objects and maintain the orbital element (OE) sets on each of these objects (18:8). The OE sets are used to predict the position of any object at any time. These predictions have many important operational applications that include: collision avoidance, satellite decay and impact predictions, satellite maneuver identification, warning of a satellite passing over a specific geographic area, and warning of attack on US space assets (7:12-10, 12-11). Therefore, maintaining the accuracy of the OE sets used to make these predictions is essential.

Based on the current satellite growth rate, the SSC will be maintaining surveillance on about 10,000 objects by the year 2000 (17:588). Correspondingly, the number of observations on these objects received and processed by the SSC will also rise. Given this growth rate, the tracking limits of the SSN, and current computational limits, the capacity

of the SSC will eventually be reached. In order to maintain the required orbit prediction accuracy on this steadily increasing number of objects, new or upgraded sensors and computers will be required. However, in the future military budget climate, money for these upgrades may not be available. USSPACECOM may also find itself under pressure to shut down some of its older sensors that are deemed too expensive to operate.

1.2 Problem

The problem which USSPACECOM will eventually be faced with is how to maintain orbit prediction and OE set accuracy on an increasing number of objects while possibly having to (1) decrease the number of sensors, (2) decide where to place new sensors, and/or (3) decide which sensor(s) or computer system(s) to upgrade with limited available funding. In other words, how to operate the SSC and SSN as efficiently as possible with minimum resources (sensors and computer systems).

1.3 Research Objective

There are two objectives of this research. The first is to analyze USSPACECOM's current sensor tasking methodology, focusing on current operational procedures and methods of classifying the earth satellite population. The second is to develop and demonstrate a model from which you can determine the effects of observation rate and correction interval on the accuracy of an OE set. This research is intended to provide the basis for the development of a quantitative cost/benefit assessment model to allow USSPACECOM to assess the effects of alterations to the SSN on orbit prediction accuracies.

This research is being performed at the request of the 1st Command and Control Squadron at Cheyenne Mountain AFB, Colorado.

1.4 Scope of Research

This effort is divided into five specific areas of research and analysis. The first area will be an analysis of the SSN. The second area will be an analysis of the earth satellite population and USSPACECOM's current method of classifying satellites. The third area

will be the development of a highly accurate "truth" model used to produce simulated observations from the sensors of the SSN. The fourth area will be the development of a differential corrector (DC) used to correct satellite orbital elements based on a set of "truth" observations. The last area will be a statistical analysis of output from the differential corrector to estimate the position accuracy of various observation rate - correction interval combinations on a set of representative satellites.

1.4.1 Analysis of the SSN. The purpose of this analysis is to determine the methods currently used to task sensors of the SSN to gather observational data, and to update satellite orbital element sets. This data will establish a baseline for comparison with results from the dynamics model. In the performance of this analysis, the following specific questions will be examined:

- What are the locations and operational characteristics of SSN sensors?
- What are the capabilities of the SSN?
- How are the sensors of the SSN tasked and how was that method developed?
- How are the sensor observation data processed?
- What are the operational requirements for orbital element accuracy?
- How does the SSN classify the objects it tracks?
- How does USSPACECOM update orbital elements?
- How does atmospheric refraction affect SSN sensor observations?
- What are the error characteristics of the SSN sensors?

The answers to these questions, and the results of this analysis, will be presented in the Literature Review.

1.4.2 Analysis of Earth Satellite Population. In addition to understanding the current methods used to task sensors to gather observational data on earth satellites and to update satellite orbital elements, an understanding of the satellite orbital characteristics is essential. The purpose of analyzing the earth satellite population is to examine the orbital characteristics of satellites in earth orbit and select a representative sample for analysis.

1.4.3 Truth Model Development. The truth model is intended to produce highly accurate "truth" observations of earth orbiting satellites. These truth observations will simulate actual SSN sensor observations received by USSPACECOM and be used to correct OE sets.

1.4.4 Differential Corrector Development. The differential corrector model is intended to update satellite orbital elements based on simulated observations from the truth model and output the vector magnitude of the error between the "truth" position and the predicted, position for each observation. Since the results from this model will be compared to actual data from USSPACECOM, we will attempt to simulate methods used by USSPACECOM as closely as possible and model the composition and characteristics of the SSN as realistically as possible.

1.4.5 Statistical Analysis. A statistical analysis of the output from the differential corrector will be performed to determine the statistical mean and variance of the steady-state position error of a satellite based on a given observation rate and correction interval. These estimations can, in turn, be used to show the effect of observation rate and correction interval on the true position error of a satellite.

1.5 Limitations of Research

In performing this research, we will limit our analysis to only objects cataloged by NORAD as of 1 March 1990. Due to various problems encountered in transferring orbital element set data from USSPACECOM to AFIT, and time restrictions due to thesis submittal requirements, this set was the most current complete set of data available for analysis.

II. LITERATURE REVIEW

2.1 Introduction

This purpose of this chapter is to provide a review of literature and information pertinent to this research. The goal of the literature review is to lay the ground work for the research effort. The following subjects are covered in the review:

- SSN sensor types and characteristics.
- Composition of the SSN.
- SSN sensor locations, limits, and coverage areas.
- Error associated with SSN sensors.
- SSC satellite classification methodology.
- SSC sensor tasking methodology.
- SSN sensors observation processing methodology.
- SSC observation processing and orbital element correction methodology.
- Previous analyses of SSN capabilities.

2.2 SSN Sensor Types and Characteristics

The SSN uses two basic types of sensors: optical and radar sensors. Optical sensors measure the visible energy emitted or reflected by objects and are typically used to track deep-space objects.¹ Radar sensors measure high-frequency radio waves reflected by objects and are typically used to track both near-earth² and deep-space objects.

2.2.1 Radar Sensors. The development of radar has been called the greatest advance in the remote sensing of objects since the invention of the telescope in 1608 (1:1). The radar saw its first major use during World War II and the Battle of Britain. Since

¹Orbital period greater than or equal to 225 minutes (24:223).

²Orbital period less than 225 minutes (24:223).

that time, the basic principle of the system has not changed but the technology supporting the system has changed dramatically.

Regardless of the type of radar, all radars operate on the same general principle. A beam of electromagnetic energy is transmitted from an antenna toward a target. The physical characteristics of the target will determine if the energy is absorbed, reflected, or some combination of both. If any of the energy is reflected, the target itself becomes an antenna and re-emits the electromagnetic energy in all directions. The direction of the strongest reflection is typically in the direction of the radar transmitter.

In general, for a given observation, the total reflected energy received by the radar may be used to characterize the target in terms of detectability and measuring ability of the radar. The ability of a radar to detect and track a target can be shown to be a function of the average power of the transmitter, the time the target is illuminated by the radar beam, and the geometry of the radar-target situation (1:4).

An important defined quantity based on the geometry of a target is called radar cross section (RCS). RCS (σ) is defined as

$$\sigma = 4\pi \times \frac{\Psi_r}{\Psi_i} \quad (2.1)$$

where Ψ_r is defined as the reflected power per unit solid angle in the direction of the source, and Ψ_i is defined as the power per unit area of the transmitted signal (1:66, 110). The units for σ are generally m^2 or dBm^2 . If a target were to scatter the radiation uniformly, the RCS would be the area from which the power was extracted from the incident wave (1:66). If the target can be modeled as a sphere with constant area cross section from all viewing angles, the RCS may be modeled as a single value (1:80). The larger the value for RCS, the larger the quantity of reflected energy or target echo.

The echo returned by a simple point target will be an exact reproduction of the transmitted signal. However, the signal is shifted in time due to range delay, shifted in frequency by the Doppler shift due to the target's radial velocity, and shifted in amplitude due to the geometry of the radar and target situation (1:2-3). By analyzing these shifts in frequency, the range and velocity of the target may be determined.

2.2.1.1 Radar Functions. There are two basic functions carried out by a radar: search and detection (29:4). Search is the methodology used by the radar to look for targets within a specified field of view. Detection is the ability of the radar to identify a target in its field of view. These terms are independent of the type of radar being discussed. However, the method of employment varies for different types of radars.

For mechanical radars, the search methodology is based on a rotating antenna or rotating feedhorn. The assembly may be sending energy, receiving energy, or both. Another name for the rotating antenna is *mechanical tracker* and is the name most often used in the SSN. If the same antenna transmits and receives, the system is called a *mono-static* system. However, if separate antennas transmit and receive, the system is referred to as a *bi-static* system.

For a phased-array radar, the searching methodology is based on electronically changing the phase of the transmitted signal. The face of the radar is composed of groupings of electronically steerable antennas. The individual antennas emit phase-coherent radiation to emit a plane wave of radiation in the desired direction. However, since the phased-array radar is not limited to a direction normal to the antenna as the mechanical radar is, the search methodology varies greatly from the methodology of the mechanical tracker (29:8).

The search philosophy for each type of radar is different based on its strengths and limitations. However, both methods are based on the probability of a target being in a specific sector of observation. While a mechanical tracker may search in a circular pattern, the probability of detecting the target improves if the location of the target can be limited to a certain sector for search. In a similar manner, the phased-array develops an *a posteriori* probability of a target being in a certain cell of observed space. The search is then begun in the cell with the highest probability of containing a target (29:8).

Detection, the second function of a radar, is the process of determining the presence of a target in the presence of competing electromagnetic signals. These competing signals arise from many sources. The most common sources of these signals are background radiation, undesirable echo, or the radar receiver (1:1). The limiting precision (standard deviation) of angular measurements associated with target detection will be on the order of

one tenth of the half-power beamwidth for the targets which can be distinguished against their background radiation (1:54).

Assuming the radar search method locates and then detects the target, the electromagnetic energy may then be used to determine several characteristics of the target. The characteristics of interest are velocity, range, azimuth and elevation.

The time delay between the transmitted pulse and the corresponding received pulse will be an indication of the target range. This relationship may be expressed as:

$$\Delta t_r = \frac{2R}{c} \quad (2.2)$$

where c is the speed of light, Δt_r is the return delay time of the pulse, and R is the range (1:3).

The velocity of the target may be calculated from the shift of the center frequency of the radar pulse. The center frequency of the returned pulse will be shifted from the transmitted pulse, f_t , by:

$$f_t + f_d = f_t \frac{(c + v_r)}{(c - v_r)} \quad (2.3)$$

where f_d is the frequency of the Doppler shift, c is the velocity of light in a vacuum, and v_r is the radial velocity of the target (1:3).

The remaining characteristics are azimuth and elevation. With these additional pieces of information, the position of the target may be determined in detail. To determine azimuth and elevation, measurements are taken directly from the mechanical devices accomplishing the tracking (mechanical tracker) or from the electronics controlling the wave front (phased-array).

2.2.1.2 SSN Radar Sensors. There are three types of radar sensors in the SSN: mechanical radars, phased-array radars, and a radar interferometer. Mechanical radars are either fan type or steerable trackers. The fan-type radars are large fixed antennas with mechanically moving feeds which scan a swath of space a couple degrees above the

horizon. Primarily designed to detect incoming ballistic missiles, they can also detect orbiting objects as they pass through the radar's field of view (FOV) (26:6). Mechanical steerable tracking radars use dish-type antennas and can track only one object at a time. Most radars of this type are used to track deep-space objects.

Phased-array radars are the backbone of the SSN, providing over 60 percent of the observations sent to the SSC (17:585). They electronically steer the tracking beam by phasing the energy emitted from thousands of small transmitters. They are capable of directing the beam in many directions and switching targets in milliseconds. Thus, they can simultaneously track several hundred objects (17:585) (26:6).

The one radar interferometer in the SSN consists of three transmitters and six receivers, positioned roughly along the 33rd parallel between Georgia and California (23:40). Each transmitter and receiver is approximately 30 feet wide and 2 miles long. Together, they create, in effect, a radar fence 5,000 miles long and 15,000 miles high capable of detecting all satellites with an inclination greater than 33 degrees³ (17:585).

2.2.2 Optical Sensors. An optical sensor must also search for and detect a satellite crossing the sky to provide data to update orbital elements. As the sensor tracks satellites across the sky, changes in right ascension and declination are recorded. These changes in angles can be converted into orbital elements for the target satellite. The accuracy of the sensor in measuring these angles directly affects the accuracy of the orbital elements.

The basic requirements for an electro-optical tracking device are: sensor, positioning system, and a command and control system for the positioning system (6:70). More specifically, the system must comprise a sensor, gimbal, tracker, and gimbal control.

The sensor is composed of an electronic detector, optics, and associated electronics. The Ground-based Electro-Optical Deep-Space Surveillance (GEODSS) sensors are the primary optical sensors used by the SSN. GEODSS uses a low-light-level charge-coupled-device (CCD), computer analysis, and large telescopes to provide observational data to the SSC in real time (7:12-12).

³Approximately 85 percent of the current satellite population. See Figure 5.5.

The gimbal is a mounting device which stabilizes the sensor and provides control of the tracking motion. The tracker is an additional piece of equipment which identifies the target and keeps the sensor pointing at the target. The CCD is an electronic device which records the impact of photons on the sensor. The gimbal control is the motor, gears and electronics required to operate the gimbal (6:72-73).

2.3 Space Surveillance Network Composition

The Space Surveillance Network is a conglomerate of 25 ground-based radar and optical sensors used for space surveillance (23:42-43). The 25 sensors are of 19 different designs, with only seven of the 25 sensors being designed specifically for the SSN as tracking sensors (18:7) (23:39-43). The remaining 19 sensors were originally designed with other primary missions, such as ballistic missile warning, missile testing, or scientific research and development, and were adapted to the SSN because of their capabilities (23:39-43).

Because of inherent limitations, most of the sensors of the SSN are unable to track objects smaller than 10 cm in diameter (17:587). In addition to the 7,000 objects larger than 10 cm currently tracked, it is estimated that there are 48,000 to one million objects ranging in size from one cm to 10 cm in diameter. It is believed that objects less than one cm number into the billions (17:587) (23:39).

The sensors of the SSN are operationally divided into three categories based on which agency has operational control over the sensor and when the sensors provide support to the SSN. Those categories are: dedicated, collateral, and contributing sensors.

2.3.1 Dedicated Sensors. Dedicated sensors are those with a primary mission of space surveillance. There are seven dedicated sensors in the SSN with the majority of them being optical systems. The premier dedicated system is the GEODSS. GEODSS was designed to replace the Baker-Nunn camera system (7:12-12). There are four operational GEODSS sites (with one more planned) roughly spaced evenly around the globe to give complete coverage of all satellites in geosynchronous orbit (17:586). The operational sites are: Socorro, New Mexico; Taegu, South Korea; Maui, Hawaii; and Diego Garcia in the Indian Ocean (23:39).

The Maui Optical Tracking Identification Facility (MOTIF) is co-located with the GEODSS site at Maui. It is similar in capability to the GEODSS systems but also has an infrared detection capability (23:39). Both of these optical systems are limited to night observations in clear weather (23:39).

The radar at Eglin AFB, Florida is the only dedicated phased-array radar sensor in the SSN. It is also the only phased-array radar capable of tracking both near-earth and deep-space objects (23:39). The radar interferometer, or Naval Space Surveillance (NAVSPASUR) System, operated by the Navy, is also a dedicated sensor.

2.3.2 Collateral Sensors. Collateral sensors are those sensors operationally controlled by USSPACECOM with a primary mission other than space surveillance. They support the SSN when not performing their primary missions. There are ten collateral sensors in the SSN. They consist primarily of the phased-array radars ringing the Northern Hemisphere, watching for ballistic missile launches.

The PAVE PAWS system consists of four identical two-face phased-array radars with a primary mission of SLBM detection. Space surveillance is their secondary mission (23:40). The radars are located at: Cape Cod AFB, Massachusetts; Beale AFB, California; Robins AFB, Georgia; and Eldorado AFB, Texas. These radars track only near-earth objects (18:7).

The Ballistic Missile Early Warning System (BMEWS) consists of a mechanical fan radar at Clear AFB, Alaska, a two-faced phased-array radars at Thule AFB, Greenland and a three-face phased-array radar at Fylingdales Moor, United Kingdom. These radars have a primary mission of ICBM detection and a secondary mission of space surveillance (23:40). These radars track only near-earth objects (18:7).

The Perimeter Acquisition Radar Attack Characterization System (PARCS) is a phased-array radar located at Cavalier, North Dakota. It has a primary mission of SLBM detection and a secondary mission of space surveillance (23:40). It tracks only near-earth objects (18:7).

The last two collateral sensors are the COBRA DANE phased-array radar at Shemya AFB, Alaska, and the steerable mechanical-tracking radar at Pirinlik, Turkey. Both have

a primary mission of intelligence collection and a secondary mission of space surveillance (23:39). They both track only near-earth objects (18:7).

2.3.3 Contributing Sensors. Contributing sensors are those sensors not under direct USSPACECOM operation control, but which, by agreement, provide support to the SSN when not performing their primary mission. There are eight contributing sensors in the SSN.

The Air Force Maui Optical Station (AMOS) is a optical telescope system which performs scientific research and development tasks for Air Force Material Command. It is co-located with the MOTIF and GEODSS systems on Maui (23:40). It is used for tracking deep-space objects (18:7).

The steerable mechanical-tracking radars on Kaena Point in Hawaii, and Antigua and Ascension Islands in the Atlantic Ocean are used to support missile testing out of the Western and Eastern test ranges (23:40). These sensors all perform near-earth tracking (18:7).

The Advanced Research Projects Agency (ARPA) Lincoln Tracking and Identification Radar (ALTAIR) and the ARPA-Lincoln Coherent Observables Radar (ALCOR) on Kwajalein Atoll in the Pacific Ocean are operated by the Army in support of Army, Navy, and Air Force missile testing (23:40). ALTAIR performs deep-space tracking while ALCOR, performs near-earth tracking (18:7).

Finally, the Millstone and Haystack radars located on Millstone Hill in Massachusetts perform scientific research and development. They are operated by Lincoln Labs for the Massachusetts Institute of Technology (23:40). When supporting the SSN, they both perform deep-space tracking (18:7).

Table 2.1 provides a summary of sensor category, sensor type (phased-array radar, mechanical-tracking radar, radar interferometer, or optical sensor), and sensor mission (near-earth or deep-space).

Table 2.1. SSN Sensor Category, Type and Mission.

2.4 Space Surveillance Network Coverage and Limitations

To provide the best possible coverage of the space environment, USSPACECOM has attempted to locate the sensors around the earth based on mission requirements and limitations of the sensor. All collateral and contributing sensors were located in the areas best suited to support their primary missions. The GEODSS optical deep-space sensors were located as near the equator and as equally spaced about the earth as possible to provide optimal viewing geometry for all geostationary satellites.

Table 2.2 contains a summary of the various sensor locations. Table 2.3 contains a summary of the range, azimuth, and elevation limitations for the sensors. Figure 2.1 is a representation of the worldwide locations of SSN sensors.

2.5 Space Surveillance Network Sensor Accuracies

2.5.1 Radar Sensor Error. Error is the difference in the true position of the target and the position indicated by the radar. The purpose of error analysis is to provide a description of this error. This description will allow the magnitude of error to be estimated under any set of operating conditions. In general, the error will be a function of the time of measurement, the value of the quantity to be measured, and the environmental conditions present during the measurement (1:318).

For purposes of analysis, error is commonly divided into two components: systematic (bias) and random (noise). Systematic errors are characterized by their predictability and may be eliminated from the final measurement. If the error is the same for all possible observation conditions, a single number may be used to represent the error and then subtracted from the measurement. In general, the measured values will vary around a mean value (true bias) (1:318).

If the bias error is constant for extended lengths of time compared to the calibration and operation time of the system, then the error may be removed through calibration. If errors are introduced as a function of the measured quantity, then the speed at which this quantity varies will determine how much of the error appears as systematic and random error.

(Compiled from (35 3.12 to 3.28) and (14))

Figure 2.1. Worldwide SSN Sensor Locations.

This definition of systematic and random error implies there is no rigid dividing line between the two quantities. To break up the quantities, an arbitrary time must be chosen where a majority of error remains constant. The constant errors may then be classified as bias (systematic) and the rest accounted for as noise (random) (1:322).

A statistical description of errors allows the decomposition of the radar system into several independent components or elements. The components of error are then measured or calculated in a root-mean-square (RMS) process and added together to obtain an overall system error. The underlying assumption is the absence of correlation between the multiple elements. In practice, it has been found safe to ignore the correlation between multiple elements unless there is a clear physical link which would result in a common variation of two or more elements (1:324).

2.5.1.1 Noise. The principal source of noise in a radar system is thermal radiation. This radiation is received from the environment and is characterized as either internal or external to the system. External noise is defined as natural background radiation while internal noise is the interference created by the electrical components of the radar system. Additionally, noise may be created from the clutter of unwanted targets picked up by system side-lobe patterns (1:4-5).

As radars advanced, they obtained extended range and accuracy. As part of the development effort, several studies were performed to determine the effect of thermal noise. Using a Gaussian approximation of a pulsed beam shape, Swerling of RAND Corporation derived the following expressions for the limiting precision (standard deviation) on a constant amplitude target. Equation (2.4) is for $(S/N) \ll 1$ and Equation (2.5) is for $(S/N) \gg 1$.

$$\sigma_{min} = .58 \frac{\Theta}{(S/N)\sqrt{n}} \quad (2.4)$$

$$\sigma_{min} = .49 \frac{\Theta}{\sqrt{(S/N)n}} \quad (2.5)$$

where Θ is the half-power beamwidth, n is the number of pulses received between the half-power points on the one way pattern, and σ_{min} is the standard deviation (1:51).

2.5.1.2 Classification and Description of Errors. The list below characterizes sources of error in radar measurements. These errors may be seen in angle error, range error, or both. In general, the error is divided into electrical components, mechanical components, and environmental components:

- **Radar-Dependent Tracking Errors:** The bias components of the errors are mostly the result of boresight error, wind torque (in unshielded antennas), and servo unbalance and drift in moving antennas. The random component of this error comes from thermal noise and multipath effects, as well as the random portions of the bias elements (1:325-326).
- **Multipath Error:** The multipath effect comes from the reflection of the main lobe by the ground at low elevation angles. This error is reduced once the target rises more than one beamwidth above the horizon due to the relatively small beamwidths used for tracking applications. However, even very small signals will result in disturbing the null position of the tracking servo (1:327). Multipath is a major source of error in elevation measurements. The effect on azimuth is not as pronounced, but the effect on elevation is serious. Multiple reflections are most adverse when measurements are being taken as the target is near the horizon (1:55).
- **Antenna/Servo-Torque Error:** The analytical evaluation of this error requires extensive knowledge of the open-loop transfer function. The wind torque becomes greater as the size of an unshielded antenna increases (1:331-335).
- **Collimation and Drift Errors:** If the electrical system of the radar is stable, this error depends on the care exercised in calibration. Certain environmental factors contribute to this error and change too quickly to be removed by calibration. To conduct a complete review, the position of the axis must be determined as a function of: frequency of operation in the radar band, tuning of the system, phase or gain variations in the receivers, signal strength, and temperature or intensity of thermal radiation (1:335-339).

- **Radar-Dependent Translation Errors:** This refers to the translation of data into a usable form (1:339). These errors are most often the result of physical problems with the radar equipment.
- **Non-Radar Components:** These errors are mostly target dependent. They indicate the dependence of detection on the physical characteristics of the actual target. Additionally, atmospheric effects may be included in this category.

The sources of angle error are summarized in Table 2.4 and the sources of range error are summarized in Table 2.5. The components of range and angle error combine to give velocity error in the final solution.

Table 2.4. Classification and Description of Angle Errors.

Error	Bias	Noise
Radar-Dependent Tracking Error	-Boresight axis setting and drift -Torque due to wind/gravity -Servo unbalance and drift	-Thermal -Multipath -Servo -Torque -Deflection due to acceleration of antenna
Radar-Dependent Translation Errors	-Pedestal leveling -Azimuth alignment -Orthogonality of axis -Pedestal flex due to gravity or heating	-Bearing wobble -Data gear non-linearity and backlash -Data takeoff non-linearity and granularity -Pedestal deflection due to acceleration
Target-Dependent Tracking Error	-Dynamic lag	-Dynamic lag -Glint -Scintillation -Beacon modulation
Propagation Error	-Average tropospheric refraction -Average ionospheric refraction	-Variation in tropospheric refraction -Variation in ionospheric refraction

Compiled from (1:326)

2.5.2 Propagation Effects. The propagation of the electromagnetic signal is a problem for radar systems just as it is for communication systems. In fact, some state that the radar system is just an extension of a communication system (29:16). Because of the

Table 2.5. Classification and Description of Range Errors.

Error	Bias	Noise
Radar-Dependent Tracking Error	-Zero range setting -Range discriminator shift -Receiver delay	-Thermal -Multipath -Servo -Variation in receiver delay
Radar-Dependent Translation Error	-Range oscillator (velocity of light) -Data take-off zero setting	-Range resolver -Internal jitter -Data gearing -Data take-off -Range oscillator stability
Target-Dependent Tracking Error	-Dynamic lag -Beacon delay	-Dynamic lag -Glint -Scintillation -Beacon jitter
Propagation Error	-Average tropospheric refraction -Average ionospheric refraction	-Variation in tropospheric refraction -Variation in ionospheric refraction

Compiled from (1:373)

importance of the propagation process, the causes of error resulting from the process are further detailed below.

2.5.2.1 Attenuation. The basis of attenuation calculations in the troposphere are based on the original work of Van Vleck in 1947. The result of Van Vleck's analysis were equations which provided absorption per distance as a function of wavelength, pressure, temperature, and type of gas in the atmosphere (1:468).

The greatest attenuation is caused by clouds and rain due to the effects of water vapor and oxygen. For X-band radar (10,000 MHz), the attenuation may be as great as 1 dB per mile. However, for C-band (5000 MHz), the attenuation is only one-eighth as great (1:468). Studies by Millman in 1958 showed that radars operating above 100 MHz will not suffer attenuation greater than approximately 1 dB even under the worst conditions of ionospheric density (daytime values) (1:470-471).

An additional problem with water vapor and oxygen is the ability of the molecule to extract energy from the radar wave. Since atmospheric molecules are able to extract energy from a radar wave, they are also able to emit energy at radar frequencies. This

emission is received as noise in the radar receiver and is characterized by the temperature of the atmospheric molecule (1:473-474).

2.5.2.2 Surface Reflection. The effect of surface reflection has received much attention in the study of radar effects. The results of this work indicate a coefficient of polarization remains near unity for horizontal polarization for elevations near 0 degrees. For vertical polarization, the coefficient may vary significantly until the system reaches an elevation of 10 degrees. In general, there are no rules for determining an estimate of the reflection coefficient. A value of 0.3 is used in cases where no other information is available. The impact of reflection must be evaluated when the angle of incidence is below a minimum given by the following equation (1:475):

$$E_{min} = \frac{\sqrt{h_{ft}}}{4000} \text{ radians} \quad (2.6)$$

where h_{ft} is the altitude of the target in feet. For a satellite with an altitude of 200 kilometers, $E_{min} \approx 11^\circ$.

Another aspect of surface reflection is clutter. Clutter is any scattering element which interferes with radar system operation (1:95). The major impact of clutter is generated by the side-lobe pattern of the radar. This error is radar-design-dependent and based on the antenna construction and transmitted power.

2.5.2.3 Tropospheric Refraction. The effect of tropospheric refraction on radio communication paths is often referred to as the "4/3 earth's radius correction." Tropospheric refraction has the effect of increasing the line of sight path length beyond the geometrical limits. Early radar calculations used the same methodology with good results for objects below 50,000 feet. The current process relies on the exponential reference atmosphere described by the National Bureau of Standards (1:477-478).

The refractive index of air (for frequencies below approximately 20,000 mc) may be described by the Smith-Weintraub constants in the following equation:

$$N = (n - 1) \times 10^6 = \frac{77.6}{T} \left(P + \frac{4810p}{T} \right) \quad (2.7)$$

where T is the atmospheric temperature in degrees Kelvin, P is the total pressure of the atmosphere in millibars, p is the partial pressure of the water vapor component, n is the refractive index, and N is a scaled up value referred to as the "refractivity" (1:477-478). Refractivity of the atmosphere has been shown to vary by the time of the day and time of the year. Changes of 20 to 40 N units are common for diurnal cycles. This implies the refractivity of a single site may change by more than 100 N units over the course of a year (1:481-482).

The refraction of the troposphere causes an extra time delay in the transmission of the signal and an increase in the elevation angle measured by the antenna. The ray follows the path of "minimum delay" to get to the target and return. The errors in range and elevation have been found to be proportional to the refractivity along the measurement path of the ray (1:479).

The National Bureau of Standards describes a way to calculate the total bending of a ray based on the equation below:

$$\Delta E_t = E_o - E_e = (bN_s + a) \times 10^{-6} \text{ radians} \quad (2.8)$$

where E_o is the angle that the ray arrives at the earth, E_e is the angle the ray would have arrived at had there been no atmosphere, and ΔE_t represents the total bending of the ray. The values b and a are functions of the elevation angle E_o . For an elevation above 5° , b is approximately the cotangent of E_o and a is approximately 0. Therefore (1:479-481):

$$\Delta E_t \approx N_s \cot E_o \times 10^{-6} \text{ radians} \quad (2.9)$$

The temporal fluctuations in the range, elevation, and azimuth of the target are caused by variation in the troposphere drifting through the beam of the radar. These errors are in addition to the regular bias errors caused by the stratified nature of the

atmosphere. Based on the work of Muchmore and Wheeler, the standard deviation of the range (σ_r) and angle (σ_a) measurements may be calculated from:

$$\sigma_r = \sqrt{2l_o L \Delta \bar{N}^2} \times 10^{-6} \text{radians} \quad (2.10)$$

$$\sigma_a = \sqrt{\Delta \bar{N}^2 L / l_o} \times 2 \times 10^{-6} \text{radians} \quad (2.11)$$

In these equations, l_o is the scale length of the tropospheric anomalies causing the fluctuation, L is the path length containing the anomalies, and $\Delta \bar{N}^2$ is the mean square refractivity variation of the anomalies (1:485-486).

2.5.2.4 Ionospheric Refraction. The effects of the ionosphere must be taken into account for targets over 60 to 70 miles above the surface. The refraction effects are all dependent on the operating frequency of the system and vary directly with the square of the wavelength (1:490).

The refractivity of the ionosphere may be written as a function of the radar frequency:

$$N_i = (n - 1) \times 10^6 = \sqrt{\frac{N_e e^2}{\epsilon_o m \omega^2}} \times 10^6 \cong \frac{1}{2} \frac{N_e e^2}{\epsilon_o m \omega^2} \quad (2.12)$$

where N_e is the electron density per m^3 , e is the charge of the electron, m is the electron mass, ω is the frequency, and ϵ_o is the permittivity of free space. If you insert the values for the known constants, this equation reduces to:

$$N_i \cong 40 \left(\frac{N_e}{f^2} \right) = \frac{1}{2} \left(\frac{f_c}{f} \right)^2 \quad (2.13)$$

where f is the frequency of the radar and $f_c = 9\sqrt{N_e}$ is the critical frequency of the medium (1:491).

2.5.3 Optical Sensor Error. Like the radar sensor, the function of an optical sensor is to acquire the target, and track it. Again, like the radar, the physical limits of the optical system impact its ability to acquire, track, and point.

For optical systems, tracking is the movement of the instrument line of sight to follow the movement of the target. Pointing is the average direction of the instrument line of sight. Therefore, tracking error is a time-varying component which measures the difference in how the sensor should follow the target and how it actually follows the target. Pointing error is the static component which measures the difference in where the instrument should be pointing versus where it is pointing. To obtain a total error, these components of error are averaged over the dwell time of the track⁴ (32:40).

2.5.3.1 Acquisition Error. The acquisition performance of the sensor system is aided by the appropriate design of the CCD and lens subsystems. The target may be detected as long as its image occupies one or more picture elements (pixels) of the CCD. However, this assumes the CCD is flawless. Inoperable pixels may result in the target being missed or detected too late to accurately track (32:44). The missed or late target track will severely corrupt the data for orbit element determination.

The other general sources of acquisition error are air turbulence, visual magnitude of the target, and background radiation. The turbulence of the atmosphere degrades the sensor ability to acquire the target. Turbulence increases the effects of refraction and introduces deviations to the azimuth and elevation measurements of the target. Visible magnitude is the apparent brightness of the target. If the target is not bright enough to register on the CCD, a missed or late target error may occur. Background radiation also impacts target magnitude. If the background is brighter than the target, the target will "wash out" and not be visible (32:45).

A general factor of all electronic equipment is the emission of random thermal noise. Thermal noise is the generation of electrons due to the temperature of the equipment. For a CCD, these extra electrons will be translated into false images for very brief periods of time. It is possible to eliminate this random error by observing the target for long periods of time. However, the time available for tracking may not be sufficient if you are attempting to observe a low-earth satellite passing quickly through the field of view (32:47).

⁴The required observation time necessary for the mission.

2.5.3.2 Tracking Error. Tracking is the stabilization of the line of sight of the system while following the target. Tracking is measured by a separate sensor which detects the difference in the sensor boresight and the sensor line-of-sight. For precise tracking, the allowable error is measured against predetermined object size. If the target passes through the allowable range of the predetermined size, the tracking mechanism moves the sensor to place the target into an optimal position. The measure of this motion is called response time. Response time is based on the acceleration rate and constant velocity ability of the sensor (32:50).

Gimbals provide the support, stability, and movement for the optical sensor. Gimbal performance may be evaluated from four areas: angular range, balance, stiffness, and bearing size. Angular range refers to the azimuth (compass) motion and elevation (measured from horizon to zenith) motion of the gimbal. The desired azimuth range is 360 degrees, but 270 degrees is acceptable for most tracking applications. Elevation should cover the full range of 0 to 90 degrees. The gimbal should have its mass equally distributed to provide stability. The stiffness and bearing size are design variables which depend on the overall system requirements (4:116).

In general, the tracking errors are independent of the gimbal size. However, smaller systems are quicker and easier to control and are more capable of rejecting undesirable disturbances. On the other hand, large systems are harder to disturb. Other errors may be limited by spreading the image over two or more pixels. This would reduce the movement of the system. However, the size of the image is limited by the physical characteristics of the optics and the range to the target. For most satellite tracking applications, a satellite's dimensions are very small in comparison to the altitude. Therefore the size of the image may not cover multiple pixels.

Various disturbance errors such as wind, seismic forces, gyroscope noise, and electronic noise have all been measured or computed. They may be factored into the calculations for position and subtracted to obtain the final answer. The typical tracking error for advanced telescopes is a standard deviation of less than 500 nanoradians (32:53). Tracking rate is the velocity the sensor must swivel to follow the target. The faster the target moves, the sooner the target leaves the sensor field of view. The major causes of error

in this component are the forces acting on the gear and drive mechanism in the gimbal. These forces are defined as friction, coulomb, and viscous.

The friction force (sometimes called stiction) is the torque required to break loose the gears and start motion. The coulomb force is a constant force developed from the motion of the gears and is independent of motion. The viscous force is directly dependent on the rate of the gear motion. The effects of the forces may be overcome through the use of hydrostatic oil bearings and compressed air bearings where high angular rates are required (i.e., for a low-earth satellite). The drawback to these types of bearings are their high cost to manufacture and maintain (32:57). As an additional improvement in gimbal operation, new instrumentation techniques are available to provide inertial control to the gimbal (5:154).

2.5.3.3 Pointing Error. Pointing is the requirement to maintain a constant direction value for azimuth and elevation for the sensor. Pointing error is a static measurement taken when the sensor is not moving. For most satellite tracking applications, this is not applicable (except for geostationary orbits observed from the equator). The current system requirements are for less than a 5 microradian difference above 20 degrees in elevation measurement. The key to pointing control is in the thermal control of the gimbal device.

All metals expand when heated. When the gimbal structure heats up and expands, small errors in pointing are detected. The key is to control the expansion through insulation or active cooling (32:60).

For overall system performance, various manufacturing errors may be detected and subtracted out since they will remain constant with time. Common gimbal errors include axis misalignment and incorrect mass allocation of the gimbal structure (heavier on one side than the other).

2.5.4 Sensor Bias and Sigma. All of these effects combine to create unique errors for each sensor which vary for each observation. These errors must be removed from the observations if an accurate correction to the element set is to be obtained. Most

major known sources of error are typically removed by the individual sensors prior to forwarding the observations to the SSC. However, the SSC must still track and account for any remaining errors.

The SSC uses a simple method to quantify errors. Sensor observations are gathered on a satellite for which highly accurate orbital data is known. The observations are compared to predicted observations using the accurate orbital data and the residuals calculated. The residuals are statistically analyzed and the mean error, or bias, and the standard deviation of the error, or sigma, are computed (11:4-1) (36:76,239) (24:205).

There are two methods used for generating the highly accurate orbital data. The first is using the output from a special perturbations correction to generate accurate ephemeris from which the accurate predicted observations can be obtained (24:205). The second is to use ephemerides from an outside agency such as the Defense Mapping Agency (DMA), GPS, or the Naval Astronautics Group (NAG) (24:205). A common calibration satellite used is a Navy Transit Navigation System satellite.⁵ This satellite has an onboard transponder which is used to obtain highly-accurate positional data. Ephemerides obtained from DMA for this satellite have an accuracy on the order of five meters (11:4-2).

The SSC tasks all sensors to routinely gather observations on calibration satellites. An SSC program called SPCALX is executed daily to calculate the sensor biases and sigmas (24:205) (36:239-241). These values are stored in the LOWB file for use in processing the observations and correcting the elements (24:206.1). They are also routinely monitored by SSC personnel for degradations in the sensors.

Tables 2.6 and 2.7 provide a representative sample of observation sigmas and biases for each of the sensors of the SSN. The majority of these values are compiled from the 22 September 92 daily weights and biases message released by the SSC. When data was not included in the message for a particular sensor, data from the November 1988 AFSPACECOM/DOA Metric Accuracy Study was used (11:4-2 to 4-6).

⁵For example, NORAD Catalog Number 6909.

2.6 Orbit Classifications

There are two reasons for creating orbital classes. The first is a shorthand to make communication easier; informal classes serve this purpose. The second reason is because they share some characteristic that makes them worthy of a class. Gabbard classes divide the satellite population into similar tasking characteristics.

2.6.1 Informal Classes. Since the Space Surveillance Center's orbit propagation models handle orbits with periods less than 225 minutes differently than those greater than or equal to 225 minutes, a satellite is typically classified as near-earth or as deep-space based on its period (16:1). In addition to the near-earth or deep-space classification, other types of orbits are often considered as classes. For instance, geosynchronous satellites have periods that match the earth's rotation rate. Geostationary satellites are geosynchronous satellites that remain above the same sub-point on the earth's surface.

Besides period classifications there are also inclination classes. A prograde orbit has an inclination less than 90 degrees while a retrograde orbit has an inclination greater than 90 degrees. Zero inclination orbits are termed "equatorial." Less obvious, but no less important, are the two critical inclinations. Satellites at a critical inclination have a stationary argument of perigee. Other satellites are termed sun-synchronous because the ascending node regresses at the same rate as the earth's angular rate about the sun.

2.6.2 Gabbard Classes. For tasking, the SSN classifies satellites using what are called the Gabbard classes. There are 32 Gabbard classes. The 32 Gabbard classes divide the satellite population according to perigee and apogee altitude. The classes are one of the factors used by the SSN for tasking the network's sensors. Table 2.8 lists the actual classes and the perigee and apogee limits for each of the classes. Figures 2.2 through 2.4 provide a method to visualize each of the 32 classes.

The reasons for the particular classes are (25:144):

1. The altitude below 575 kilometers is a region where satellites will experience relatively severe atmospheric drag. Eccentric orbits of small debris will commence to circularize when perigee drifts below this limit.

Table 2.8. Gabbard Classes.

Gabbard Class	Apogee Altitude		Perigee Altitude	
	Min	Max	Min	Max
	km	km	km	km
1	0	575	0	575
2	575	1000	0	575
3	575	1000	575	1000

27	35000	∞	2000	3000
28	35000	∞	3000	3700
29	35000	∞	3700	5555
30	35000	∞	5555	11110
31	35000	∞	11110	35000
32	35000	∞	35000	∞

Compiled from (25.143-144)

2. The altitude area between 575 and 1,000 kilometers contains atmosphere of tenuous density but sufficient to noticeably perturb general perturbations orbits.
3. The altitude area above 1,000 kilometers does not contain enough atmosphere to be a factor in general perturbations orbit predictions.
4. The altitude limits of 2,000, 3,000, 5,555, and 11,110 kilometers provide convenient references to qualitative differences in the effect of eccentricity or to radar sensor single and double-bang range capabilities.
5. The limit at 35,000 kilometers is slightly below true circular synchronous altitude and was selected instead of true synchronous to ensure that Class 32 would contain all nearly-circular synchronous satellites.

2.7 Sensor Tasking Methodology

The sensors of the SSN are tasked by the SSC to gather observations on all earth-orbiting satellites. In an attempt to make the most efficient use of SSN and SSC resources, a method called "Selective Tasking" is used (35:3-10). The three goals of Selective Tasking, as defined by USSPACECOM Regulation 55-12, are:

- Obtain the correct number and dispersion of observations for each satellite.
- Ensure the most efficient use of the Space Surveillance Network.
- Ensure that the observations on high-interest satellites are obtained and forwarded on a priority basis.

The three basic underlying concepts of Selective Tasking, as defined by USSPACECOM Regulation 55-12, are:

- **Observation Regulation.** Sets upper and lower limits on the number of observations collected on a given satellite. Controlling the amount of data gathered ensures the most efficient use of the SSN.
- **Observation Requirements.** Observation requirements are dependent on the orbital parameters and mission of the satellite. A routine satellite in a stable orbit will require less observations than a high-interest, maneuverable satellite.
- **Observation Dispersion.** Observations spread out around the entire orbit are more useful than the same number of observations clustered in one area.

Observational data requirements in terms of the number, quality, dispersion, and priority of observations will vary based on a satellite's mission, orbital parameters, and by the sensors capable of tracking the satellite. Orbital analysts in the SSC use three programs, called RTASK, DSTASK, and BNPLAN, to determine the routine tasking requirements for all satellites. As stated in NORAD Technical Publication 008,⁶ RTASK uses the results from a "System Capability Study" performed between September 1973 and April 1974 to determine the number observations required for all near-earth satellites (24:212,223). The

⁶Dated 6 April 1992, last updated 8 October 1991.

results of this study, as shown in Table 2.9, were implemented in 1974 and have been in use since that time (24:212). We found no references indicating that observation requirements from a more recent study were in use.

As seen in Table 2.9, no observation requirements were set for Gabbard Classes 19 through 32 (deep-space classes). This was because of the lack of sensor coverage for deep-space objects at that time and, therefore, a lack of a sufficient number of observations to support this empirical study. The operational requirement for these classes is 30 observations per LUPI (length of update interval), where LUPI equal to 30 days for non-synchronous satellites and 60 days for synchronous satellites (24:213). The programs DSTASK and BNPLAN are used to recommend tasking for these deep-space objects. DSTASK is used to determine the actual tasking for all deep-space sensors (36:75). BNPLAN then uses the tasking set by DSTASK to generate an observing schedule for optical sensors (36:75).

These three programs are periodically executed (typically daily) to determine required tasking. In addition, tasking monitoring programs also keep track of the number of observations received compared with the tasking level. This program flags any satellites which are not getting the required quantity of observations (24:225-226). SSC orbital analysts can make any necessary changes to this tasking based on current mission requirements. This sensor-specific tasking is then forwarded to all sensors of the SSN using a system of numeric tasking categories and alphabetic tasking suffixes to describe the observation data requirements for each satellite. The tasking categories and suffixes are also used to regulate the flow of observations from the sensors of the SSN to the SSC.

2.7.1 Tasking Categories and Suffixes. Tasking categories define the priority of getting observational data on the satellite and the precedence for transmitting that data to the SSC. They are also used to resolve conflicts when multiple satellites requiring observational data are in the sensors field of view at the same time and the sensor is unable to gather the required amount of data on all satellites. Tasking suffixes define the actual amount of observational data that must be gathered for the satellite and the frequency of data collection. The one exception to this definition of category and suffix combination is

the NAVSPASUR sensor. It uses only tasking categories to define both the priority and amount of observational data required.

2.7.2 Near-Earth Sensor Tasking. The categories used with near-earth mechanical and phased-array radars are (36:73):

- Category 1: Events of the highest priority. Used for satellites requiring instantaneous observational data (i.e., new foreign launches, satellites in final stages of decay, and near-earth satellites performing maneuvers). Data is sent by IMMEDIATE precedence unless FLASH precedence is requested by the SSC.
- Category 2: Special events of high priority. Satellites of high priority but not requiring instantaneous data (i.e., satellites capable of performing maneuvers, de-orbiting satellites, and domestic launches). Data is sent by PRIORITY precedence unless IMMEDIATE precedence is requested by the SSC.
- Category 3: All routine satellites. Data sent by ROUTINE precedence unless otherwise requested.

Tables 2.10 and 2.11 describe the tasking suffixes used with near-earth mechanical and phased-array radars.

As mentioned above, NAVSPASUR uses categories alone to define both the priority and amount of observational data required. Those categories are (36:73-74):

- Category 1: Same as Category 1 for mechanical and phased-array radars above.
- Category 2: Same as Category 2 for mechanical and phased-array radars above.
- Category 3: Satellites with orbital parameters making them difficult to track and, therefore, requiring continuous observations. Kickapoo-referenced⁷ observations required on all passes. Data is sent by ROUTINE precedence.
- Category 4: Satellites in stable orbits. One Kickapoo referenced observation from the most westerly pass during each successive 24-hour period. Data is sent by ROUTINE precedence.

⁷Kickapoo is the name of the town where the main NAVSPASUR receiver is located.

Table 2.10. Near-Earth Mechanical-Tracking Radar Tasking Suffixes.

Tasking Suffix	Description
A	Maximum data on all available passes.
B	1 1/2 minutes of data on all available passes.
C	1 1/2 minutes of data on four passes/day.
D	1 minute of data above 15° elevation, centered about culmination, for 2 passes/day separated by 12 ± 4 hours. Used for calibration satellites.
E	1 observation/day. Select portion of pass providing the best quality data.
F	1 1/2 minutes of data on 2 passes/day.
G	1 observation/pass for 2 passes/day. Select portion of pass providing the best quality data. Use 1 ascending and 1 descending pass when possible.
H	3 observations/pass for all available passes.
J	10 observations/pass for all available passes.
S	Special tasking as set by SSC.
T	Final TIP tasking; maximum data on all available passes.

Table 2.11. Near-Earth Phased-Array Radar Tasking Suffixes.

Tasking Suffix	Description
A	Maximum data on all available passes.
B	15 observations/pass on all available passes.
C	5 observations/pass on all available passes.
D	3 observations/pass on all available passes.
E	1 observations/pass on all available passes.
F	1 observation/day.
G	2 observations/day.
H	3 observations/day.
J	4 observations/day.
K	1 observation/day on an ascending pass.
L	1 observation/day on a descending pass.
M	2 observations/day. 1 ascending pass and 1 descending pass.
P	9 observations/pass above 7° elevation, for 2 passes/day. separated by 12 ± 4 hours. Used for calibration satellites.
S	Special tasking requirements as set by SSC.
T	Final TIP tasking; maximum data on all available passes.

Compiled from (36:79)

- Category 5: Satellites of special importance. Observation requirements as set by the SSC. Data is sent by ROUTINE precedence.
- Category 6: Satellites requiring low data rates. One Kickapoo-referenced observation every 36 hours alternating between ascending and descending passes. Data is sent by ROUTINE precedence.

Each sensor tasked to gather observations on near-earth satellites receives a weekly tasking message from the SSC. This message lists that sensor's tasking requirements for all near-earth satellites (36:68). Updates to this message are made by the SSC as requirements and mission dictate.

For the majority of the satellite population (routine near-earth satellites), only four sensors are tasked to gather observations (3). This tasking is presented in Table 2.12. If these sensors are not able to gather the minimum required observations, or if circumstances require additional observations, other sensors will be tasked based on the following Sensor Tasking Priority List (12:Appendix 2) (3):

745, 399, 393, 382, 363, 354, 331, 932, 337, 349, 342, 394, 388, 386, 384

Table 2.12. Typical Tasking for Routine Near-Earth Satellites.

Sensor Number	Sensor Name	Tasking
745	NAVSPASUR	Category 3 for all satellites with inclinations $> 30^\circ$.
399	EGLIN	Category 3H for all satellites.
396	PARCS	Category 3H for all satellites with inclinations $\geq 30^\circ$.
382	ELDORADO	Category 3H for all satellites with inclinations $< 50^\circ$. Category 3F for all satellites with inclinations $\geq 50^\circ$.

2.7.3 Deep-Space Sensor Tasking. The categories used with all sensors that track deep-space satellites are (36:74):

- Category 1: Same as Category 1 for mechanical and phased-array radars above.
- Category 2: Same as Category 2 for mechanical and phased-array radars above.

- Category 3: Routine satellites and satellites that have not been tracked in the last 4 to 30 days. Data sent by PRIORITY precedence.
- Category 4: Satellites that have not been tracked in the last 2 to 4 days. Data sent by ROUTINE precedence.
- Category 5: Satellites that have not been tracked in last 1 to 2 days. Data sent by ROUTINE precedence.

Tables 2.13 and 2.14 describe the tasking suffixes used with deep-space radar and optical sensors.

Table 2.13. Deep-Space Optical Sensor Tasking Suffixes.

Tasking Suffix	Description
A	Maximum data on all available passes.
B	15 observations/pass on all available passes.
C	4 observations/pass on 1 pass/day.
D	4 observations/pass on 2 passes/day separated by at least 15° of true argument of latitude.
E	4 observations/pass on 2 passes/day separated by at least 30° of true argument of latitude.
F	3 observations/pass on 1 pass/day. Used for calibration satellites
M	4 observations/pass on a minimum of 2 passes/day to verify position. If object not detected or orbit deviation suspected, change to S.
N	4 observations/pass on 1 pass/day every even-numbered days.
O	4 observations/pass on 1 pass/day every odd-numbered days.
Q	4 observations/pass on 1 pass/day every 5 days.
R	Special tasking as set by the SSC.
S	An in-track or cross-track search once/day. When object found, change to suffix E.
T	Final TIP tasking. 3 observations/pass on 3 passes/day. If object not detected, change to suffix S.

Compiled from (36:84-86)

Each sensor tasked to gather observations on deep-space satellites receives a daily tasking message from the SSC. This message lists the sensor's tasking requirements for all deep-space satellites (36:68). Updates to this message are made by the SSC as requirements and mission dictate.

Table 2.14. Deep-Space Radar Sensor Tasking Suffixes.

Tasking Suffix	Description
A	Maximum data on all available passes.
B	15 observations/pass on all available passes.
C	4 observations/pass on 1 pass/day.
D	4 observations/pass on 2 passes/day separated by at least 1 hour.
E	4 observations/pass on 2 passes/day separated by at least 2 hours.
F	3 observations/pass on 1 pass/day. Used for calibration satellites
M	4 observations/pass on a 2 passes/day to verify position. If object not detected or orbit deviation suspected, maximum data required.
N	4 observations/pass on 1 pass/day every even-numbered days.
O	4 observations/pass on 1 pass/day every odd-numbered days.
Q	4 observations/pass on 1 pass/day every 5 days.
R	Special tasking as set by the SSC.
S	An in-track or cross-track search once/day. When object found, maximum data required.
T	10 observations/pass on all available passes.

2.8 SSN Sensor Observation Processing Methodology

The SSC receives observations from a group of diverse types of sensors. Some of the sensors were originally designed for other missions and were adapted to the SSN because of their capabilities. Because of these differences, not all sensors report their observations in the same format. Table 2.15 describes all observation types that the SSC is programmed to handle.

Table 2.15. Observation Data Types.

Observation Type	Observational Data Gathered by the Sensor
0	Time, range rate.
1	Time, azimuth, elevation.
2	Time, azimuth, elevation, range.
3	Time, azimuth, elevation, range, range rate.
4	Time, azimuth, elevation, range, range rate, azimuth rate, elevation rate, range acceleration
5	Time, right ascension, declination.
6	Time, range.

Compiled from (24:211)

Of the sensors currently comprising the SSN, all mechanical-tracking and phased-array radar sensors, with the exception of EGLIN, report Observation Type 3. Eglin and NAVSPASUR report Observation Type 2. All optical sites report Observation Type 5.

The processing methodology of observations at each sensor site is site dependent. The sensors respond to taskings generated by RTASK or requested by the analyst at the SSC. Based on the transmitted tasking category and suffix, the internal software at the site selects the best pass and observations to support the tasking (2).

The only software commonality between operations is thought to be among similar sensors. Sensors which achieved initial operational capability in the same time span may process observations with similar software. However, this is not certain since on-site programmers have the ability to reprogram the systems. A recent example of this ability was reported to have improved the processing ability of the sensor at Eglin Air Force Base (22:5).

On an annual basis, sensors of the SSN report more than 32,000 uncorrelated targets (UC'Ts) to the SSC; however, only 5 percent are actually UC'Ts (22:5). The reprogramming at Eglin was designed to reduce the number of UC'Ts by collecting multiple observations before labeling the target as uncorrelated. The effort at Eglin resulted in a reduction of uncorrelated tracks from 175 to 70 and uncorrelated targets from 3500 to 800 (22:5).

2.9 Observation Processing and Orbital Element Correction

2.9.1 SSC Observation Processing. All incoming observation data and electronic messages are sent through the system input processor (SIP). The SIP serves as a filter to sort out sensor observations from other electronic messages. All observations are then routed to the POBS program in the SSC (35:5-6). The flow of observational data is shown in Figure 2.5.

The POBS program converts the observation from sensor format to internal SSC format for processing. Additionally, the observations are sorted and error checked. Observations which have no errors other than satellite number are routed to the various other

Figure 2.5. Processing Flow of Observations.

programs. From the POBS program, observations are routed to three possible programs based on their "association status": ELMAIN, TRACKS, or POMP (35:5-6).

The association status (ASTAT) of an observation is determined by comparing the observed location of the satellite to its predicted location. To be fully associated (ASTAT 1), the observed location must fall within limits established around the predicted location (24:158). These limits form a volume in space and are referred to as height (Δh radial location), time (Δt in-track location), and plane (β). As limits are exceeded, the association status changes. The limits for these measures are: $\Delta h = 10$ kilometers, $\Delta t = 0.05$ minutes, and $\beta = 0.05$ degrees (24:158). Table 2.16 outlines the ASTAT and limits used by the SSC.

Table 2.16. Association Status.

ASTAT	Limits
1	Meets β , Δh , and Δt
2	Meets β . Within $4 \times \Delta h$ and $4 \times \Delta t$
3	Meets only β
4	β limit exceeded

Compiled from (24:158)

ELMAIN verifies correct satellite number tag by computing residuals and comparing the residuals to acceptable threshold values of plane, time, and height. The purpose of this analysis is to determine the association status of the satellite. The purpose of the association process is to determine the proper "tag" for the observation (24:157). If the satellite has Association Status 1 (ASTAT 1), the observation is routed to the file VOBS (24:159). Observations with ASTAT 2 or 3 are routed to the UVOB file (35:5-6) (24:157). Satellites with ASTAT 4 are routed to the un-associated observations file (UAOB) (24:159).

The TRACKS program combines observations from multiple sensors to create tracks on satellites and build initial element sets. The initial element set is then refined by a differential correction process. Once refined, the element set is compared to the satellite file (SATF) and a degree of correlation is established. If the TRACKS program cannot build an element set, the observations are routed to the UVOB file. Any observations meeting ASTAT 2, 3, or 4 criteria and deep-space object criteria are routed to the VOBS file and the "deep-space hold bucket" (35:5-7).

The POMP program identifies observations which might be associated with a satellite breakup or new launch. POMP uses a plane check to verify the observations. Verified observations are routed to the launch and breakup processor. Observations which are not verified are routed to the UVOB file (35:5-7).

The RETAG program is the next step in processing observations from the UVOB file. This program is automatically initiated every 30 minutes or when there are 140 observations in the UVOB file. RETAG correlates each observation in the UVOB file with each element in the SATF. If an observation correlates to ASTAT 1 or if the satellite is forced tagged to 1, the observation is then routed to the VOBS file. If the correlation is ASTAT 2 or 3 and a trouble flag (see Table 2.17) has been set, the RETAG program routes the observation to the partially associated observation (PAOB) file. If the ASTAT is 3 or 4 and a trouble flag has not been set, the observation is routed to the UAOB file. If an observation is ASTAT 3 and one of the three best candidate satellites has a trouble flag set, RETAG will route the observation to the PAOB file. All observations in the PAOB file that are more than 5 days old are routed to the UVOB file (35:5-8).

Table 2.17. Trouble Flags.

Flag Name	Description
SALAUN	Launch Flag
SAMNVR	Maneuver Flag
SABKUP	Satellite Breakup
SALOST	Lost Satellite Flag
SANDK	Decay Flag

Compiled from (35:5-8)

2.2.2 Differential Correction: Batch and Sequential. Differential correction is a method by which a new estimated state (i.e., the orbital elements) is determined by calculating the state (orbital elements) that "best fits" the orbit based on a set of sensor observations. The SSC uses two methods to differentially correct element sets from received observations: batch and sequential. Table 2.18 outlines the programs used for the types of correction based on the perturbation theory used for the correction.

Table 2.18. Differential Correction Programs.

Sequential		Batch	
Program	Theory	Program	Theory
ELMAIN	General Perturbation	BATCH ELREC FLINT	General Perturbation
STAGEX	Special Perturbation	MANDC	Special or General Perturbation

Compiled from (35:5-9 5-10)

Sequential processing uses the old matrix of elements (GMAT for general perturbation and HMAT for special perturbation) and the new observations or observation track. This procedure results in a time weighting of the observations with more weight being placed on newer observations. Batch processing uses more observations over a longer span than sequential processing. For batch processing, all observations directly contribute to the correction process. There is no time weighting of observations. However, there is a weighting of the sensor observations based on the accuracy of the sensor (35:5-9).

The advantage of sequential correction is the speed of the computer run. However, sequential corrections can only be run on stable orbits since a single bad observation will seriously impact the correction process. A bad observation and, therefore, a bad residual

will have less of an effect on a batch correction because of the larger number of observations used (35:5-10).

2.9.2.1 Automatic Element Set Maintenance. Observations, once processed by ELMAIN or POBS, are placed into holding files. Once the required time has passed or the necessary observations have been collected, the differential correction process begins. However, because of the large number of satellites, it is not feasible to update all of them manually. To provide for automatic updates, there are several programs used to process the observational data (35:5-10). The key element to the process is a table called the satellite control list (SCL).

The SCL is a table in the SCCEX program. The SCCEX program controls the execution and data exchange between all application programs used by the SSC (25:119) (24:204). Within the SCCEX program, the control list is used to control the time sequence of events required to maintain the element sets (35:5-10). To do this, the SCL is divided into two sections. Section 1 is for updating element sets requiring special perturbation and Section 2 is for updating elements requiring general perturbation (35:5-10). The flow of the automated correction process is shown in Figure 2.6.

ELMAIN is the core of the automated differential correction process. This program takes observations and performs a general sequential correction. If the correction is successful, the satellite's GMAT and SATF files are updated. If the correction fails, the satellite is identified for batch correction. ELMAIN will not attempt to correct element sets of satellites which have been tagged for batch correction. All satellites with a HOTF number are tagged for STAGEX processing and are not routed through ELMAIN (35:5-10).

As part of the automated process, the program ELANLX is manually called by the analyst on a regular basis. This program measures the accuracy of the general perturbations element sets. ELANLX compares the predicted position of the satellite with the most current verified observation. If the vector magnitude (VMAG) of the difference (the residual) is greater than 14 kilometers the satellite is selected and marked for BATCH correction in the SCL (35:5-11).

Figure 2.6. Differential Correction Process Flow

An additional automated program is ELTRAN. ELTRAN is time activated based on the expiration of the DUTI number. DUTI is defined as the time interval between runs of BATCH or another correction process (24:203). The typical DUTI for routine satellites is three (indicating three eight-hour periods) (13:Atch 1) (3). If the DUTI has expired, ELTRAN will tag the satellite for BATCH correction (24:204.3).

BATCH is an automatically called program which attempts a general perturbation correction by using only verified observations. If the correction process is successful, the SATF and GMAT files will be updated. If the correction is not successful, the satellite will be tagged for correction by the program ELREC (35:5-12).

ELREC is automatically called based on elapsed time. This program reads satellite numbers from the control list and then attempts a general perturbation correction. However, unlike the BATCH program, ELREC has the ability to access the PAOB and UAOB file and edit observations prior to the correction process. If the correction process is successful, the SATF and GMAT files will be updated. If the process fails, the satellites

are listed on the control list for the lost object differential corrector (LOBDC) program correction. The analyst will receive a message on the console and must manually correct using LOBDC (35:5-12).

2.9.2.2 Manual Element Set Maintenance. The program MANDC provides the analyst manual control of the differential correction process. MANDC will directly queue the ELTRAN program to process the observations and conduct the correction process (24:204.1). This program is used to process those satellites with non-routine orbits (special-interest satellites). The processing of observations remains the same for a manually-corrected satellite.

2.10 Summary of Past SSN Assessments

Since the beginnings of the SSN there have been several assessments of sensors, network capabilities, and tasking operations. As of September 1992, assessments were still being conducted with the goal of continual process improvement (30). For the purpose of this research, two past assessments were evaluated and are summarized below.

2.10.1 Space Surveillance Program Architecture Report. This study sought to examine the workings of the SSN and examine possible shortfalls in the system. The initial assessment of the SSN indicated there were two general requirements for adequate space surveillance: accuracy and timeliness (31:3-5). Both of these requirements are based on required actions and responses for a wartime environment. The study found that if the timeliness requirement was dropped, the accuracy of the current sensors met the accuracy requirement for catalogue updates (31:3-5).

Based on the worldwide deployment of sensors for the SSN, the flow of information from the sensors to the SSC was of special interest to this study. The study specifically identified the command and control structure, the data processing capability, and the communication systems associated with the gathering of satellite observation information (31:4-1). The study concluded that the requirements of the catalogue support mission

is primarily a function of information throughput capability and sensor tasking priorities (31:3-5).

2.10.2 Final Report of the Surveillance Command and Control Study. This study was directed by the Secretary of the Air Force for Acquisition, Space, and SDI Programs in 1988. The stated purpose of this report was to baseline the current capability of the SSN to support anti-satellite (ASAT) operations. The primary interest of this report was: sensor accuracies, the tracking of single versus multiple targets, and timeliness (9:1-1). To examine these areas, five area studies were accomplished: Flash Elset generation, Orbit Prediction Accuracy, Individual Sensor Calibration, SSC Capability, and Sensor Coverage (9:1-3).

The Flash Elset study was conducted to determine the ability of a sensor to generate an accurate Flash Elset. The Flash Elset study was directly applicable to the ASAT mission. The Orbit Prediction Accuracy study was conducted to test the different propagation theories with respect to accuracy, time dependence, and amounts of sensor data. The Sensor Calibration study was conducted to verify the accuracy of the sensors in the SSN. The SSC Capability study was conducted to evaluate the operations of the SSC. The Sensor Coverage study was conducted to evaluate the locations of the sensors in the SSN relative to the ASAT mission.

Of primary interest to this research were the Sensor Calibration study, SSC Capability study, and the Orbital Prediction Accuracy study. The Sensor Calibration study provided measurement biases and standard deviations (σ) for sensor measurements. This information was input into our differential corrector and used to analyze the satellite population. The SSC Capability study provided background information into the operation of the SSC and the sensor tasking methodology. The Orbital Prediction Accuracy study provided background on the orbital prediction problem.

These area studies resulted in several conclusions (9:1-13):

- The computer usage and processing time increased as the complexity of the orbit prediction model increased.

- The computer processing time increased as the quantity of observations increased.
- Certain gaps in the sensor coverage caused noticeable delays in the processing of information.

2.10.2.1 Sensor Calibration Study. This study examined accuracy in terms of azimuth, elevation, range, and range rate measurements (9:1-10). Even though sensor calibration is relatively stable, all sensors must be calibrated on a regular basis (10:3-3). The interval of calibration varies from sensor to sensor, but the process must be routinely accomplished to maintain observation accuracy (10:2-15).

Calibration is accomplished by tasking the sensor to track a satellite with a known and stable orbit (10:2-15). These observations are then sent to the SSC and processed on calibration analysis programs. These analysis programs generate the values for bias and standard deviation (σ) (10:2-15). The updated calibration results are then distributed to the sensors via electronic message on a daily basis (2).

This study used the Navy Transit satellite as a known object for sensor calibration (10:3-1). After the readings were taken, the observations were processed through the SSC computer systems to generate biases and standard deviations. This study noted that there are multiple sources of error which will impact the values of bias and σ . Examples of these errors are: refraction, signal to noise ratio, and satellite-dependent physical characteristics (i.e., shape, orientation, and surface area) (10:3-1). However, all of these errors are accounted for in the values for bias and σ published by the SSC.

2.10.2.2 Orbital Prediction Accuracy Study. To determine the accuracy of an orbital prediction model, three studies were conducted. These studies looked at historical data, simulation results, and historic data from NAVSPASUR (9:1-7). These studies indicated errors are highest when the time span of data is short. This error was seen to level out after three hours of available tracking data (9:1-8). This study also found the quality of the prediction was directly proportional to the accuracy of the sensor⁸ providing the information (9:1-9).

⁸In terms of bias and σ .

The evaluation of the orbit prediction theories indicated that special perturbation theory is always the best predictor. However, the application of this theory takes considerable computer time. General perturbation theory will provide adequate results but there is some accuracy penalty. However, the accuracy penalty was determined acceptable if five or six hours of observations were utilized (9:1-9).

2.10.2.3 SSC Capability Study. The SSC Capability study was important because of the ASAT nature of the original project. Researchers needed to determine how sensor tasking would impact the generation of elsets. This study determined that tasking was important to ensure the proper dispersion and number of observations were gathered for a satellite (10:2-14). To maintain the elsets, this study recommended orbits be determined every 1-2 days for LEO satellites and 7-10 days for high orbit satellites (11:3-9).

III. THEORETICAL BACKGROUND

3.1 Element/Covariance Propagation

This section establishes the dynamics used in the propagation portion of our dynamics model as well as the perturbations analysis of our satellite constellation. The dynamics used are based strictly on the J_2 perturbations. Section 3.1.1 shows the derivation of the state solution for the elements, and Section 3.1.2 establishes the state-transition matrix.

3.1.1 The State Solution. Since we are dealing with mean Keplerian orbital elements, we are interested in the non-periodic terms¹ in the time rate of change in the orbital elements. The terms in the expansion of the disturbing function (R) which do not include the mean anomaly, the only periodic term, are the secular terms. It has been shown the secular portion of the J_2 disturbing function is (37:83):

$$R_{2,sec} = -\frac{\mu J_2 R_\oplus^2}{2a^3 (1-e^2)^{3/2}} \left(\frac{3}{2} \sin^2 i - 1 \right) \quad (3.1)$$

Reference (37:47-48) provides the disturbing-function form of the Lagrange planetary equations:

$$\dot{a} = \frac{da}{dt} = \frac{2}{na} \frac{\partial R}{\partial M_0} \quad (3.2)$$

$$\dot{e} = \frac{de}{dt} = \frac{1-e^2}{na^2 e} \frac{\partial R}{\partial M_0} - \frac{\sqrt{1-e^2}}{na^2 e} \frac{\partial R}{\partial \omega} \quad (3.3)$$

$$\dot{i} = \frac{di}{dt} = \frac{\cot i}{na^2 \sqrt{1-e^2}} \frac{\partial R}{\partial \omega} - \frac{1}{na^2 \sqrt{1-e^2} \sin i} \frac{\partial R}{\partial \Omega} \quad (3.4)$$

$$\dot{\Omega} = \frac{d\Omega}{dt} = \frac{1}{na^2 \sqrt{1-e^2} \sin i} \frac{\partial R}{\partial i} \quad (3.5)$$

$$\dot{\omega} = \frac{d\omega}{dt} = \frac{\sqrt{1-e^2}}{na^2 e} \frac{\partial R}{\partial e} - \frac{\cot i}{na^2 \sqrt{1-e^2}} \frac{\partial R}{\partial i} \quad (3.6)$$

$$\dot{M}_0 = \frac{dM_0}{dt} = -\frac{2}{na} \frac{\partial R}{\partial a} - \frac{1-e^2}{na^2 e} \frac{\partial R}{\partial e} \quad (3.7)$$

¹Also called secular.

Using the Lagrange planetary equations, we can derive expressions for the time rate of change in the orbital elements. First, we must find the time derivative of the orbital elements due to $R_{2,sec}$. The expressions for these time derivatives are listed below:

$$\dot{a} = 0 \quad (3.8)$$

$$\dot{e} = 0 \quad (3.9)$$

$$\dot{i} = 0 \quad (3.10)$$

$$\dot{\Omega} = -\frac{3\mu J_2 R_\oplus^2 \cos i}{2a^5 (1-e^2)^2 n} \quad (3.11)$$

$$\dot{\omega} = \frac{3\mu J_2 R_\oplus^2 (3 + 5 \cos 2i)}{8a^5 (1-e^2)^2 n} \quad (3.12)$$

$$\dot{M}_0 = \frac{3\mu J_2 R_\oplus^2 (1 + 3 \cos 2i)}{8a^5 (1-e^2)^{3/2} n} \quad (3.13)$$

Strictly speaking, the NORAD two-line element sets do not contain the semi-major axis (a). Instead, the Kozai mean motion (n_k) is used. Solving this problem involves a two-step process. First, we must eliminate the semi-major axis in favor of the mean motion (n). Second, we must express the mean motion as a function of the Kozai mean motion.

First, using the identity between n and a (Equation 3.14), we rewrite Equations 3.8-3.13 without a .

$$a = \left(\frac{\mu}{n^2} \right)^{1/3} \quad (3.14)$$

$$\dot{n} = 0 \quad (3.15)$$

$$\dot{e} = 0 \quad (3.16)$$

$$\dot{i} = 0 \quad (3.17)$$

$$\dot{\Omega} = -\frac{3J_2 R_\oplus^2 n^{7/3} \cos i}{2\mu^{2/3} (1-e^2)^2} \quad (3.18)$$

$$\dot{\omega} = \frac{3J_2 R_\oplus^2 n^{7/3} (3 + 5 \cos 2i)}{8\mu^{2/3} (1 - e^2)^2} \quad (3.19)$$

$$\dot{M}_0 = \frac{3J_2 R_\oplus^2 n^{7/3} (1 + 3 \cos 2i)}{8\mu^{2/3} (1 - e^2)^{3/2}} \quad (3.20)$$

Notice that the orbital elements which are functions of time (Ω, ω, M_0) have time derivatives ($\dot{\Omega}, \dot{\omega}, \dot{M}_0$) which are themselves not functions of elements that change with time or with time itself. Since the Kozai mean motion is defined as in Equation 3.21, if we replace n with n_k in Equation 3.15, we have to redefine the mean anomaly at epoch to be constant (i.e., $\dot{M}_0 = 0$).

$$n_k \equiv n + \dot{M}_0 \quad (3.21)$$

Integration of Equations 3.15–3.20 with respect to time yields:

$$n_k(t) = n_{k,0} \quad (3.22)$$

$$= n_0 + \frac{3J_2 R_\oplus^2 n_0^{7/3} (1 + 3 \cos 2i_0)}{8\mu^{2/3} (1 - e_0^2)^{3/2}} \quad (3.23)$$

$$e(t) = e_0 \quad (3.24)$$

$$i(t) = i_0 \quad (3.25)$$

$$\Omega(t) = \Omega_0 - \frac{3J_2 R_\oplus^2 n_0^{7/3} \cos i_0}{2\mu^{2/3} (1 - e_0^2)^2} (t - t_0) \quad (3.26)$$

$$\omega(t) = \omega_0 + \frac{3J_2 R_\oplus^2 n_0^{7/3} (3 + 5 \cos 2i_0)}{8\mu^{2/3} (1 - e_0^2)^2} (t - t_0) \quad (3.27)$$

$$M(t) = M_0 + n_{k,0} (t - t_0) \quad (3.28)$$

Next, since the two-line orbital element sets contain the Kozai mean motion, we need to find n_0 in terms of $n_{k,0}$. We can rewrite Equation 3.23 as:

$$n_{\kappa,0} = n_0 \left\{ 1 + \frac{3J_2 R_\oplus^2 n_0^{4/3} (1 + 3 \cos 2i_0)}{8\mu^{2/3} (1 - e_0^2)^{3/2}} \right\} \quad (3.29)$$

or,

$$n_{\kappa,0} = n_0 \left(1 + \epsilon n_0^{1/3}\right) \quad (3.30)$$

where,

$$\epsilon \equiv \frac{3J_2 R_\oplus^2 (1 + 3 \cos 2i_0)}{8\mu^{2/3} (1 - e_0^2)^{3/2}} \quad (3.31)$$

As long as $\epsilon n_0^{4/3}$ in Equation 3.30 is small then we can make the approximation that the n_0 inside the parentheses is nearly $n_{\kappa,0}$.

$$n_0 = \frac{n_{\kappa,0}}{1 + \epsilon n_0^{4/3}} \quad (3.32)$$

$$n_0 \approx \frac{n_{\kappa,0}}{1 + \epsilon n_{\kappa,0}^{4/3}} \quad (3.33)$$

Actually, by nesting Equation 3.32 four times and substituting $n_{x,0}$ for n_0 , n_0 is correct through $O((\epsilon n_0^{4/3})^4)$.

$$n_0 \approx \frac{n_{\kappa,0}}{1 + e \frac{n_{\kappa,1}}{1 + e \frac{n_{\kappa,2}}{1 + e \frac{n_{\kappa,3}}{1 + e \frac{n_{\kappa,4}}{1 + e n_{\kappa,5}}}}}}} \quad (3.34)$$

Equation 3.34 can be rewritten as a power series,

$$n_0 \approx n_{a,0} \left(1 - \frac{1}{3} n_{a,0}^{\frac{1}{3}} + \frac{7}{3} n_{a,0}^{\frac{2}{3}} - 7 n_{a,0}^{\frac{4}{3}} + \frac{1925}{81} n_{a,0}^{\frac{15}{3}} \right) \equiv f(n_{a,0}) \quad (3.35)$$

In order for the power series to converge, we assumed $\epsilon n_0^{4/3}$ was small. Figure 3.1 is a plot of the magnitude of ϵ in canonical² units with an eccentricity range of 0 to .92.³ Because the maximum mean motion in canonical units is 1, it is accurate to say that the value of $\epsilon n_0^{4/3}$ remains small for satellites with eccentricities less than .92.

Figure 3.1. Epsilon (ϵ) Values over Area of Interest (Canonical Units).

If Equation 3.35 is substituted into Equation 3.30, we would expect the two sides to be nearly equal. To find the error induced in extracting n_0 from $n_{k,0}$, subtract $n_{k,0}$ from the result.

$$\text{error} = f(n_{k,0}) \left(1 + \epsilon (f(n_{k,0}))^{4/3} \right) - n_{k,0} \quad (3.36)$$

²In canonical units, μ is $1 \text{ DU}^3/\text{TC}^2$, R_E is 1 DU . R_E is also the minimum semi-major axis, thus the maximum mean motion is $1 \text{ DU}/\text{TC}$.

³The maximum eccentricity of any satellite in the current population is 0.92.

Since our approximation is good to order $(\epsilon n_0^{4/3})^4$, if $\epsilon n_0^{4/3}$ is maximized then the magnitude of the error will also be at its maximum. Figure 3.2 shows the maximum error induced for all possible $n_{\kappa,0}$ and i_0 combinations.⁴

Figure 3.2. Error Induced in Extracting n_0 from $n_{\kappa,0}$.

Figure 3.2 shows clearly that the power-series expansion is very good for most mean motions and even at its worst it is less than 1×10^{-8} deg/day in error.

Summarizing the important equations so far:

$$n_{\kappa}(t) = n_{\kappa,0} \quad (3.37)$$

$$e(t) = e_0 \quad (3.38)$$

$$i(t) = i_0 \quad (3.39)$$

$$\Omega(t) = \Omega_0 + \frac{3J_2 R_p^2 n_0^{7/3} \cos i_0}{2\mu^{1/2} (1 - e_0^2)^2} (t - t_0) \quad (3.40)$$

⁴The maximum eccentricity without impacting the earth's surface was computed for each value of $n_{\kappa,0}$ and used along with i_0 in computing ϵ .

$$\omega(t) = \omega_0 + \frac{3J_2 R_\oplus^2 n_0^{7/3} (3 + 5 \cos 2i_0)}{8\mu^{2/3} (1 - e_0^2)^2} (t - t_0) \quad (3.41)$$

$$M(t) = M_0 + n_{\kappa,0} (t - t_0) \quad (3.42)$$

where,

$$n_0 \approx n_{\kappa,0} \left(1 - \epsilon n_{\kappa,0}^{\frac{4}{3}} + \frac{7}{3} \epsilon^2 n_{\kappa,0}^{\frac{8}{3}} - 7\epsilon^3 n_{\kappa,0}^4 + \frac{1925}{81} \epsilon^4 n_{\kappa,0}^{\frac{16}{3}} \right)$$

$$\epsilon \equiv \frac{3J_2 R_\oplus^2 (1 - 3 \cos 2i_0)}{8\mu^{2/3} (1 - e_0^2)^{3/2}}$$

Now, since we have the solution to the state variables for any time (t) given the state at some initial time (t_0), we can find the state-transition matrix analytically (by taking the partials of the state solution with respect to the initial state variables).

3.1.2 The State-Transition Matrix. The state-transition matrix is used in propagating the covariance of an estimated state. In our case, the state variables are:

$$\mathbf{x}^T = \begin{bmatrix} n_\kappa & e & i & \Omega & \omega & M \end{bmatrix} \quad (3.43)$$

and the state-transition matrix $\Phi(t, t_0)$ is defined as:

$$\Phi(t, t_0) \equiv \frac{\partial \mathbf{x}(t)}{\partial \mathbf{x}(t_0)} \quad (3.44)$$

The partials in Φ can be written more extensively as:

$$\Phi(t, t_0) = \begin{bmatrix} \frac{\partial n_\kappa(t)}{\partial n_{\kappa,0}} & \frac{\partial n_\kappa(t)}{\partial e_0} & \frac{\partial n_\kappa(t)}{\partial i_0} & \frac{\partial n_\kappa(t)}{\partial \Omega_0} & \frac{\partial n_\kappa(t)}{\partial \omega_0} & \frac{\partial n_\kappa(t)}{\partial M_0} \\ \frac{\partial e(t)}{\partial n_{\kappa,0}} & \frac{\partial e(t)}{\partial e_0} & \frac{\partial e(t)}{\partial i_0} & \frac{\partial e(t)}{\partial \Omega_0} & \frac{\partial e(t)}{\partial \omega_0} & \frac{\partial e(t)}{\partial M_0} \\ \frac{\partial i(t)}{\partial n_{\kappa,0}} & \frac{\partial i(t)}{\partial e_0} & \frac{\partial i(t)}{\partial i_0} & \frac{\partial i(t)}{\partial \Omega_0} & \frac{\partial i(t)}{\partial \omega_0} & \frac{\partial i(t)}{\partial M_0} \\ \frac{\partial \Omega(t)}{\partial n_{\kappa,0}} & \frac{\partial \Omega(t)}{\partial e_0} & \frac{\partial \Omega(t)}{\partial i_0} & \frac{\partial \Omega(t)}{\partial \Omega_0} & \frac{\partial \Omega(t)}{\partial \omega_0} & \frac{\partial \Omega(t)}{\partial M_0} \\ \frac{\partial \omega(t)}{\partial n_{\kappa,0}} & \frac{\partial \omega(t)}{\partial e_0} & \frac{\partial \omega(t)}{\partial i_0} & \frac{\partial \omega(t)}{\partial \Omega_0} & \frac{\partial \omega(t)}{\partial \omega_0} & \frac{\partial \omega(t)}{\partial M_0} \\ \frac{\partial M(t)}{\partial n_{\kappa,0}} & \frac{\partial M(t)}{\partial e_0} & \frac{\partial M(t)}{\partial i_0} & \frac{\partial M(t)}{\partial \Omega_0} & \frac{\partial M(t)}{\partial \omega_0} & \frac{\partial M(t)}{\partial M_0} \end{bmatrix} \quad (3.45)$$

Eliminating the easy ones:

$$\Phi(t, t_0) = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ \frac{\partial \Omega(t)}{\partial n_{\kappa,0}} & \frac{\partial \Omega(t)}{\partial \epsilon_0} & \frac{\partial \Omega(t)}{\partial i_0} & 1 & 0 & 0 \\ \frac{\partial \omega(t)}{\partial n_{\kappa,0}} & \frac{\partial \omega(t)}{\partial \epsilon_0} & \frac{\partial \omega(t)}{\partial i_0} & 0 & 1 & 0 \\ t - t_0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} \quad (3.46)$$

In order to do the remaining six partials in Equation 3.46 we need the derivatives of ϵ and n_0 .

$$\frac{d\epsilon}{di_0} = -\frac{9J_2 R_p^2 (\sin 2i_0)}{4\mu^{2/3} (1 - \epsilon_0^2)^{3/2}} \quad (3.47)$$

$$\frac{d\epsilon}{d\epsilon_0} = \frac{9J_2 R_p^2 (1 + 3 \cos 2i_0)}{8\mu^{2/3} (1 - \epsilon_0^2)^{5/2}} \epsilon_0 \quad (3.48)$$

$$\frac{dn_0}{dn_{\kappa,0}} = 1 - \frac{7}{3} \epsilon n_{\kappa,0}^{\frac{4}{3}} + \frac{77}{9} \epsilon^2 n_{\kappa,0}^{\frac{8}{3}} - 35 \epsilon^3 n_{\kappa,0}^4 + \frac{36575}{243} \epsilon^4 n_{\kappa,0}^{\frac{16}{3}} \quad (3.49)$$

$$\frac{dn_0}{d\epsilon} = n_{\kappa,0} \left(-n_{\kappa,0}^{\frac{4}{3}} + \frac{14}{3} \epsilon n_{\kappa,0}^{\frac{8}{3}} - 21 \epsilon^2 n_{\kappa,0}^4 + \frac{7700}{81} \epsilon^3 n_{\kappa,0}^{\frac{16}{3}} \right) \quad (3.50)$$

The six partials are:

$$\frac{\partial \Omega(t)}{\partial n_{\kappa,0}} = -\frac{7J_2 R_p^2 n_0^{\frac{4}{3}} \cos i_0}{2\mu^{\frac{1}{3}} (1 - \epsilon_0^2)^2} \cdot \frac{dn_0}{dn_{\kappa,0}} \cdot (t - t_0) \quad (3.51)$$

$$\frac{\partial \Omega(t)}{\partial \epsilon_0} = \left(-\frac{6\epsilon_0 J_2 R_p^2 n_0^{\frac{4}{3}} \cos i_0}{\mu^{\frac{1}{3}} (1 - \epsilon_0^2)^3} - \frac{7J_2 R_p^2 n_0^{\frac{4}{3}} \cos i_0}{2\mu^{\frac{1}{3}} (1 - \epsilon_0^2)^2} \cdot \frac{dn_0}{d\epsilon} \cdot \frac{d\epsilon}{d\epsilon_0} \right) \cdot (t - t_0) \quad (3.52)$$

$$\frac{\partial \Omega(t)}{\partial i_0} = \left(\frac{3J_2 R_p^2 n_0^{\frac{4}{3}} \sin i_0}{2\mu^{\frac{1}{3}} (1 - \epsilon_0^2)^2} - \frac{7J_2 R_p^2 n_0^{\frac{4}{3}} \cos i_0}{2\mu^{\frac{1}{3}} (1 - \epsilon_0^2)^2} \cdot \frac{dn_0}{d\epsilon} \cdot \frac{d\epsilon}{di_0} \right) \cdot (t - t_0) \quad (3.53)$$

$$\frac{\partial \omega(t)}{\partial n_{\kappa,0}} = \frac{7J_2 R_p^2 n_0^{\frac{4}{3}} (3 + 5 \cos 2i_0)}{8\mu^{\frac{1}{3}} (1 - \epsilon_0^2)^2} \cdot \frac{dn_0}{dn_{\kappa,0}} \cdot (t - t_0) \quad (3.54)$$

$$\frac{\partial \omega(t)}{\partial \epsilon_0} = \left(\frac{3\epsilon_0 J_2 R_p^2 n_0^{\frac{4}{3}} (3 + 5 \cos 2i_0)}{2\mu^{\frac{1}{3}} (1 - \epsilon_0^2)^3} + \frac{7J_2 R_p^2 n_0^{\frac{4}{3}} (3 + 5 \cos 2i_0)}{8\mu^{\frac{1}{3}} (1 - \epsilon_0^2)^2} \cdot \frac{dn_0}{d\epsilon} \cdot \frac{d\epsilon}{d\epsilon_0} \right) \cdot (t - t_0)$$

(3.55)

$$\frac{\partial \omega(t)}{\partial i_0} = \left(-\frac{15 J_2 R_\oplus^2 n_0^{\frac{7}{2}} \sin 2i_0}{4 \mu^{\frac{3}{2}} (1 - e_0^2)^2} + \frac{7 J_2 R_\oplus^2 n_0^{\frac{5}{2}} (3 + 5 \cos 2i_0)}{8 \mu^{\frac{3}{2}} (1 - e_0^2)^2} \cdot \frac{dn_0}{d\epsilon} \cdot \frac{d\epsilon}{di_0} \right) \cdot (t - t_0) \quad (3.56)$$

In Section 3.1.1, we derived the state solution as a function of time. We used the state solution equations to derive an analytic Φ . We will use Φ , provided in Equations 3.46 through 3.56, for propagating our state-covariance.

3.2 Differential Correction

This section reviews the differential correction theory used in our model. The estimation algorithm we used in this research is a sequential estimator, specifically a Bayes filter algorithm, as presented in (38:55-94). The Bayes filter is basically a weighted least squares filter modified to use the previous state estimate and the covariance of that estimate as the first data input to the filter. Before discussing the Bayes filter, a review of least squares estimation is required.

3.2.1 Least Squares Estimation. Least squares is the basis for estimation theory. Least squares estimates the state of a dynamic system at some time t_0 ($\mathbf{x}(t_0)$) by using a series of actual measurements, or observations ($\hat{\mathbf{O}}(t_i)$) taken at different times t_i . In orbit determination, least squares attempts to determine the orbit most likely to produce the observational data. The estimate is determined by minimizing the sum of the squares of the residuals between the actual observations ($\hat{\mathbf{O}}(t_i)$) and predicted observations ($\mathbf{O}(t_i)$) based upon a reference state. Weighted least squares comes from associating an observation weighting, or instrument covariance matrix ($\mathbf{Q}(t_i)$), with each observation vector $\hat{\mathbf{O}}(t_i)$.

A set of observation data at different times t_i which is linearly related to the system state at that time can be written as

$$\hat{\mathbf{O}}(t_i) = \mathbf{H}_i \mathbf{x}(t_i) + \mathbf{e}_i \quad (3.57)$$

where e_i is the true error in the data and H_i is the linear relationship between the observations and the state at time t_i ($x(t_i)$).

In a linear dynamical system, the state at time t_i can be written as a function of the state at time t_0 as shown in Equation 3.58 below.

$$x(t_i) = \Phi(t_i, t_0) x(t_0) \quad (3.58)$$

Solving Equation 3.57 for e_i and expressing it in terms of state at time t_0 gives the following:

$$e_i = \hat{O}(t_i) - H_i \Phi(t_i, t_0) x(t_0) \quad (3.59)$$

$$= \hat{O}(t_i) - T_i x(t_0) \quad (3.60)$$

where the observation matrix, T_i , as defined in Equation 3.61, relates the observations at time t_i to the state vector at the epoch time, t_0 .

$$T_i \equiv H_i \Phi(t_i, t_0) \quad (3.61)$$

Using a matrix shorthand notation, we can define the total observation data vector, $\hat{O}$, the total observation matrix, T , and the total instrument covariance matrix Q , to be as shown in Equations 3.62, 3.63, and 3.64.

$$\hat{O} \equiv \begin{bmatrix} \hat{O}(t_1) \\ \hat{O}(t_2) \\ \vdots \\ \hat{O}(t_N) \end{bmatrix} \quad (3.62)$$

$$T \equiv \begin{bmatrix} T_1 \\ T_2 \\ \vdots \\ T_N \end{bmatrix} = \begin{bmatrix} H_1 \Phi(t_1, t_0) \\ H_2 \Phi(t_2, t_0) \\ \vdots \\ H_N \Phi(t_N, t_0) \end{bmatrix} \quad (3.63)$$

$$Q \equiv \begin{bmatrix} Q_1 & 0 & \cdots & 0 \\ 0 & Q_2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & Q_N \end{bmatrix} \quad (3.64)$$

where N is the total number of independent observations, $\hat{O}(t_i)$.

Replacing the true error $\mathbf{e}$ and the true state $\mathbf{x}(t_0)$ with the residual $\mathbf{r}$ and the estimated state $\bar{\mathbf{x}}(t_0)$, Equation 3.60 can be restated as

$$\mathbf{r} = \hat{\mathbf{O}} - T \bar{\mathbf{x}}(t_0) \quad (3.65)$$

The probability of obtaining these particular residuals is then shown by Equation 3.66.

$$P(\mathbf{r}) = (2\pi)^{-\frac{N}{2}} |\mathbf{Q}| e^{(-\frac{1}{2}\mathbf{r}^T \mathbf{Q}^{-1} \mathbf{r})} \quad (3.66)$$

To determine the state estimate $\bar{\mathbf{x}}$ which maximizes $P(\mathbf{r})$, the quantity $(\mathbf{r}^T \mathbf{Q}^{-1} \mathbf{r})$ must be minimized. This results in the minimization problem

$$\frac{\partial}{\partial \bar{\mathbf{x}}} \left((\hat{\mathbf{O}} - T \bar{\mathbf{x}})^T \mathbf{Q}^{-1} (\hat{\mathbf{O}} - T \bar{\mathbf{x}}) \right) = 0 \quad (3.67)$$

which, when solved for the estimated state, $\bar{\mathbf{x}}(t_0)$, gives

$$\bar{\mathbf{x}}(t_0) = (T^T \mathbf{Q}^{-1} T)^{-1} T^T \mathbf{Q}^{-1} \hat{\mathbf{O}} \quad (3.68)$$

where the quantity $(T^T \mathbf{Q}^{-1} T)^{-1}$ is the covariance of the estimated state, $P_{\bar{\mathbf{x}}}$.

In orbit determination, the dynamics are very non-linear. However, if the difference between the true state and a reference state ($\delta \mathbf{x}$) is small, the non-linear dynamics may be linearized about this reference state, $\mathbf{x}^*$. In addition, the observation data is also a nonlinear function of the time, t_i , and the state at that time, $\mathbf{x}(t_i)$. This observation relationship can be written as shown in Equation 3.69.

$$\mathbf{O}(t_i) = \mathbf{G}(\mathbf{x}(t_i), t_i) \quad (3.69)$$

This relationship can also be linearized through the use of a Taylor series expansion and written in the form shown in Equation 3.70

$$\mathbf{e}_i \approx \frac{\partial G}{\partial \mathbf{x}} \delta \mathbf{x}(t_i) = H_i \delta \mathbf{x}(t_i) \quad (3.70)$$

where $\mathbf{e}_i$ is the true error in the actual observation data and H_i is the data linearization matrix for the observations at time t_i .

The residuals between actual observation data and calculated observations based upon the reference state are then calculated as shown in Equation 3.71.

$$\mathbf{r}_i = \hat{\mathbf{O}}(t_i) - \mathbf{G}(\mathbf{x}(t_i), t_i) \quad (3.71)$$

The state transition matrix, $\Phi(t, t_0)$ relates changes to the state at time t_i to changes at time t_0 as shown in Equation 3.72.

$$\delta \mathbf{x}(t_i) = \Phi(t_i, t_0) \delta \mathbf{x}(t_0) \quad (3.72)$$

The residual vector $\mathbf{r}_i$ is then written as shown in Equation 3.73.

$$\mathbf{r}_i \approx H_i \delta \mathbf{x}(t_i) = H_i \Phi(t_i, t_0) \delta \mathbf{x}(t_0) = T_i \delta \mathbf{x}(t_0) \quad (3.73)$$

Using the same method that arrived at Equation 3.68 for linear least squares, the correction to the estimated state can be determined as shown in Equation 3.74.

$$\delta \mathbf{x}(t_0) = (T^T Q^{-1} T)^{-1} T^T Q^{-1} \mathbf{r} \quad (3.74)$$

with the covariance of the estimated state being as shown in Equation 3.75.

$$P_{\mathbf{x}} = (T^T Q^{-1} T)^{-1} \quad (3.75)$$

The new estimate of the state is determined as shown in Equation 3.76.

$$\bar{\mathbf{x}}(t_0) = \mathbf{x}^*(t_0) + \delta\mathbf{x}(t_0) \quad (3.76)$$

3.2.2 Bayes Estimation Algorithm. The Bayes filter uses the old estimate of the state, $\bar{\mathbf{x}}_{old}$, and the state covariance of the old estimate, P_{old} as the initial data point along with a new set of observations ($\hat{\mathbf{O}}$) and their associated covariance (Q_{new}).

Equations 3.62 through 3.64 as presented in Section 3.2.1 above are then rewritten as

$$T = \begin{bmatrix} I \\ T_{new} \end{bmatrix} \quad (3.77)$$

$$Q = \begin{bmatrix} P_{old} & 0 \\ 0 & Q_{new} \end{bmatrix} \quad (3.78)$$

$$\mathbf{r} = \begin{bmatrix} \bar{\mathbf{x}}_{old} - \mathbf{x}^* \\ \hat{\mathbf{O}} - G(\mathbf{x}(t_i), t_i) \end{bmatrix} \quad (3.79)$$

The inverse of the new covariance, P_{new}^{-1} is then calculated as shown in Equation 3.81.

$$P_{new}^{-1} = (T^T Q^{-1} T)^{-1} \quad (3.80)$$

$$= P_{old}^{-1} + (T_{new}^T Q_{new}^{-1} T_{new})^{-1} \quad (3.81)$$

Once the new covariance is calculated, the correction to the state, $\delta\mathbf{x}$ is then calculated as shown in Equation 3.83.

$$\delta\mathbf{x}(t_0) = P_{new} T^T Q^{-1} \mathbf{r} \quad (3.82)$$

$$= P_{new} (P_{old}^{-1} (\bar{\mathbf{x}}_{old} - \mathbf{x}^*) + T_{new}^T Q_{new}^{-1} \mathbf{r}_{new}) \quad (3.83)$$

If the reference state ($\mathbf{x}^*$) has converged to a solution, the new estimate of the state is as shown in Equation 3.84.

$$\bar{\mathbf{x}}(t_0) = \mathbf{x}^*(t_0) + \delta\mathbf{x}(t_0) \quad (3.84)$$

The entire sequential estimation process can be summarized using Equations 3.81, 3.83, and 3.84. Given the prior estimate of the state and the state covariance ($\bar{\mathbf{x}}_{old}$ and P_{old}) and a set of new observations ($\hat{\mathbf{O}}$) and associated covariance (Q), a new estimate can be determined.

3.3 Numerical Calculation of the Observation Matrix.

As seen in Section 3.2, the observation matrix is calculated using Equation 3.85.

$$T_i = H_i \Phi(t_i, t_0) \quad (3.85)$$

This is an $m \times n$ matrix where m is the number of observation measurements and n is the number of state elements. It relates the observations at time t_i to the state vector at the epoch time, t_0 . As discussed in Section 3.1, simplifications were made in the algorithm used to determine the state transition matrix ($\Phi(t_i, t_0)$). Because of these simplifications, we did not want to use Equation 3.85 to calculate T_i . Since the NORAD orbital model, SGP4 was available, a numerical method for calculating this matrix was used.

Given an observation consisting of four measurements and a state consisting of six elements, an expansion of Equation 3.85 becomes:

$$T_i = \begin{bmatrix} \frac{\partial O_1(t_i)}{\partial x_1(t_0)} & \frac{\partial O_1(t_i)}{\partial x_2(t_0)} & \frac{\partial O_1(t_i)}{\partial x_3(t_0)} & \frac{\partial O_1(t_i)}{\partial x_4(t_0)} & \frac{\partial O_1(t_i)}{\partial x_5(t_0)} & \frac{\partial O_1(t_i)}{\partial x_6(t_0)} \\ \frac{\partial O_2(t_i)}{\partial x_1(t_0)} & \frac{\partial O_2(t_i)}{\partial x_2(t_0)} & \frac{\partial O_2(t_i)}{\partial x_3(t_0)} & \frac{\partial O_2(t_i)}{\partial x_4(t_0)} & \frac{\partial O_2(t_i)}{\partial x_5(t_0)} & \frac{\partial O_2(t_i)}{\partial x_6(t_0)} \\ \frac{\partial O_3(t_i)}{\partial x_1(t_0)} & \frac{\partial O_3(t_i)}{\partial x_2(t_0)} & \frac{\partial O_3(t_i)}{\partial x_3(t_0)} & \frac{\partial O_3(t_i)}{\partial x_4(t_0)} & \frac{\partial O_3(t_i)}{\partial x_5(t_0)} & \frac{\partial O_3(t_i)}{\partial x_6(t_0)} \\ \frac{\partial O_4(t_i)}{\partial x_1(t_0)} & \frac{\partial O_4(t_i)}{\partial x_2(t_0)} & \frac{\partial O_4(t_i)}{\partial x_3(t_0)} & \frac{\partial O_4(t_i)}{\partial x_4(t_0)} & \frac{\partial O_4(t_i)}{\partial x_5(t_0)} & \frac{\partial O_4(t_i)}{\partial x_6(t_0)} \end{bmatrix} \quad (3.86)$$

The elements of this matrix could be calculated numerically by using the definition of a derivative. The definition of a derivative results in the evaluation of the $[i, j]$ element of T_i as shown in Equation 3.87.

$$\frac{\partial O_j(t_i)}{\partial x_k(t_0)} = \lim_{\Delta x_k \rightarrow 0} \frac{O_j(\mathbf{x}(t_0) + \Delta x_k(t_0), t_i) - O_j(\mathbf{x}(t_0), t_i)}{\Delta x_k(t_0)} \quad (3.87)$$

If Equation 3.87 is evaluated, not as $\lim_{\Delta x_k \rightarrow 0}$, but as Δx_k approaches an incrementally small value, the elements of the observation matrix, T_i , can be expressed as:

$$\frac{\partial O_j(t_i)}{\partial x_k(t_0)} \cong \frac{O_j(x(t_0) + \Delta x_k(t_0), t_i) - O_j(x(t_0), t_i)}{\Delta x_k(t_0)} \quad (3.88)$$

3.4 Variance Reduction Techniques

We considered two variance reduction techniques available for our use. The first technique uses common random numbers (CRNs). The second technique uses antithetic variates which are random numbers that come in pairs such that they cancel out their effects when averaged. For an excellent source on the subject of variance reduction see (21:Chapter 11). The following is a brief overview of these two techniques.

3.4.1 Common Random Numbers (CRNs). Common random numbers is a variance reduction technique applicable to experimental testing of different system configurations. The general principle behind the application of CRNs is that differences in performance between alternate combinations, or system configurations, of an experiment should be due to differences only in the system configurations and not in the experimental conditions. Therefore, the different system configurations should be tested under as close to identical experimental conditions as possible. In simulation, the experimental conditions are the random variates generated for use in the model (21:613-614).

The ideal use of CRN is to use the same random number, or random number stream, for exactly the same purpose in one system configurations test as another. This is called "synchronization." This synchronization gives you a high confidence that the difference in performance between different system configurations is due only to the different configurations, and has no contribution inserted due to different experimental conditions (generated random variates) (21:617).

3.4.2 Antithetic Variates (AVs). Antithetic variates is a variance reduction technique applicable to a single system configuration. The general principle of AVs is to perform experimental test on the system in pairs such that an observation on one run is negatively correlated to an observation on the other run. If the two observations are then

averaged and the single data point used in the analysis, that data point should be closer to the expected value of that observation than if the two observations were independent (21:628-629).

AV attempts to include a negative correlation by using complementary pairs of random numbers. For example, if the first random number of a pair was a uniform 0 to 1 random number (U_k), the second number in the pair, its complement, would become $1 - U_k$ where the subscript k represents a particular uniform random number observation. The fundamental requirement that a model should satisfy for AVs to work is that its response to a random number used for a particular purpose be monotonic, in either direction. As in CRN, synchronization must also be applied (21:629-630).

IV. METHODOLOGY

The basic methodology we used in this research and analysis consisted of a four-step process:

1. Perform an analysis of the earth's satellite population in order to select a representative sample of satellites for analysis.
2. Develop a "truth model" to produce highly accurate, simulated SSN sensor observations of the sample satellites.
3. Develop a differential corrector to correct the satellites orbital elements, and calculate the vector magnitude of the error between the "truth" position and the position predicted by the USSPACECOM/NORAD orbital model. Run this model for each of the representative satellites using different observations rates and correction intervals.
4. Perform a statistical analysis on this data trying to determine a steady-state position error for different observation rate/correction interval combinations.

4.1 Analysis of Earth Satellite Population

There are two primary reasons for analyzing the satellite population. The first reason is to characterize the composition of earth orbiting objects as completely as possible. Prior to undertaking any analysis of earth orbiting satellites, an understanding of their characteristics and composition is essential. The second reason for performing this analysis is to be able to develop an initial classification scheme to allow the selection of a representative sample of satellites for further analysis as part of this research effort.

4.1.1 Satellite Composition Analysis. We chose to examine the composition of the most current NORAD two-line element set file available to us. This was the March 1990 two line element set file (1990.TLE). To do this, a FORTRAN program, REDUCE.TLE.FOR, was written to select the first occurrence of each satellite's two line element set from this file and to output it into a Mathematica readable file OE9003.FIX. The OE9003.FIX file contains this first occurrence of each satellite in the 1990.TLE file unless it does not pass a

series of simple tests as summarized in Appendix F.3.¹ Each entry into the OE9003.FIX file contains the epoch, a counter number, the NORAD catalog number, and the nine orbital elements from the NORAD two-line element set: Kozai mean motion (n_k), the first time derivative of mean motion divided by two ($\dot{n}/2$), the second time derivative of mean motion divided by six ($\ddot{n}/6$), inclination (i_0), node (Ω_0), argument of perigee (ω_0), eccentricity (e_0), bstar (B^*), and finally the mean anomaly at epoch (M_0).

Once in Mathematica-readable format, we processed graphs of each of the above elements and variables that are derivable from the ones provided, such as the true anomaly. The main purpose of the graphs was to allow easy examination of the distributions of each variable. We were especially interested in two areas: correlations between any two orbital elements and how the satellite population fell into the various Giabbard classes. On occasion we generated plots showing the relationships between three variables. In particular, we used 3 variable plots to determine if there is a relation between B^* and the $\dot{n}/2$ and $\ddot{n}/6$ terms. However, the problem with this investigation was attempting to see a three-dimensional space which was limited to a two-dimensional sheet of paper.

4.1.2 Perturbations Analysis. Since the J_2 perturbations are the primary source of perturbing effects on most earth orbiting satellites, this was the only perturbation effect analyzed. We wanted to identify the magnitude of this perturbation effect on the satellites in the current population. As shown in Section 3.1.1, the only three orbital elements affected by J_2 perturbations are the mean anomaly, argument of perigee, and ascending node. The time derivatives of these three elements were plotted as a function of the elements that affect the magnitude of the perturbations (mean motion, eccentricity, and inclination). These plots allowed us to visualize the relative perturbing effects on the satellites in the current population.

In addition, a propagation routine for the differential corrector model was required. This routine had to perform two functions. First, determine the orbital elements after some propagation time given the elements prior to propagation. Second, determine the state covariance matrix after a given propagation time given the state covariance prior to

¹The satellites in the OE 9003 FIX file are henceforth referred to as the "Current Population."

propagation. As shown in Section 3.1.1, after deriving the secular time-rate-of-change of each orbital element, it was possible to analytically integrate the equations with respect to time. This allows the expression of the orbital elements as a function of time. By differentiating these expressions with respect to the orbital elements, it is possible to find the state transition matrix as a function of time.

Had this not been possible, we would have been forced to perform a numerical integration routine to find the elements and state-transition matrix after some propagation time. We decided that an analytic approach was preferable over a numeric approach due to the computational time involved.

4.1.3 Classification Scheme Development. An orbital-element-based classification scheme was developed based on both the analysis of the current composition of satellites and the analysis of the effect of J_2 perturbations. The classes were based strictly on only the three orbital elements that influence the magnitude of the J_2 perturbations. The code that performed the actual separation of all satellites in the current population into their respective classes was the same code that decoded the 1990.TLE file.

A basic assumption made in the development of this classification scheme is that that satellites with similar perturbation effects would have similar observation requirements for maintaining the orbital element sets.

4.1.4 Representative Satellite Selection. After the satellite population was divided into their various classes, we selected a representative satellite from each class. The satellite closest to the "average" satellite was selected. To determine which satellite was closest to the average, the mean and variance of each class was calculated for the relevant orbital elements. Then, the deviation from the mean of each orbital element was weighted by the variance of the element (smaller variances having larger significance). We selected the satellite with the smallest overall deviation as our representative satellite. In other words, to make our selection we formed an n dimensional Gaussian distribution, and determined which satellite occurred closest to the mean.

4.2 SGP Program Library

In an attempt to simulate the methods used by USSPACECOM as closely as possible, we used the SGP4 and SDP4 orbital models in use by USSPACECOM. The specific models used throughout this research come from the SGP program library. This library contains a set of Turbo Pascal² 6.0 units and documentation written by Dr. Thomas S. Kelso (19). The main components of this library are the SGP4 and SDP4 orbital models which were converted from NORAD FORTRAN code as published in Reference (16). The remaining units contain routines that are either necessary for SGP4's operation or aid in interfacing SGP4 with both the truth model programs and the dynamics model programs. The library consists of the following units:

- *SGP4SDP4*. Full implementation of NORAD SGP4 and SDP4 models.
- *SGP_INIT*. Contains constants, variables, and type declarations needed to initialize *SGP4SDP4*.
- *SGP_INTF*. Constants, variables, and type declarations needed to interface between *SGP4SDP4* and *SGP_CONV* (and other programs).
- *SGP_MATH*. Various trigonometric and mathematical routines.
- *SGP_TIME*. Time based routines for converting among time systems.
- *SUPPORT*. General support routines for machine dependent features.
- *SGP_CONV*. Routines for converting two line data and SGP4 state vectors.
- *SGP_IN*. Routines to simplify input of data (with error checking).
- *SGP_OUT*. Routines to output program results in standard formats.
- *SGP_OBS*. Observer dependent routines for calculating topocentric information.
- *MINMAX*. Minimum/maximum functions.
- *SOLAR*. Routines for calculating the position of the sun and if a satellite is in earth umbral eclipse.

²Turbo Pascal is a trademark of Borland International

A copy of the complete SGP Library Documentation is located in Appendix A. The source code listings of all SGP Library routines used in this research are in Appendix B.

4.3 Truth Model

The purpose of the "truth model" is to produce highly accurate "truth" observations. These observations are used to simulate the observations gathered by sensors of the SSN for a specific earth-orbiting satellite. To allow a Monte Carlo analysis, the model is capable of producing multiple random sets of observations at various specified observations rates. The methodology used in the selection of the number of random sets and observation rates is presented in Section 4.5.

4.3.1 Model Development. The primary element required for this truth model is a highly accurate orbital propagator. A commercially available orbital model, the High Precision Orbit Propagator (HPOP) program, Version 1.1, produced by Microcosm, Inc. of Torrance, CA was used for our research. HPOP uses the Runge-Kutta-Fehlberg method of order 7(8) to integrate the equations of motion. It also includes accurate models for all of the major perturbations affecting an earth-orbiting satellite and all major predictable motions of the earth that affect a satellite's apparent position (15:1-2). These perturbation models include:

- Geopotential effects. Uses an unclassified 21×21 spherical harmonic expansion model (Goddard Earth Model 10B) of the earth geopotential.
- Solar and lunar gravitational effects. Assumes point masses and uses the U.S. Naval Observatory compressed ephemeris to predict the positions of the sun and moon.
- Atmospheric drag. Assumes single-collision specular reflection and uses the Harris-Priester atmospheric model, modified to take into account the diurnal bulge, to compute the atmospheric density.
- Solar radiation pressure.
- Precession of the equinox.
- Nutation.

- Diurnal rotation.
- Barycentric displacement.

The HPOP model produces highly accurate earth centered inertial (ECI) position and velocity vectors, at specified time intervals, over a specified length of time, for a given input ECI state vector. However, our research uses a satellite orbital element set, not an ECI state vector, as the initial data point. Additionally, our research needs the model output expressed as sensor observation data (azimuth or right ascension, elevation or declination, range, and range rate), not ECI state vectors. Three Turbo Pascal interface programs, HPOP_IN, CONVERT, and RSELECT, written by Dr. Thomas S. Kelso, were provided to translate HPOP data into the formats required for our research.

HPOP_IN uses SGIP Library routines, primarily the procedures of SGP4 and SDP4 in the unit *SGP4SDP4*, to convert satellite orbital element set data into an ECI position and velocity state vector. It places this data, along with the specified interval for propagation and the propagation step size, into the input format required for HPOP.

CONVERT converts each of the HPOP "truth" ECI position and velocity vectors into SSN sensor observations (e.g., time, azimuth, elevation, range, range rate) given the SSN sensor locations, observational limitations, and data types. For our research, the SSN locations, limitations, and data types used are listed in Tables 2.2, 2.3, and 2.15 respectively. CONVERT uses the SGIP library procedure *Calculate_Obs* or *Calculate_RADec* from the unit *SGP_OBS*, to perform the ECI to topocentric coordinate transformation of the ECI position and velocity vectors to either azimuth, elevation range and range rate observations or right ascension and declination observations. Additionally, CONVERT incorporates the effects of atmospheric refraction on the different types of observations.

RSELECT uses the observation file created by CONVERT and performs three functions: indexes the file by day of observation, adds random noise to the individual observations, and generates random observation files based on the required maximum number of observations per day and random observation sets.

To make the random selection, RSELECT first indexes the observation file to separate the observations by day. Based on the required number of observations per day, RSELECT

then creates the files by randomly selecting observations based on the required *maximum* number of observations per day.

To reduce the variance in the observations, these observation sets are inclusive. For example, the observations which would be included in the 2 observations-per-day set are included in the 4, 6, 8 and 10 observations-per-day set. Likewise, the two additional observations used to make the 4 observations-per-day set from the 2 observations-per-day set are used in the 6, 8, and 10 observations-per-day sets. This process is continued until the last two random observations chosen are added to only the 10 observations-per-day set.

Based on the required number of random sets, RSELECT uses a different random number seed to select observations from the indexed days. The seed numbers were created using the SLAM simulation software (28). These seed numbers were then hard coded into the Turbo Pascal unit *Gauss2*. This unit uses a numerical procedure to create a Gaussian random number with a mean of zero based on the input seed number (27:213-237). This random number process is located in a function called *GRandom* and used by RSELECT. The purpose of this random number process is twofold: specific seed numbers allow for repetition of results while still inducing a random process into the observation processing methodology.

In addition to the observation conversion and selection process performed in CONVERT and RSELECT, these programs also pass, unchanged, the ECI position vector produced by HPOP. This vector is used within the differential corrector to calculate the vector magnitude of the true position error (VMAGT).

When combined, these four truth model programs take a satellite orbital element set and create from it a specified number of sets of random observations at various specified observation rates. The flow of the truth model is shown in Figure 4.1.

4.3.2 Model Execution. The elements of the truth model are executed to flow as shown in Figure 4.1. A description of the execution method and input/output file formats for each of the elements of the truth model follows.

Figure 4.1. Truth Model Flow.

4.3.2.1 HPOP_IN. The program HPOP_IN accepts as input a *.2LE file containing at least one two line element set of the format seen in Appendix F.6. It utilizes a user-friendly windows-style interface to allow easy selection of the *.2LE input file, the propagation step size, and the time interval for propagation. Its output consists of SV-satnr.els files, where SV- indicates a "state vector" file, and satnr and els indicate respectively, the satellite and element set number used to create the position/velocity state vector. HPOP_IN creates this file, formatted as seen in Appendix C.2, for each of the two line element sets in the input *.2LE file. The Turbo Pascal source code listing for this program is in Appendix C.1

4.3.2.2 HPOP. HPOP accepts as input the SV-satnr.els state vector file, produced by HPOP_IN. It is executed using the following execution command format:

`hpop < SV-satnr.els > PV-satnr.els`

where PV- indicates the HPOP created output file containing the propagated, time-tagged, ECI position and velocity vectors for the input satellite data. Reference Appendixes C.2 and C.3 for the format and an example of HPOP input files. A sample of an HPOP output file is in Appendix C.4.

4.3.2.3 CONVERT. This program accepts as input the HPOP created PV-satnr.els file of the format seen in Appendix Section C.4. It reads data from a *.OBS file containing SSN sensor locations and a *.LIM file containing SSN sensor observation limits. It uses a user friendly windows style interface allowing easy selection of the *.OBS, and *.LIM data files, and the PV-satnr.els input file. Its output consists of an OB-satnr.els file, formatted the same as the RSELECT output sample shown in Appendix Section C.8, containing the observing sensor, observation time, observations (azimuth or right ascension, elevation or declination, range, and range rate), and the truth ECI position (X, Y, and Z). The Turbo Pascal source code for this program is located in Appendix C.5.

4.3.2.4 RSELECT. This program accepts as input a CONVERT created OB-satnr.els file. It uses a user friendly windows-style interface allowing easy selection of this

input file. The maximum observation rate and number of random sets of observations desired are entered as command line parameters in the following format:

RSELECT nn mm

where nn is the maximum observation rate (even number of observations/day) desired and mm is the number of sets of random observations (1 to 26) desired. It's output consists of mm different RO-satnr.nnX files for each of nn/2 different observation rates. In this file name nn indicates the observation rate and X is an alphabetic index (A, B, C, ..., Z) corresponding to different randomly-selected sets of observations. For example, if a maximum observation rate of 10 per day (nn = 10) and 10 random sets (mm = 10) is specified, RSELECT will create 10 random observation files (A through J) each for observation rates 2, 4, 6, 8, and 10. The output is formatted the same as shown in Appendix C.8. The Turbo Pascal source code listing of this program is in Appendix C.6.

4.3.3 Model Verification. The truth model was verified as two components. The first component was the HPOP program itself. The second component consisted of the three Turbo Pascal interface programs, HPOP IN, CONVERT, and RSELECT.

The HPOP program is an off-the-shelf, commercial, orbital propagation program. The accuracy of the program was advertised to be on the order of 12 meters or better (1:5:1). However, we had no means available to verify this level of accuracy. To test the program, ECI position and velocity vectors from HPOP were compared to the output of SGP4/SDP4 for various test satellites. The results of this comparison indicated the level of accuracy would be sufficient for the purpose of our research. This program may be replaced by some other special perturbations code if it cannot be validated as suitable for this purpose.

The HPOP IN, RSELECT, and CONVERT programs were verified by Dr. Kelso prior to our use. However, to ensure proper performance of the programs, we stepped through each procedure and watched execution using the debug capability of Turbo Pascal.

4.4 Differential Corrector

The purpose of this model is to differentially correct the orbital elements for a satellite using observations created from the truth model, and output a time-tagged vector magnitude of the error between the "truth" position and the calculated, or predicted, position (VMAGT) for each observation. The specific elements corrected will be from the NORAD two-line element set: bstar (B^*), inclination (i_0), right ascension of the ascending node (Ω_0), eccentricity (e_0), argument of perigee (ω_0), mean anomaly (M_0), and mean motion (n_0). Because the results from this model will be compared to actual data from USSPACECOM, the model will attempt to model the composition and characteristics of the SSN as realistically as possible. Additionally, it will use the same SGP4/SDP4 orbital models used by USSPACECOM.

4.4.1 Model Development. The differential corrector was coded using Turbo Pascal, Version 6.0, primarily due to the existence of the SGP Libraries' validated Turbo Pascal code for the USSPACECOM/NORAD orbital models, SGP4 and SDP4 (presented in Section 4.2). This model consists of two primary elements: the actual differential corrector (DC) algorithm and the orbital element/covariance-propagation algorithm. Additionally, various secondary elements providing for the input and output of required data and variable initialization and manipulation are included in the model.

Upon initiation, the model first reads the data files containing the SSN sensors location data (latitude, longitude, and altitude) and weighting data (observation sigmas) as presented in Tables 2.2 and 2.6. The estimated state is initialized to the same orbital elements used to initialize the truth model. The estimated state covariance matrix is also initialized.

It was necessary to "guess" a value of the initial state covariance estimate which would give some confidence in the initial state estimate² and keep the "start up" time to a reasonable level. However, we did not want to give too much confidence in the state estimate and prevent the model from correcting the elements. After examination of the covariances of various test satellites, a value of 1.0×10^{-7} was chosen. For simplicity, a

²The same elements used to generate the truth observations were input as the initial state estimate

diagonal matrix was used and coded to allow easy changes if results showed that the initial "guess" was severely affecting the "start-up" time.

Once the initializations are complete, the first batch of observations is read into the program. The batch size (number of observations used in one correction) is equal to the product of the specified observation rate in observations per day (OPD), and the specified correction interval, or length of update interval (LUPI), in days. For example, given an OPD of 4 (observations-per-day) at a LUPI of 2 (days), the batch size would be 8 observations. As the observations are input, a check is performed to determine the observation type (reference Table 2.15) based on the sensor reporting the observation.

The predicted VMAGT for each observation is then calculated. The observation time and the current state estimate is passed to SGP4/SDP4, which calculates a predicted ECI position (r_x, r_y, r_z) . VMAGT is calculated as the simple vector magnitude of the difference between the this ECI position and the truth ECI position $(r_{x_t}, r_{y_t}, r_{z_t})$ as shown in the following equation.

$$\text{VMAGT} = \sqrt{(r_{x_t} - r_x)^2 + (r_{y_t} - r_y)^2 + (r_{z_t} - r_z)^2} \quad (4.1)$$

The estimated state and covariance are then propagated to the new epoch time. The time of last ascending node passage prior to the last observation processed was chosen as the new epoch time because this is how USSPACECOM propagates the majority of satellite epochs (24:259). Because of simplifications used in the development of the propagation routine, described in detail in Section 4.4.1.2 below, we expected the model to induce some error in the propagated state and covariance. Because of this known source of error, the estimated state and covariance were propagated prior to differential correction. This allowed the DC to correct the errors induced by the propagation routine and provide the "best" possible estimate for the calculation of VMAGT.

A batch of observation data and the propagated state and covariance are passed to a differential correction routine, described in detail in Section 4.4.1.1 below. Upon convergence, the DC returns a corrected state and covariance, which are then declared the new estimates. Another set of VMAGTs is calculated for the current observation batch

based on the newly corrected state. While this data is not used in the analysis, it is useful as a check to ensure the DC is providing "good" corrections. The flow of the dynamics model is shown in Figure 4.2.

4.4.1.1 Differential Correction Algorithm. As explained in Section 2.9 above, USSPACECOM uses a combination of sequential and batch correction methods to correct satellite orbital elements. In this research, we simplified the correction methodology to use only a Bayes, sequential estimation, correction method as presented in Section 3.2.

The correction routine begins when passed the current estimated state, $\hat{\mathbf{x}}$, and covariance along with a batch of observations, $\hat{\mathbf{O}}_i$. These observations are indexed by time and the sensor producing the observations. A reference state, $\mathbf{x}^*$, is set equal to the current estimated state, $\hat{\mathbf{x}}$. For each observation time t_i , a predicted set of observations, $\mathbf{O}_i$, is calculated using SGP4/SDP4. SGP4/SDP4 calculates the predicted observations as a function of t_i and the current reference state, $\mathbf{x}^*$.

$$\mathbf{O}_i = \mathbf{O}_i(\mathbf{x}^*(t_0), t_i) \quad (4.2)$$

The residual vector, $\mathbf{r}_i$, is then calculated as shown in Equation 4.3.

$$\mathbf{r}_i = \hat{\mathbf{O}}_i - \mathbf{O}_i \quad (4.3)$$

An observation matrix T_i is then calculated for each t_i . Because the sensors of the SSN report different types of observations (reference Section 2.8), T_i could take on different dimensions for each of the different observation types reported. The SSN sensors we modeled only report three observations types: Three, Two, and Five (reference Section 2.8).

For computational simplicity, T_i was given a constant dimension (4x7) based on Observation Type Three, which reports largest set of data (azimuth, elevation, range, and range rate). The observation matrix for Type Three observations is shown below in

Figure 4.2. Differential Corrector Model Flow.

Equation 4.4.

$$T_i = \begin{bmatrix} \frac{\partial Az(t_i)}{\partial B_0^*} & \frac{\partial Az(t_i)}{\partial i_0} & \frac{\partial Az(t_i)}{\partial \Omega_0} & \frac{\partial Az(t_i)}{\partial e_0} & \frac{\partial Az(t_i)}{\partial \omega_0} & \frac{\partial Az(t_i)}{\partial M_0} & \frac{\partial Az(t_i)}{\partial n_0} \\ \frac{\partial El(t_i)}{\partial B_0^*} & \frac{\partial El(t_i)}{\partial i_0} & \frac{\partial El(t_i)}{\partial \Omega_0} & \frac{\partial El(t_i)}{\partial e_0} & \frac{\partial El(t_i)}{\partial \omega_0} & \frac{\partial El(t_i)}{\partial M_0} & \frac{\partial El(t_i)}{\partial n_0} \\ \frac{\partial \rho(t_i)}{\partial B_0^*} & \frac{\partial \rho(t_i)}{\partial i_0} & \frac{\partial \rho(t_i)}{\partial \Omega_0} & \frac{\partial \rho(t_i)}{\partial e_0} & \frac{\partial \rho(t_i)}{\partial \omega_0} & \frac{\partial \rho(t_i)}{\partial M_0} & \frac{\partial \rho(t_i)}{\partial n_0} \\ \frac{\partial \dot{\rho}(t_i)}{\partial B_0^*} & \frac{\partial \dot{\rho}(t_i)}{\partial i_0} & \frac{\partial \dot{\rho}(t_i)}{\partial \Omega_0} & \frac{\partial \dot{\rho}(t_i)}{\partial e_0} & \frac{\partial \dot{\rho}(t_i)}{\partial \omega_0} & \frac{\partial \dot{\rho}(t_i)}{\partial M_0} & \frac{\partial \dot{\rho}(t_i)}{\partial n_0} \end{bmatrix} \quad (4.4)$$

The observation matrix for Type Two observations (azimuth, elevation, and range) will contain a row of zeros as shown below in Equation 4.5.

$$T_i = \begin{bmatrix} \frac{\partial Az(t_i)}{\partial B_0^*} & \frac{\partial Az(t_i)}{\partial i_0} & \frac{\partial Az(t_i)}{\partial \Omega_0} & \frac{\partial Az(t_i)}{\partial e_0} & \frac{\partial Az(t_i)}{\partial \omega_0} & \frac{\partial Az(t_i)}{\partial M_0} & \frac{\partial Az(t_i)}{\partial n_0} \\ \frac{\partial El(t_i)}{\partial B_0^*} & \frac{\partial El(t_i)}{\partial i_0} & \frac{\partial El(t_i)}{\partial \Omega_0} & \frac{\partial El(t_i)}{\partial e_0} & \frac{\partial El(t_i)}{\partial \omega_0} & \frac{\partial El(t_i)}{\partial M_0} & \frac{\partial El(t_i)}{\partial n_0} \\ \frac{\partial \rho(t_i)}{\partial B_0^*} & \frac{\partial \rho(t_i)}{\partial i_0} & \frac{\partial \rho(t_i)}{\partial \Omega_0} & \frac{\partial \rho(t_i)}{\partial e_0} & \frac{\partial \rho(t_i)}{\partial \omega_0} & \frac{\partial \rho(t_i)}{\partial M_0} & \frac{\partial \rho(t_i)}{\partial n_0} \\ 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 \end{bmatrix} \quad (4.5)$$

The observation matrix for type five observations (right ascension and declination) will contain a two rows of zeros as shown below in Equation 4.6.

$$T_i = \begin{bmatrix} \frac{\partial \alpha(t_i)}{\partial B_0^*} & \frac{\partial \alpha(t_i)}{\partial i_0} & \frac{\partial \alpha(t_i)}{\partial \Omega_0} & \frac{\partial \alpha(t_i)}{\partial e_0} & \frac{\partial \alpha(t_i)}{\partial \omega_0} & \frac{\partial \alpha(t_i)}{\partial M_0} & \frac{\partial \alpha(t_i)}{\partial n_0} \\ \frac{\partial \delta(t_i)}{\partial B_0^*} & \frac{\partial \delta(t_i)}{\partial i_0} & \frac{\partial \delta(t_i)}{\partial \Omega_0} & \frac{\partial \delta(t_i)}{\partial e_0} & \frac{\partial \delta(t_i)}{\partial \omega_0} & \frac{\partial \delta(t_i)}{\partial M_0} & \frac{\partial \delta(t_i)}{\partial n_0} \\ 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 \\ 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 \end{bmatrix} \quad (4.6)$$

In this model, the elements of the observation matrix were calculated numerically using Equation 3.88, restated below, as presented in Section 3.3.

$$\frac{\partial O_j(t_i)}{\partial x_k(t_0)} \approx \frac{O_j(\mathbf{x}(t_0) + \Delta x_k(t_0), t_i) - O_j(\mathbf{x}(t_0), t_i)}{\Delta x_k(t_0)} \quad (4.7)$$

The incrementally small Δx_k values used were experimentally determined by comparing the significant figures in the SGP4/SDP4 calculated observations shown below.

$$O_j(x(t_0), t_i) \quad (4.8)$$

and

$$O_j(x(t_0) + \Delta x_k(t_0), t_i) \quad (4.9)$$

The matrix sums $T_i^T Q_i^{-1} T_i$ and $T_i^T Q_i^{-1} r_i$ are then calculated for each t_i . The sensor covariance matrix, Q_i , is dependent on the sensor reporting the observations. As with the T_i matrix, it will be a different dimension based on the observation type of the sensors, but for the purpose of this model is held at a constant dimension (4x4). Equations 4.10, 4.11, and 4.12 show the weighting matrix for Observation Type Three, Two, and Five, respectively.

$$Q_i = \begin{bmatrix} \sigma_{A_{t_i}}^2 & 0.0 & 0.0 & 0.0 \\ 0.0 & \sigma_{E_{t_i}}^2 & 0.0 & 0.0 \\ 0.0 & 0.0 & \sigma_{r_i}^2 & 0.0 \\ 0.0 & 0.0 & 0.0 & \sigma_{r_i}^2 \end{bmatrix} \quad (4.10)$$

$$Q_i = \begin{bmatrix} \sigma_A^2 & 0.0 & 0.0 & 0.0 \\ 0.0 & \sigma_{E_{t_i}}^2 & 0.0 & 0.0 \\ 0.0 & 0.0 & \sigma_{r_i}^2 & 0.0 \\ 0.0 & 0.0 & 0.0 & 0.0 \end{bmatrix} \quad (4.11)$$

$$Q_i = \begin{bmatrix} \sigma_{A_{t_i}}^2 & 0.0 & 0.0 & 0.0 \\ 0.0 & \sigma_{r_i}^2 & 0.0 & 0.0 \\ 0.0 & 0.0 & 0.0 & 0.0 \\ 0.0 & 0.0 & 0.0 & 0.0 \end{bmatrix} \quad (4.12)$$

As the matrix sums $T_i^T Q_i^{-1} T_i$ and $T_i^T Q_i^{-1} r_i$ are calculated for each t_i , the running sums

$$\sum T_i^T Q_i^{-1} T_i \quad (4.13)$$

and

$$\sum T_i^T Q_i^{-1} r_i \quad (4.14)$$

are maintained.

After all observations have been processed. The new state covariance, P_{new}^{-1} , is calculated as shown in Equation 4.15.

$$P_{new}^{-1} = P_{old}^{-1} + \sum T_i^T Q_i^{-1} T_i \quad (4.15)$$

where P_{old}^{-1} is the old, or *a priori*, inverse state covariance.

The state correction estimate is then calculated as shown in Equation 4.16

$$\delta x(t_0) = P_{new} (P_{old}^{-1} (\bar{x}_{old} - x^*) + \sum T_i^T Q_i^{-1} r_i) \quad (4.16)$$

with the corrected reference state then being calculated as shown in Equation 4.17.

$$x_{k+1}^*(t_0) = x_k^*(t_0) + \delta x(t_0) \quad (4.17)$$

To prevent the DC from attempting to correct certain elements to a value outside their allowable range, some checks and limits routines were implemented. The three elements of concern were B^* , e_0 , and n_0 . First, a maximum absolute value of 1.0 was set for B^* . If this limit was exceeded, the corrected B^* value was reset to the uncorrected, or previous reference value. This value was chosen as a reasonable value based on the statistical analysis of the current population. Additionally, if this B^* limit is exceeded, B^* is removed from the RMS calculation for convergence.

The maximum limits for e and n were set based on Equations 4.18 and 4.19, which express the maximum value of one element as a function of the other.

$$e_{max}(n_0) = 1 - R_\oplus (n_0^2/\mu)^{1/3} \quad (4.18)$$

$$n_{max}(e_0) = (1 - e_0)^{3/2} \sqrt{\mu/R_\oplus^3} \quad (4.19)$$

A value of 0.0 was set as the lower limit for each of these elements. A check was first performed on e_0 . If outside these limits, the corrected e_0 was reset to the previous reference value. Similarly, if n_0 was outside these limits, the corrected value was reset to the previous reference value.

The correction is then checked for convergence. We used the weighted root mean square (RMS) of the calculated state corrections as shown in Equation 4.20.

$$RMS = \sqrt{\frac{\delta \mathbf{x}^T(t_0) P^{-1}(+) \delta \mathbf{x}(t_0)}{7}} \quad (4.20)$$

If the weighted RMS value is less than 0.01, the process is considered converged. The corrected reference state, $\mathbf{x}_{k+1}^*$, and corrected covariance, $P(+)$, are passed out of the differential correction routine and then declared the new estimates. If convergence is not declared, the differential process begins again using $\mathbf{x}_{k+1}^*$ as the new reference state.

4.4.1.2 Propagation Routine. Prior to performing differential correction, the epoch of the current estimated element set is moved to the time of the last ascending node crossing prior to the last observation processed. To do this, an analytic method was decided upon for computational efficiency and because this is how the majority of satellite epochs are propagated (24:259). Once propagated to the new time, the state covariance matrix is propagated to provide an estimate of how good the new state vector is.

The elements used by SGP are mean Keplerian orbital elements. The mean elements, in a sense, average out the perturbations over an orbit and, thus, are only accurate for longer-term predictions. To avoid any cumulative effects of propagating the orbit to any place in its path, the ascending node crossing is used to provide a consistent point to average

the orbit. This also reflects what is done by the SSC's current differential correction techniques as can be shown in Figures 5.8 thru 5.11. As can be seen, the sum of the true anomaly (ν) and the argument of perigee (ω) is fairly close to 0 or 2π only when the inclination and the eccentricity are close to 0 does the sum of the two appear to be fairly random. The divergence at higher eccentricities is due to convergence problems of extracting the true anomaly from the mean anomaly.

To propagate the mean Keplerian orbital elements, we decided to initially perform element propagation for J_2 perturbations only. Also, the air drag and resonance effects are not considered. Additionally, we made no attempt to incorporate the $\dot{n}$ and $\ddot{n}$ terms into the propagation. Section 3.1 explains the derivation of the propagated elements and the state transition matrix.

Since the longest propagation time is going to be on the order of ten days, the exclusion of the resonance terms is expected to have only a small impact. For satellites in a very low orbit, the assumption that there is no air drag is not expected to be a good one. To account for the dynamics model errors, a de-weighting or forgetting factor is used in deciding how good the estimate is. The forgetting factor is actually a 7×7 matrix that is a function of propagation time. Additionally the forgetting factor could be modified to account for the air drag and resonance shortcomings of the propagator. However, we decided against implementing this due to our time restrictions. We made another simplification in our model to assume the forgetting matrix was a diagonal matrix with all the elements being identical, this effectively reduces our forgetting matrix into a forgetting scalar. Reference (24:202) provides the baseline forgetting scalar, used by USSPACECOM, that we will use, providing it does not over emphasize or deemphasize the estimate. Over emphasis will manifest itself as an estimate which refuses to change thus the first and last pass residuals grow. Over deemphasis will be estimates which fluctuate wildly. The last pass residuals will be low but first pass residuals will be high.

4.4.2 Model Execution. The primary program implementing this model is called DIFC. Six additional Turbo Pascal units provide routines necessary to support the main

program DIFC. Source code listings for these units, described below, can be found in Appendix D.

- *DC_INIT*. Unit containing constants, variables, and declarations needed to initialize the DC and interface the DC with the other routines.
- *DC_CALC*. Unit containing routines for performing the differential correction calculations and variable manipulations required by DC.
- *PROP*. Unit containing routines for propagating the elements and their covariance.
- *LOWB*. Unit containing routines for reading SSN sensor locations and weights data.
- *DC_OUT*. Unit containing routines to output program results in standard formats.

DIFC accepts as input a *2LEsatnr.DAT* file containing the initial estimated state (orbital elements), a *COV'satnr.DAT* file containing the initial estimated state covariance, and a *RO-satnr.nnX* file, specified in a command line parameter, containing random observations. Recall that this file contains random observation set *X*, at observation rate *nn*, for satellite *satnr*. DIFC automatically reads the *SENSORS.OBS* and *SENSORS.COV* data files containing the SSN sensor location and weighting data. The correction interval and desired number of corrections are specified as command line parameters in the following format:

DIFC RO-satnr.nnX aa bb

where *aa* is the desired correction interval in days and *bb* is the desired number of corrections to be performed. Be aware that the product *aa* $\times$ *bb* must be less than the total number of days of observation data in the *RO-satnr.nnX* file.

DIFC outputs three different files:

- File *Fsatnrnn.aaX* containing observation time (expressed in days since epoch of the original estimate elset) and the VMAGT prior to differential correction.
- File *Lsatnrnn.aaX* containing observation time (expressed in days since epoch of the original estimate elset) and the VMAGT after differential correction.

- File `Rsatnrnn.aaX` containing error flags, initial and corrected elements and covariances, and any other information not directly required for the statistical analysis, but of possible use in analyzing adverse or interesting trends appearing in the data.

where `satnr` indicates the satellite number, `nn` indicates the observation rate in obs/day, `aa` indicates the correction interval in days, and `X` is an alphabetic index corresponding to different random observation sets.

4.4.3 Model Verification. Verification of program algorithms and data flow were performed by checking sample case calculations with either independent programs or hand calculation. The following verification procedures were used:

- **Matrix and Vector Operations.** Intensive verification of all matrix and vector operations used within our differential corrector model was performed using the MatLab⁴ numeric computation software package, QuatroPro⁵ spreadsheet calculation software, and in some cases hand calculations. Test routines were placed in the program to print the values of matrix and vector elements prior to, and following, all operations. These same input values were used to perform the same matrix or vector operations using one or both of the software packages discussed above. This procedure was performed several times, for different test cases, throughout the development of the model.
- **Numerical Calculation of Observation Matrix Elements.** Numerical accuracy of the variables used to calculate the elements of the observation matrix were verified manually. Test routines were placed in the programs to print the values of the variables used to calculate the elements of the T_i matrix ($O_j(\mathbf{x}(t_0), t_i)$, $O_j(\mathbf{x}(t_0) + \Delta \mathbf{x}_i(t_0), t_i)$, and $\Delta \mathbf{x}_i(t_0)$). The number of significant digits present in the difference calculations were examined.
- **Dynamics Model Flow.** The proper data flow of information in the program, as well as the input and output of data by the program was verified by examining

⁴MatLab is a trademark of The MathWorks, Inc.

⁵QuatroPro is a trademark of Borland International.

various test print routines and performing a line by line program trace monitoring various variables. This procedure was performed several times, for different test cases, throughout the development of the model.

4.5 Statistical Analysis.

The overall purpose of this research is to develop and demonstrate a model from which the effects of observation rate and update intervals on the accuracy of an orbital element set can be determined. Therefore, the purpose of this analysis is to see if the steady-state VMAGT value can be determined for the various observation rate update interval combinations tested, and if the value can be determined, show how observation rate and update interval affect it. The following sections will review how the values of observation rate and correction interval tested were determined, how the number of Monte Carlo runs was determined, and discuss the variance reduction and data analysis techniques used.

4.5.1 Observation Rate/Update Interval Selection. The differential corrector model will be run using various observation rates and correction interval combinations for various sample satellites. A review of the average observation rates recommended in the System Capability Study (reference Table 2.9) and used by the USSPACECOM tasking program, as described in Section 2.7, show required average observation rates of between one and five observations-per-day. A review of the typical observation tasking for routine satellites, as shown in Table 2.12, shows current observation tasking on routine satellites being between approximately four and nine observations-per-day. Based on these values, we chose to examine observation rates of two, four, six, and eight observations-per-day.

The SSC's automatic element set update process flags a routine satellite for a differential correction every 24 hours (reference Section 2.9.2.1). Based on this data, we decided to examine update intervals of two, four, six, and eight days.

4.5.2 Monte Carlo Analysis. One purpose of simulation is to thoroughly examine an alternative by generating values for the random variable at frequencies indicated by the

distribution of the random variable (20:494). Of interest to this research is the random variable representing the vector magnitude difference between the computed position and actual position of a satellite. This quantity is referred to as VMAGT. The measurement of this variable may be treated as a random variable because of the inaccuracies involved with the sensor devices. These inaccuracies are expressed as average error (bias) and standard deviation (sigma) and are sensor dependent. The result is a correctable measured position with a definable variation.

In order to gain some insight into the ability of our differential corrector to correct orbital elements, Monte Carlo simulations will run for the various combinations of correction interval (LUP1) and number of batches used for correction. Observations will be calculated for a period of 60 days. To test the ability of the differential corrector, a factorial experiment will be created. With correction intervals of every two, four, six, and eight days, this gives 30, 15, 10, or 7 batches, respectively. For each of these combinations, the differential corrector will be run based on an observation rate of two, four, six, and eight observations per day.

Of major concern to the simulation is the number of trials for each factor combination required to gather the necessary data. The very precision and reliability of the estimate is determined by the number of simulation trials. To estimate the number of trials, we utilized a method suggested by Lapin (20:508-509).

First, we *guessed* a value for the sample deviation. Based on the assumption of a uniform distribution, Lapin suggests the following rule of thumb for making such a guess:

$$\sigma_s = \frac{\text{Largest Value} - \text{Smallest Value}}{6} \quad (4.21)$$

Since the SSC flags observations for element set update if the position error is 14 kilometers or greater, we set our largest value to 14 km. The smallest possible value is 0 km and indicates a perfect prediction of the satellite position with respect to the measured position. Based on Equation 4.21, $\sigma_s = 2.333$ kilometers.

To determine n , the number of trials, the levels of precision (d) and reliability (z) must be established. Lapin defines precision as the maximum deviation from the true value

the experimenter is willing to accept. z is the normal deviate for the required reliability. Lapin provides, without proof, the following formula for determining the required number of trials:

$$n = \frac{z^2 \sigma_g^2}{d^2} \quad (4.22)$$

As an initial trial, we select a value for d , based on 10 percent of the largest value. Therefore, $d = 1.4$ kilometers. At the .90 reliability level, the normal deviate is $z = 1.65$. Based on these choices, Equation 4.22 gives a value

$$n = \frac{(1.65)^2 (2.333)^2}{(1.4)^2} = 7.56 \approx 8$$

At the .95 reliability level, $z = 1.96$ and the value for Equation 4.22 becomes $n = 10.67$. For the purpose of our Monte Carlo simulation, we chose to execute 10 runs for each case.

4.5.3 Variance Reduction. Of the two variance-reduction methods discussed in Section 3.4, the only variance-reduction technique we will use is common random numbers. As discussed in Section 3.4, a fundamental requirement for using AVs is that the random variables must be monotonic. After some inspection of our model, we determined the random numbers are not monotonic for the following reasons:

- For the observation selections, it is expected that an observation that fell relatively close in time to another in one replication, would not behave any differently in its antithetic pair replication since both observations would occur at a different time but still close to each other. The maximum benefit would occur if the observations were spread out (supposedly).
- For the observation noise, an error equally in one direction probably would not behave much differently than its antithetic pair observation. A negative large error would have an antithetic pair error of a large positive error — both impact the system

negatively. In general, observations closer to the mean behave better than ones more distant.

4.5.4 Data Analysis. The major measure of performance of the differential corrector model for the various satellite/LUPI/OPD combinations tested is the steady-state VMAGT value. To determine this value, the point at which steady-state was reached had to first be declared. This declaration was set at the 24th day unless a visual inspection of the raw data plotted with a four-day moving average showed that steady-state occurred later. From the point at which steady-state is declared, the VMAGT mean and variance for each of the 10 Monte Carlo runs was computed as shown in Equations 4.23 and 4.24

$$\overline{\text{VMAGT}}_x = E(\text{VMAGT}_x) = \frac{\sum_{i=1}^N \text{VMAGT}_{x,i}}{N} \quad (4.23)$$

$$\text{Var}(\text{VMAGT}_x) = \frac{\sum_{i=1}^N (\text{VMAGT}_{x,i} - \overline{\text{VMAGT}}_x)^2}{N - 1} \quad (4.24)$$

where x indicates the one of the 10 different Monte Carlo runs (A thru J), and N is the total number of VMAGT measurements taken since steady-state was declared for a given runs.

A 99 percent confidence level (99% CL) for each VMAGT ($99\text{CL}(\text{VMAGT}_x)$) was then calculated for each of the 10 runs as shown in Equation 4.25

$$99\text{CL}(\text{VMAGT}_x) = \overline{\text{VMAGT}}_x + 2.32635 \left(\sqrt{\text{Var}(\text{VMAGT}_x)} \right) \quad (4.25)$$

where 2.32635 represents the one-sided standard normal 99 percent confidence level.

Using variations of Equations 4.23 and 4.24 with the mean, variance, and 99 percent confidence level values calculated from all 10 Monte Carlo runs ($x = A$ through J), the following means and variances were then calculated:

$E(E(\text{VMAGT}_x))$	$\text{Var}(E(\text{VMAGT}_x))$
$E(\text{Var}(\text{VMAGT}_x))$	$\text{Var}(\text{Var}(\text{VMAGT}_x))$
$E(99\text{CL}(\text{VMAGT}_x))$	$\text{Var}(99\text{CL}(\text{VMAGT}_x))$

Recall that the $100(1 - \alpha)$ confidence interval for any value $Z(n)$ can be calculated as shown below:

$$E(Z(n)) \pm z_{\alpha/2} \left(\sqrt{\text{Var}(Z(n))} \right) \quad (4.26)$$

Using Equation 4.26 with $\alpha = 0.05$ ($z_{\alpha/2} = 1.96$) the 95 percent confidence intervals for $E(\text{VMAGT}_x)$, $\text{Var}(\text{VMAGT}_x)$, and $99CL(\text{VMAGT}_x)$ are calculated as shown in the three equations below:

$$E(E(\text{VMAGT}_x)) \pm 1.96 \left(\sqrt{\text{Var}(E(\text{VMAGT}_x))} \right) \quad (4.27)$$

$$E(\text{Var}(\text{VMAGT}_x)) \pm 1.96 \left(\sqrt{\text{Var}(\text{Var}(\text{VMAGT}_x))} \right) \quad (4.28)$$

$$E(99CL(\text{VMAGT}_x)) \pm 1.96 \left(\sqrt{\text{Var}(99CL(\text{VMAGT}_x))} \right) \quad (4.29)$$

The results from Equation 4.25 were also used in the performance of an analysis of variance (ANOVA). For each LUP/OPD/Monte Carlo run, the 99 percent CL was calculated. Using LUP and OPD as main effects, a two factor ANOVA was conducted on the 99 percent CL for each satellite. This analysis allowed quantitative determinations concerning the effects of LUP and OPD on observed VMAGT.

Once all of this statistical data is computed, the data from each sample satellite will be examined with respect to four performance measures:

1. "First-pass" VMAGT values
2. "Last-pass" VMAGT values
3. OPD effect on the 99 percent CL.
4. LUP effect on the 99 percent CL.
5. Statistical differences in OPD, LUP, and OPD/LUP interaction effects.

V. ANALYSIS OF EARTH SATELLITE POPULATION

The analysis portion of the earth satellite population was divided into four categories. The first section deals with the composition of the current population.¹ The second section deals with an analysis of the J_2 perturbations. The third section deals with the development of a satellite classification scheme based on orbital elements. The fourth section combines the results of population, J_2 , and classification analysis to select representative satellites based on our classification scheme.

5.1 Satellite Composition Analysis

Included in Appendix E are the various graphs which were developed as part of the satellite composition analysis. We have included the more interesting findings in this chapter. The analysis was done on the most current data available. Appendix F contains the code and some brief descriptions as to how the current satellite population data set was determined.

Table 5.1 shows the populations of each of the 32 Gabbard Classes. The most populous classes have altitudes less than 2000 km, except for Class 32, which includes the geosynchronous satellites, and Classes 17 and 26, which, in general, are transfer vehicles. Figure 5.1 shows the density of satellites in Classes 1-16.

It is difficult to make any conclusions about the distributions of satellites in the Gabbard classes. However, the relative numbers indicate most of the satellites fall into eight different classes.²

Besides the distributions of satellites in the Gabbard classes, we analyzed the distributions of the two-line elements in the current population. Table 5.2 gives the minimum, mean, median, and maximum for each of the orbital elements in the two-line element sets.

Figures 5.2 through 5.7 show the distributions of eccentricity, inclination, and Kozai mean motion. The distributions of the other elements are in Appendix E.

¹Current population refers to the first two line element set after 1 March 1990. The 1990 population is assumed to represent the current population of satellites.

²5108 satellites out of 6092 fall into eight classes.

Table 5.1. Satellite Population Within Each Gabbard Class.

Gabbard Class	Qty.	Pct. %	Apogee Altitude		Perigee Altitude

Figure 5.4. Frequency Histogram — Inclination.

Figure 5.5. Cumulative Distribution — Inclination.

Figure 5.6. Frequency Histogram -- Kozai Mean Motion.

Figure 5.7. Cumulative Distribution -- Kozai Mean Motion.

After examining the single variable cases we generated some two-variable plots. These plots show if there is a relation between any two orbital elements. For instance, Figure 5.8 shows a correlation between the argument of perigee and mean anomaly.

Figure 5.8. Scatter Plot - Argument of Perigee and Mean Anomaly.

Figure 5.9 shows that the correlation is even more pronounced when the mean anomaly at epoch is converted to the true anomaly at epoch.³

This correlation indicates the sum of the true anomaly at epoch and the argument of perigee is nearly constant. This finding is consistent with the ICACS procedure of propagating an orbit to its ascending node crossing. The only case where the ascending node crossing is not well defined is when the inclination is near zero. Figure 5.10 shows the relation between the inclination and the angular difference from the node.

As Figure 5.10 shows, most of the large deltas from the node occur at near zero inclination. There is error introduced by performing a power series expansion to change

³Some errors are introduced in extracting the true anomaly from the mean anomaly. The errors are greatest when eccentricity is large.

Figure 5.9. Scatter Plot -- Argument of Perigee and True Anomaly.

Figure 5.10. Scatter Plot Angle from Node and Inclination.

the mean anomaly into the true anomaly and this is more pronounced at the higher eccentricities. Figure 5.11 provides some idea as to how large the error is in the power series expansion.

Figure 5.11. Scatter Plot -- Angle from Node and Eccentricity.

When both sources of angular differences from the node are taken into account, there are very few satellites which are not at the ascending node.

Another interesting result is the relationship between eccentricity and the Kozai mean motion depicted in Figure 5.12. The triangular shape is due to the fact that for a particular orbit, the Kozai mean motion has a limited eccentricity, otherwise the orbit intersects the surface of the earth. Equation 5.2 (Figure 5.13) shows the relationship between the mean motion and eccentricity to have a closed orbit which does not intersect the earth's surface.

$$R_{perigee} = \left(\frac{\mu}{n^2} \right)^{1/3} (1 - e) \quad (5.1)$$

implies,

$$e \leq 1 - \left(\frac{n^2}{\mu} \right)^{1/3} R_{\oplus} \quad (5.2)$$

Since SGP4 does not use the time derivatives of mean motion which are contained in the NORAD two-line elements, $\dot{n}/2$ and $\ddot{n}/6$, we were interested in finding if there was some way of deriving the values of $\dot{n}/2$ and $\ddot{n}/6$ from bstar (B^*) and possibly other elements. Figure 5.14 shows there is no functional relationship between B^* , $\dot{n}/2$, and $\ddot{n}/6$.⁴ The fact there is no functional relationship was also confirmed by personal interview with a member of USSPACECOM/J3SOT (8). Without the hoped for functional relation between orbital elements to determine the time derivatives of the Kozai mean motion, we do not have any way of differentially correcting $\dot{n}/2$ and $\ddot{n}/6$.

The analysis in this section allowed easy examination of the current satellite constellation composition. We examined how the satellite population fell into the various Gabbard classes with most of them falling into the low earth classes 1-6. We also examined some of the correlations between the orbital elements. First we confirmed the majority of satellites were propagated to the ascending node crossing. We also showed the limits on eccentricity given a particular Kozai mean motion. And finally, we generated a plot showing there was no functional relationship between B^* , $\dot{n}/2$, and $\ddot{n}/6$.

⁴Appendix E contains the side views of the three-dimensional plot for those of us who have trouble visualizing three dimensions on a two-dimensional sheet of paper. Figures E.7, E.8, and E.9 are the relevant scatter plots.

Figure 5.14. Scatter Plot B^* , $\dot{n}/2$, and $\ddot{n}/6$.

5.2 Perturbations Analysis

There are two reasons for looking at satellite perturbations, specifically the J_2 perturbations; to identify the magnitude of the perturbations due to J_2 , and to aid in the propagation of orbital elements. In Section 3.1.1 we derived the actual equations which would be used in the propagation algorithm within the differential corrector model. However, the examination of the magnitude of these perturbations is performed in this section.

Figure 5.15 shows the magnitude of the time derivative of the mean anomaly at epoch, $\dot{M}_0$, and this is directly the difference between the true mean motion and the Kozai mean motion. The "maximum" referred to in the graph uses the fact that the perturbations are largest when the eccentricity is at its maximum.⁵ Figure 5.16 shows the differences in $\dot{M}_0$ between the maximum possible eccentricity and a zero eccentricity.⁶

Figure 5.17 shows the magnitude of the time derivative of the ascending node, $\dot{\Omega}$. Again as before, the "maximum" referred to in the graph uses the fact that the perturbations are largest when the eccentricity is at its maximum. Figure 5.18 shows the differences in $\dot{\Omega}$ between the maximum possible eccentricity and a zero eccentricity.

Figure 5.19 shows the magnitude of the time derivative of the argument of perigee $\dot{\omega}$. And for one last time, the "maximum" referred to in the graph uses the fact that the perturbations are largest when the eccentricity is at its maximum. Figure 5.20 shows the differences in $\dot{\omega}$ between the maximum possible eccentricity and a zero eccentricity.

The next four graphs, Figures 5.21 through 5.24, show the effects of varying one of n_0 , e_0 , or i_0 , while holding the others constant. The perturbed elements for the following graphs are Ω_0 and ω_0 . We consider M_0 an unperturbed element since for our purposes we do not really use the true mean motion but instead the Kozai mean motion. The graphs are all normalized to 1 at some meaningful point for the data. The perturbations

⁵The perturbation is a function of mean motion, inclination, and eccentricity. To make the perturbation "plot-able", we eliminated the eccentricity dependence. For each mean motion value a maximum eccentricity is computed using Equation 5.2 and the result is used in the perturbation equation, thus, eliminating the eccentricity dependence. The perturbation for a given mean motion and inclination is then plotted.

⁶To see the effects of eliminating the eccentricity dependence of the perturbation, the perturbations were also computed for a zero eccentricity instead of a maximum eccentricity. The zero eccentricity result was subtracted from the maximum eccentricity result showing eccentricity's impact on the perturbation for a given mean motion and inclination.

Figure 5.15. Perturbations on Mean Anomaly at Epoch.

Figure 5.16. Eccentricity's Influence on Mean Anomaly at Epoch Perturbations.

Figure 5.17. Perturbations on the Ascending Node.

Figure 5.18. Eccentricity's Influence on Ascending Node Perturbations.

Figure 5.19. Perturbations on the Argument of Perigee.

Figure 5.20. Eccentricity's Influence on Argument of Perigee Perturbations.

due to mean motion are set to 1 at the maximum possible mean motion. Eccentricity's perturbations are set to 1 at its minimum value since the effects "explode" at very high eccentricity. And finally, the perturbations caused by inclination are normalized to 1 at the maximum perturbation value.

Figure 5.21. Mean Motion Influence on Node and Perigee Motion.

As can be seen by this section, the perturbation effects due to J_2 are very small, and eccentricity's impact is orders of magnitude less than the others since the mean motion's perturbation drops off faster than the eccentricity's perturbations can grow.

Figure 5.22. Eccentricity Influence on Node and Perigee Motion.

Figure 5.23. Inclination Influence on Node Motion.

Figure 5.24. Inclination Influence on Perigee Motion.

5.3 Classification Scheme Development

The development of an orbital-element-based classification scheme involved more of a statistical approach rather than an analysis of the current satellite population or concentration on the J_2 perturbations. After examining the distributions of satellites within the Gabbard classes and the impacts of the J_2 perturbations we decided to create our own classification scheme based on the perturbations the satellites experience. The population of satellites was divided into classes based on mean motion, eccentricity, and inclination since these are the elements which contribute to the perturbations. In the previous section the magnitudes and relative impact of $n_{x,0}$, e_0 and i_0 on both the argument of perigee (ω_0) and the ascending node (Ω_0) were examined.

In the graphs in the previous section (Figures 5.21 through 5.24), some of the critical points were highlighted. For instance we considered inclination effects on $\dot{\omega}$ and $\dot{\Omega}$. There are three divisions which occur and Table 5.3 shows the directions of the perturbations.

Table 5.3. Sign Effects on Perturbations Due to Inclination.

Inclination	Sign	
	$\dot{\omega}$	$\dot{\Omega}$
degrees	+/-	+/-
$i < 63.4350$	+	-
$63.4350 < i < 90.0000$	-	-
$90.0000 < i < 116.5648$	-	+
$i > 116.5648$	+	+

Instead of using just the four inclination ranges corresponding to the four combinations of $\dot{\omega}$ and $\dot{\Omega}$ effects, we created two additional "deadbands" about the critical inclinations. The deadbands were picked to be a total width of 0.1 radians (about 6°) wide based on a closer inspection of the distribution of satellites near this inclination with higher eccentricities (Figure E.10). Table 5.4 summarizes the six inclination classes.

Besides inclination classes, we divided the mean motion into four classes. The number of classes was picked somewhat arbitrarily but with some logic behind the decision. The first class division we decided upon was the 225 minute period used to differentiate between the SGP4 and SDP4 orbit propagation models. We also created two other divisions; one

Table 5.4. Orbital Classes Based on Inclination.

Inclination Class	Inclination		Sign	
	Min	Max	$\dot{\omega}$	Ω
	degrees	degrees	+/-	+/-
1	N/A	60.5702	+	-
2	60.5702	66.2998	0	-
3	66.2998	90.0000	-	-
4	90.0000	113.7000	-	+
5	113.7000	119.4296	0	+
6	119.4296	N/A	+	+

at the point where the perturbation level was 20 percent less than its maximum and the second at the 50 percent of maximum point. The grid-lines on Figure 5.21 in the previous section denote these divisions (see Table 5.5).

Table 5.5. Orbital Classes Based on Mean Motion.

Mean Motion Class	Mean Motion	
	Min	Max
	rev/day	rev/day
1	N/A	6.4000
2	6.4000	12.6633
3	12.6633	15.4891
4	15.4891	N/A

Due to the previous analysis on J_2 perturbations, we decided let the eccentricity classes come from the mean motion classes. Figure 5.25 illustrates what was done. By using the maximum eccentricity based on mean motion, we were able to determine the maximum value for each of the three mean motion divisions. Figure 5.25 shows the three eccentricities which are at the intersections of the mean motion and maximum eccentricity line. These three eccentricities were then plotted on Figure 5.22 in Section 5.2. Since the low eccentricity value contributes very little to the perturbations, the low eccentricity value was dropped and the remaining two eccentricities were used as the dividing lines for eccentricity classes (see Table 5.6).

Table 5.7 defines each of the classes. To better illustrate the classifications Figure 5.26 shows the eccentricity and mean motion divisions. The six inclination classes occupy

Table 5.6. Orbital Classes Based on Eccentricity.

Eccentricity Class	Eccentricity

5.4 Representative Satellite Selection

In order to pick a representative satellite from each of the newly formed classes, a Mathematica function was written to read in an entire class of satellites and then compute which satellite came closest to the 'average satellite' for the class. We decided on using this approach over using the average because we wanted to deal with actual satellites instead of a non-existent average satellite. Not all elements were used in determining the closest satellite to the 'average satellite.' The mean anomaly at epoch was not included. The reason for excluding the mean anomaly was we would expect the average to be very close to 180 degrees and which would make it very likely that satellites with a mean anomaly of 180 would be selected. Since mean anomaly changes constantly throughout the orbit it was an unnecessary restraint. Appendix F has the developed Mathematica function for performing the satellite selection, and it also lists the satellites selected in each of the classes.

Once a satellite was selected for each of the classes, we decided to hand pick a representative sample of classes (satellites) to perform our analysis on the differential corrector model. Table 5.9 shows the classes and the satellites picked. Three factors were part of the decision process at this point. First, we wanted to select classes which had particular types of satellites. For instance, Class 1 1 1 contains geosynchronous satellites. Second, the classes with the most satellites were selected for further analysis. Classes 3 1 3 and 3 1 4 were selected for this reason. And finally, some classes were selected for added diversity in our analysis. Classes 2 2 3 is an example of a class selected for added diversity.

Table 5.9. Classes Selected for Differential Corrector Model Analysis.

Class	Catalog Number	Class	Catalog Number
1 1 1	15141	3 1 1	01996
1 1 2	15259	3 1 2	14443

2 1 3	10293	3 1 4	17429
2 1 4	10393	4 1 1	20335
2 2 3	19859	4 1 2	15584

5.5 Data Discrepancies

Some problems were encountered in producing truth model data for the representative satellites selected from the mean motion range four classes (4-1-1, 4-1-2, 4-1-3, 4-1-4). Consequently, an individual cross check of each of the 67 satellites in these four classes with the Satellite Catalog (33) was performed. It was discovered that 46 of the 67 satellites in these four classes were listed as having decayed within 60 days of the orbital element set epoch data. As our testing criteria required a run of 60 days, these satellites were excluded from selection.

During the course of this inspection, we discovered 12 additional satellites included in these classes were listed as having decayed *prior to* the epoch data of the orbital element set. These satellites, and the pertinent data, are included in Table 5.10.

Table 5.10. Orbital Element Set Discrepancies.

Compiled from (33)

VI. ANALYSIS OF DIFFERENTIAL CORRECTOR MODEL

As discussed in Chapter IV, we divided the satellite population into 42 classes based on combinations of six inclination, three eccentricity, and four mean motion ranges.¹ Based on the analysis of the satellite population discussed in Chapter VI, we divided the satellite catalogue into the 33 populated classes and picked the "average" satellite from each class. These satellites are listed in Appendix F.6. From these 33 classes, we selected 12 satellites to analyze. These satellites are listed in the table below.

Table 6.1. Representative Satellites for Analysis.

Class	Catalog Number	Class	Catalog Number
1-1-1	15141	3-1-1	01996
1-1-2	15259	3-1-2	14443
1-3-2	14199	3-1-3	19643
2-1-3	10293	3-1-4	17429
2-1-4	10393	4-1-1	20335
2-2-3	19859	4-1-2	15584

Using the methodology discussed in Chapter IV, an orbital element set for each of these 12 satellites was processed through the truth model to obtain simulated sensor measurements. The model created a total of 40 random observation files; 10 random observation files for each of the four observation rates (two, four, six, and eight) to be tested. Each random observation file was then processed through DIFC for each of the four LUPIs (two, four, six, and eight days) to be tested. The first-pass and last-pass VMAGT errors (residuals) for each random observation file were calculated and stored to the appropriate files based on LUPI/OPD combination. As discussed in Chapter IV, a fixed mean motion variance limit of 10^{-15} rad²/min² was used.

6.1 Analysis of Individual Satellite VMAGT Data.

For each satellite/LUPI/OPD combination, all data from the 10 VMAGT files were plotted in conjunction with a four-day moving average using the Mathematica software plot

¹The difference between 42 classes and $6 \times 3 \times 4 = 72$ is that 30 of the combinations of i_0 , e_0 , and n_0 are impossible.

routine. Using the programming ability built into Mathematica, we constructed a program to calculate the 95 percent confidence intervals of the means, variances and 99 percent confidence levels as presented in Equations 4.27, 4.28, and 4.29. (Reference Appendix G for the Mathematica code used to perform these calculations and produce the graphs. Reference Appendix H for the VMAGT graphs and summary tables for each of the 16 LUPI/OPD combinations tested for the 12 satellites in Table 6.1.)

The following sections review each sample satellite tested, examining the data with respect to the following four performance measures:

1. "First-pass" VMAGT data. Expect to observe reasonable values (approximately 14 km or less for near-earth satellites and 20 to 40 km for deep-space satellites), a "saw-tooth" correction pattern, and no trends or serious outlying data.
2. "Last-pass" VMAGT values. Expect to observe steady-state, randomly-distributed values at a level less than first-pass values.
3. OPD effect on the 99 percent CL. Expect to observe that 99 percent CL value decreases as OPD increases.
4. LUPI effect on the 99 percent CL. Expect to observe that 99 percent CL value increases as LUPI increases.
5. Analysis of variance (ANOVA). Expect this analysis to verify statistical differences exist in 99 percent CL value results based on effects of OPD and LUPI combinations.

6.1.1 Class 1 1 1 (NORAD Catalog Number 15141). A summary of the confidence interval analysis and the VMAGT graphs for all LUPI/OPD combinations tested for this satellite are located in Appendix H.1. Data analysis with respect to the performance measures above indicate the following:

- Examination of the first-pass VMAGT values for this satellite indicated two peaks. The peaks for residual values occurred in the periods of Days 2 through 10 and Days 36 through 46. We believe this indicates a problem with the differential corrector program correcting to, and propagating, a bad state estimate. This could be

caused by the mean motion variance limit being unnecessarily large, thus reducing the confidence in a previously good estimate.

- Examination of the last-pass VMAGT values showed randomly-distributed, steady-state values at a level less than first-pass values.
- Examination of the OPD effects on the 99 percent CL show that, for all cases with this satellite, the 99 percent CL decreases as OPD increases. This was the expected result.
- Examination of the LUPI effects on the 99 percent CL show that, for the OPD 2 cases with this satellite, the 99 percent CL increases as LUPI increases. This was the expected result. However, for the OPD 4, 6, and 8 cases, the large overlapping confidence intervals make a determination impossible.
- ANOVA indicates there are differences in results based on OPD and LUPI. However, there appears to be no difference in results based on the interaction of LUPI and OPD.

6.1.2 Class 1 1 2 (NORAD Catalog Number 15259). A summary of the confidence interval analysis and the VMAGT graphs for all LUPI/OPD combinations tested for this satellite are located in Appendix II.2. Data analysis with respect to the performance measures above indicate the following:

- Examination of the first-pass VMAGT values for this satellite indicated reasonable and consistent data with expected results. However, with the data from LUPI 8, there is a noticeable peak in the data during Batch 5. This effect may be due to the DC producing a bad estimate at the end of Batch 4. Additionally, the 99 percent CL for the best possible LUPI/OPD combination (8/2) was well below the 14 km VMAG limit used by USSPACECOM.
- Examination of the last-pass VMAGT values showed randomly-distributed, steady-state values at a level less than first-pass values.

- Examination of the OPD effects on the 99 percent CL show that the 99 percent CL generally decreases as OPD increases. OPD 4 for LUPI 2 and 4 increased slightly but decreased for the 6 and 8 OPD. This decreasing trend was the expected result.
- Examination of the LUPI effects on the 99 percent CL show that, for OPD 2 cases with this satellite, the 99 percent CL increases as LUPI increases. This was the expected result. However, for the OPD 4, 6, and 8 cases, the large overlapping confidence intervals make a determination impossible.
- ANOVA indicates there are differences in results based on OPD and LUPI. Additionally, there appears to be a difference in results based on the interaction of LUPI and OPD.

6.1.3 Class 1 3 2 (NORAD Catalog Number 14199). A summary of the confidence interval analysis and the VMAGT graphs for all LUPI/OPD combinations tested for this satellite are located in Appendix H.3. Data analysis with respect to the performance measures above indicate the following:

- Examination of the first-pass VMAGT values for this satellite showed large values with occasional peaks with a slight positive slope of the data within batches. The large VMAGT values are probably due to the properties associated with the orbital dynamics associated with this class.
- Examination of the last-pass VMAGT values showed randomly-distributed, steady-state values at a level less than first-pass values.
- Examination of the OPD effects on the 99 percent CL show that, for all cases with this satellite, the 99 percent CL decreases as OPD increases. This was the expected result.
- Examination of the LUPI effects on the 99 percent CL show that, for the OPD 2 cases, the 99 percent CL increases as LUPI increases. For all other cases, the confidence intervals are very large and overlapping, and the 99 percent CL are not significantly different enough to draw any conclusions.

- ANOVA indicates there are differences in results based on OPD, but not on LUPI. Additionally, there appears to be no difference in results based on the interaction of LUPI and OPD.

6.1.4 *Class 2-1-3 (NORAD Catalog Number 10293)*. A summary of the confidence interval analysis and the VMAGT graphs for all LUPI/OPD combinations tested for this satellite are located in Appendix H.4. Data analysis with respect to the performance measures above indicate the following:

- Examination of the first-pass VMAGT values for this satellite showed small values which showed occasional peaks and a slight positive slope. The 99 percent CL for the best possible LUPI/OPD combination (8/2) was well below the 14 km VMAG limit used by USSPACECOM.
- Examination of the last-pass VMAGT values showed randomly-distributed, steady-state values at a level less than first-pass values with a slight periodic effect.
- Examination of the OPD effects on the 99 percent CL show that, for all cases with this satellite, the 99 percent CL decreases as OPD increases. This was the expected result.
- Examination of the LUPI effects on the 99 percent CL show that, for all cases with this satellite, the overlap of the 99 percent CL makes a determination impossible for this satellite. We believe this situation could be eliminated in future research by increasing the number of random observation runs.
- ANOVA indicates there are differences in results based on OPD and LUPI. There may be a difference in results based on the interaction of LUPI and OPD. However, the ANOVA results are the same to the measured accuracy and no determination can be made.

6.1.5 *Class 2-1-4 (NORAD Catalog Number 10393)*. A summary of the confidence interval analysis and the VMAGT graphs for all LUPI/OPD combinations tested for this satellite are located in Appendix H.5. Data analysis with respect to the performance measures above indicate the following:

- Examination of the first-pass VMAGT values for this satellite indicated small, reasonable, and consistent values with a slight positive slope. However, the 99 percent CL for the best possible LUPI/OPD combination (8/2) was well below the 14 km VMAG limit used by USSPACECOM.
- Examination of the last-pass VMAGT values showed randomly-distributed, steady-state values at a level less than first-pass values.
- Examination of the OPD effects on the 99 percent CL show that, for all cases with this satellite, the 99 percent CL decreases as OPD increases. This was the expected result.
- Examination of the LUPI effects on the 99 percent CL show that, for all cases with this satellite, the confidence interval overlap of the 99 percent CL makes a determination impossible for this satellite. We believe this situation could be eliminated in future research by increasing the number of random observation runs.
- ANOVA indicates there are differences in results based on OPD and LUPI. However, there is not a difference in results based on the interaction of LUPI and OPD.

6.1.6 *Class 2 2 3 (NORAD Catalog Number 19839)*. A summary of the confidence interval analysis and the VMAGT graphs for all LUPI/OPD combinations tested for this satellite are located in Appendix H.6. Data analysis with respect to the performance measures above indicate the following:

- Examination of the first-pass VMAGT values for this satellite showed small, reasonable, and consistent values with a slight positive slope. The 99 percent CL for the best LUPI/OPD combination (8/2) was well below the 14 km VMAG limit used by USSPACECOM.
- Examination of the last-pass VMAGT values showed steady-state values at a level less than first-pass values. The data also showed a slight periodic effect, damping with each successive batch correction.

- Examination of the OPD effects on the 99 percent CL show that, for all cases with this satellite, the 99 percent CL decreases as OPD increases. This was the expected result.
- Examination of the LUPJ effects on the 99 percent CL show that, for all cases with this satellite, the overlap of the 99 percent CL makes a determination impossible for this satellite. We believe this situation could be eliminated in future research by increasing the number of random observation runs.
- ANOVA indicates there are differences in results based on OPD but not on LUPJ. However, there is a difference in results based on the interaction of LUPJ and OPD.

6.1.7 *Class 3-1-1 (NORAD Catalog Number 01996)*. A summary of the confidence interval analysis and the VMAGT graphs for all LUPJ/OPD combinations tested for this satellite are located in Appendix H.7. Data analysis with respect to the performance measures above indicate the following:

- Examination of the first-pass VMAGT values for this satellite showed a severe positive slope on all batches. This trend becomes noticeable on the LUPJ 4 combinations and is extremely obvious on the LUPJ 8 combinations. Reference Figure H.62 for a good example of this trend. This trend appears to indicate that the covariance has become too exact (very small) and therefore the differential corrector is not allowing the elements to be corrected. Despite this apparent problem with the DC, the 99 percent CL for all LUPJ 2 combinations was below the 14 km VMAG limit used by USSPACECOM.
- Examination of the last-pass VMAGT values showed values less than first-pass values. However, the data showed a slight periodic effect with peaks at the beginning and end of each batch.
- Examination of the OPD effects on the 99 percent CL show that, for all cases except the LUPJ 2, OPD 8 combination, the 99 percent CL decreases as OPD increases. In the LUPJ 2, OPD 8 combination, the large overlap of the confidence intervals makes a determination impossible. These results are consistent with those expected.

- Examination of the LUPI effects on the 99 percent CL show that, for all cases with this satellite, the 99 percent CL increases as LUPI increases. This was the expected result.
- ANOVA indicates there are differences in results based on OPD and LUPI. Additionally, there is a difference in results based on the interaction of LUPI and OPD.

6.1.8 *Class 3-1-2 (NORAD Catalog Number 14443)*. A summary of the confidence interval analysis and the VMAGT graphs for all LUPI/OPD combinations tested for this satellite are located in Appendix H.8. Data analysis with respect to the performance measures above indicate the following:

- Examination of the first-pass VMAGT values for this satellite showed a slight positive slope on all batches. Despite this apparent problem with the DC, the 99 percent CL for all LUPI/OPD combinations with LUPI of 2, 4, and 6, was below 14 km VMAG limit used by USSPACECOM.
- Examination of the last-pass VMAGT values showed values less than first-pass values. However, the data showed a periodic effect with an apparent slight upward slope of the data within each batch.
- Examination of the OPD effects on the 99 percent CL show that, for all cases except all OPD 8 combinations, the 99 percent CL decreases as OPD increases. In all OPD 8 combinations, the large overlap of the confidence interval with the respective OPD 6 confidence interval makes a determination impossible. These results are consistent with those expected.
- Examination of the LUPI effects on the 99 percent CL show that, for all cases with this satellite, the 99 percent CL increases as LUPI increases. This was the expected result.
- ANOVA indicates there are differences in results based on OPD and LUPI. However, there is not a difference in results based on the interaction of LUPI and OPD.

6.1.9 Class 3-1-3 (NORAD Catalog Number 19649). A summary of the confidence interval analysis and the VMAGT graphs for all LUPI/OPD combinations tested for this satellite are located in Appendix H.9. Data analysis with respect to the performance measures above indicate the following:

- Examination of the first-pass VMAGT values for this satellite showed an positive slope on some batches. This slope is noticeable on the LUPI 6 combinations and extremely obvious on the LUPI 8 combinations. Reference Figure H.80 for a good example of this trend. This trend appears to indicate that the covariance has become too exact (very small) and therefore the differential corrector is not allowing the elements to be corrected. Despite this apparent problem with the DC, the 99 percent CL for some LUPI/OPD combinations was below 14 km VMAG limit used by USSPACECOM. The best LUPI/OPD combinations performing better than the USSPACECOM limit are the 6/4 (best LUPI) and the 4/2 (best OPD) combinations.
- Examination of the last-pass VMAGT values showed randomly-distributed, steady-state values at a level less than first-pass values. This was the expected result.
- Examination of the OPD effects on the 99 percent CL show that, for all cases except LUPI 2, OPD 4, and LUPI 2, OPD 6 combinations, the 99 percent CL decreases as OPD increases. In these two cases the large overlap of the confidence intervals makes a determination impossible. These results are consistent with those expected.
- Examination of the LUPI effects on the 99 percent CL show that, for all cases with this satellite, the 99 percent CL increases as LUPI increases. This was the expected result.
- ANOVA indicates there are differences in results based on OPD and LUPI. However, there is not a difference in results based on the interaction of LUPI and OPD.

6.1.10 Class 3-1-4 (NORAD Catalog Number 17429). A summary of the confidence interval analysis and the VMAGT graphs for all LUPI/OPD combinations tested for this satellite are located in Appendix H.10. Data analysis with respect to the performance measures above indicate the following:

- Examination of the first-pass VMAGT values for this satellite, especially the longer LUPIs, showed a similar upward sloping trend on some batches. This trend typically alternates magnitude (high-low) between batches. A good example of this is seen in Figure H.87. It appears to indicate that the covariance has become too exact (very small) and therefore the differential corrector is not allowing the elements to be corrected.
- Examination of the last-pass VMAGT values showed values less than first-pass values. However, a slight upward trend from batch to batch was noted, with later batches having growing ranges of values.
- Examination of the OPD effects on the 99 percent CL show that, for all cases with this satellite, the 99 percent CL decreases as OPD increases. This was the expected result.
- Examination of the LUPi effects on the 99 percent CL show that, for all cases with this satellite, the 99 percent CL increases as LUPi increases. This was the expected result.
- ANOVA indicates there are differences in results based on LUPi but not on OPD. Additionally, there is not a difference in results based on the interaction of LUPi and OPD.

6.1.11 *Class 4 1 1 (NORAD Catalog Number 20355).* A summary of the confidence interval analysis and the VMAGT graphs for all LUPi/OPD combinations tested for this satellite are located in Appendix H.11. Data analysis with respect to the performance measures above indicate the following:

- Examination of the first-pass VMAGT values for this satellite showed that the data was distributed over a wide range with steady-state mean values between 48 and 272 km. Examination of the OPD 6 and 8 graph (Figure H.92) shows a definite upward slope. This, like many previous satellites analyzed, seems to indicate that the covariance has become too exact (very small) and therefore the differential corrector is not allowing the elements to be corrected.

- Examination of the last-pass VMAGT values showed randomly-distributed, steady-state values at a level less than first-pass values. They are, however, much larger than other last-pass values seen in the analysis of other satellites.
- Examination of the OPD effects on the 99 percent CL show that, for all cases with this satellite, the 99 percent CL decreases as OPD increases. This was the expected result.
- Due to program run time and extremely large VMAGT values, only the LUPI two combinations were analyzed for this satellite. Therefore, no LUPI effects on the 99 percent CL could be noted.
- Due to the limited nature of the output, ANOVA was not conducted on this satellite. The absence of a complete output data set would make ANOVA comparisons unreliable.

6.1.12 *Class 4 1 2 (NORAD Catalog Number 15584).* A summary of the confidence interval analysis and the VMAGT graphs for all LUPI/OPD combinations tested for this satellite are located in Appendix H.12. Data analysis with respect to the performance measures above indicate the following:

- Examination of the first-pass VMAGT values for this satellite showed that the data was distributed over a wide range with steady-state mean values between 38 and 225 km. Examination of the OPD 6 and 8 graph (Figure H.95) shows a definite upward slope. This, like many previous satellites analyzed, seems to indicate that the covariance has become too exact (very small) and therefore the differential corrector is not allowing the elements to be corrected.
- Examination of the last-pass VMAGT values showed randomly-distributed, steady-state values at a level less than first-pass values. They are, however, much larger than other last-pass values seen in the analysis of other satellites.
- Examination of the OPD effects on the 99 percent CL show that, for all cases with this satellite, the 99 percent CL decreases as OPD increases. This was the expected result.

- Due to program run time and extremely large VMAGT values, only the LUPI two combinations were analyzed for this satellite. Therefore, no LUPI effects on the 99 percent CL could be noted.
- Due to the limited nature of the output, ANOVA was not conducted on this satellite. The absence of a complete output data set would make ANOVA comparisons unreliable.

6.2 *Tuning the Differential Corrector*

As mentioned in numerous analyses of the sample satellites in Section 6.1, our DC appears to have a problem with the correction of the elements. It appears from the VMAGT plots of many of the satellites tested that the covariance gets so small that it will not allow some, or all, of the elements to be corrected by the value that is actually needed. This would result in a "bad" estimate, and the large VMAGT values seen in the above analysis.

This problem was first noted in the validation of the differential correction model. All satellites being tested exhibited the same severe positive slope to the VMAGT data within each batch. Figure 6.1 shows the data for Class 3-1-2 (Catalog Number 14443) as encountered during validation. This is representative of the data for all test cases.

We assumed this effect was due to a bad mean motion estimate. Through experimentation, we determined that a mean motion variance "limit" of 10^{-15} seemed to perform the best. During the experimentation, the "limit" appeared to be dependent on the batch size. However, no combination of batch size, LUPI, and/or OPD multiples could be determined which worked well. Therefore, the 10^{-15} limit was hard coded into the model such that if the (7,7) element ($\sigma_{7,7}^2$) of the covariance matrix was less than this value, then $\sigma_{7,7}^2$ was set to 10^{-15} .

The model was then used on all 16 LUPI/OPD combinations for all 12 satellite (orbit) classes investigated. As illustrated by the current LUPI 8, OPD 8, VMAGT plots for Class 3-1-2, Catalog Number 14443 (Figure H.71), this limitation appeared to work for most classes. However, this limit apparently did not work for Classes 3-1-1, 3-1-3, 3-1-4,

Figure 6.1. Old VMAGT data for Class 3 1-2 (Catalog Number 14443).

4 1 1, and 4-1-2 (Catalog Numbers 01996, 19643, 17429, and, possibly, 20335 and 15584) as shown in in Sections H.7, H.9, H.10, H.11, and H.12, respectively. We believed this indicated two things: first, the limit for these satellites should have been set at a higher value, and second, the limit value required is satellite, or orbit, dependent.

In attempt to determine if the mean motion variance limit used in our model was not restrictive enough, the five classes (sample orbits) exhibiting the severe positive slope of the VMAGT data were examined. Those classes (orbits) were:

3 1 1	(Catalog Number 01996)
3 1 3	(Catalog Number 19643)
3 1 4	(Catalog Number 17429)
4 1 1	(Catalog Number 20335)
4 1 2	(Catalog Number 15584)

Assuming that the VMAGT errors were primarily in-track errors (i.e., caused by a bad mean motion estimate), a first-order-of-magnitude estimate of the change in the mean motion was made. The slope of the VMAGT data gives an approximation of the rate of change of the in-track errors in km/day. The semi-major axis, a_0 , is calculated as shown in Equation 3.14. If a circular orbit is assumed, the angular rate of change can be approximated from the the rate of change of the in-track error and the semi-major axis.

All six satellites have eccentricities less than 0.06, so the circular orbit assumption seems valid. The slopes were determined using the the longest LUPI (8) VMAGT graphs in order to get the best estimate of the slope. The largest OPD (8) was also used. This gave the smallest slope of any LUPI/OPD combination for each satellite, and therefore the smallest angular rate of change. In the case of the Class 4-1-1 and 4-1-2 orbits, the LUPI 2, OPD 8 data was used. The data for this analysis is summarized in Table 6.2.

Table 6.2. First Order In-Track Error Analysis.

Class	Catalog Number	Semi-Major Axis km	Eccentricity	In-Track Rate km/day	Angular Rate rad/min
3 1 1	01996	7277	0.05379	12.5	1.2×10^{-6}
3 1 2	14443	7255	0.02245	1.2	1.2×10^{-7}
3 1 3	19643	7231	0.00670	2.5	2.4×10^{-7}
3 1 4	17429	7242	0.01095	2.5	2.4×10^{-7}
4 1 1	20335	6768	0.00175	75	1.0×10^{-5}
4 1 2	15584	6774	0.00234	75	1.0×10^{-5}

In all of these cases, by first-order approximation, the angular rate of change of the VMAGT error is at least 10 times larger than the mean motion variance limit ($\sqrt{10^{-15}} = 3.0 \times 10^{-8}$) used in the model. This was a strong indication that the mean motion variance needed to be limited in some way.

Once a mean motion variance limit, $\sigma_{n_{lim}}^2$, has been calculated and a determination made that the limit is indeed needed ($\sqrt{\sigma_n^2} < \sigma_{n_{lim}}$), there are two methods of implementing it within the DC program.

1. Diagonal adjustment. Apply the limit to only the mean motion variance term in the covariance matrix. This adjusted covariance matrix, P_* , is shown in Equation 6.1.

$$P_a = \begin{bmatrix} \sigma_B^2 & \sigma_B \sigma_i & \sigma_B \sigma_\Omega & \sigma_B \sigma_e & \sigma_B \sigma_\omega & \sigma_B \sigma_M & \sigma_B \sigma_n \\ \sigma_i \sigma_B & \sigma_i^2 & \sigma_i \sigma_\Omega & \sigma_i \sigma_e & \sigma_i \sigma_\omega & \sigma_i \sigma_M & \sigma_i \sigma_n \\ \sigma_\Omega \sigma_B & \sigma_\Omega \sigma_i & \sigma_\Omega^2 & \sigma_\Omega \sigma_e & \sigma_\Omega \sigma_\omega & \sigma_\Omega \sigma_M & \sigma_\Omega \sigma_n \\ \sigma_e \sigma_B & \sigma_e \sigma_i & \sigma_e \sigma_\Omega & \sigma_e^2 & \sigma_e \sigma_\omega & \sigma_e \sigma_M & \sigma_e \sigma_n \\ \sigma_\omega \sigma_B & \sigma_\omega \sigma_i & \sigma_\omega \sigma_\Omega & \sigma_\omega \sigma_e & \sigma_\omega^2 & \sigma_\omega \sigma_M & \sigma_\omega \sigma_n \\ \sigma_M \sigma_B & \sigma_M \sigma_i & \sigma_M \sigma_\Omega & \sigma_M \sigma_e & \sigma_M \sigma_\omega & \sigma_M^2 & \sigma_M \sigma_n \\ \sigma_n \sigma_B & \sigma_n \sigma_i & \sigma_n \sigma_\Omega & \sigma_n \sigma_e & \sigma_n \sigma_\omega & \sigma_n \sigma_M & \sigma_{n_{lim}}^2 \end{bmatrix} \quad (6.1)$$

2. Full adjustment. In addition to the diagonal $\sigma_{n_{lim}}^2$ term, apply the limit to the 12 other covariance elements (i.e., the elements in the bottom row and right column) of the covariance matrix impacted by σ_n . This would be implemented by first creating an adjustment matrix (I_a) as shown below:

$$I_a = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & \frac{\sigma_{n_{lim}}}{\sigma_n} \end{bmatrix} \quad (6.2)$$

The adjusted covariance matrix is formed by pre-multiplying and post-multiplying the covariance matrix by the adjustment matrix as shown in Equation 6.3.

$$P_a = I_a P I_a \quad (6.3)$$

The adjusted covariance matrix then takes the form shown in Equation 6.4.

$$P_a = \begin{bmatrix} \sigma_B^2 & \sigma_B \sigma_i & \sigma_B \sigma_\Omega & \sigma_B \sigma_e & \sigma_B \sigma_\omega & \sigma_B \sigma_M & \sigma_B \sigma_{n_{lim}} \\ \sigma_i \sigma_B & \sigma_i^2 & \sigma_i \sigma_\Omega & \sigma_i \sigma_e & \sigma_i \sigma_\omega & \sigma_i \sigma_M & \sigma_i \sigma_{n_{lim}} \\ \sigma_\Omega \sigma_B & \sigma_\Omega \sigma_i & \sigma_\Omega^2 & \sigma_\Omega \sigma_e & \sigma_\Omega \sigma_\omega & \sigma_\Omega \sigma_M & \sigma_\Omega \sigma_{n_{lim}} \\ \sigma_e \sigma_B & \sigma_e \sigma_i & \sigma_e \sigma_\Omega & \sigma_e^2 & \sigma_e \sigma_\omega & \sigma_e \sigma_M & \sigma_e \sigma_{n_{lim}} \\ \sigma_\omega \sigma_B & \sigma_\omega \sigma_i & \sigma_\omega \sigma_\Omega & \sigma_\omega \sigma_e & \sigma_\omega^2 & \sigma_\omega \sigma_M & \sigma_\omega \sigma_{n_{lim}} \\ \sigma_M \sigma_B & \sigma_M \sigma_i & \sigma_M \sigma_\Omega & \sigma_M \sigma_e & \sigma_M \sigma_\omega & \sigma_M^2 & \sigma_M \sigma_{n_{lim}} \\ \sigma_{n_{lim}} \sigma_B & \sigma_{n_{lim}} \sigma_i & \sigma_{n_{lim}} \sigma_\Omega & \sigma_{n_{lim}} \sigma_e & \sigma_{n_{lim}} \sigma_\omega & \sigma_{n_{lim}} \sigma_M & \sigma_{n_{lim}}^2 \end{bmatrix} \quad (6.4)$$

We attempted to determine the mean motion variance limit, $\sigma_{n_{lim}}^2$, required by the DC using our worst behaved class, 3-1-1 (Catalog Number 01996), as a test subject (reference Appendix H.7). A single random observation file was used to limit the processing time required by the DC. Additionally, for the purposed of this "tuning," we felt that difference between different random observation files would not change the order-of-magnitude limit we were searching for.

To tune the DC, we used the sum of all VMAGTs after Day 24 ($\sum_{i=24}^N \text{VMAGT}$), as a performance measure. We selected day 24 because it was the default point at which steady-state was declared. Using both the diagonal and full adjustment methods discussed above, we ran the DC varying $\sigma_{n_{lim}}^2$ starting at 0.1. For each successive run we used a $\sigma_{n_{lim}}^2$ one order of magnitude lower. This process continued until the DC did not need to use the limit (i.e., $\sigma_{n_{lim}}^2 < \sigma_n^2$). The output from this process for each adjustment method was a listing of the incremented $\sigma_{n_{lim}}^2$ and the corresponding $\sum_{i=24}^N \text{VMAGT}$. For each method, we chose as the limit the $\sigma_{n_{lim}}^2$ corresponding to the lowest $\sum_{i=24}^N \text{VMAGT}$.

These limits were then applied and the DC model was run on all 16 LUP/OPD combinations for this class. However, the VMAGT results for both adjustment methods showed little change. This led us to believe that the DC had to be tuned for all elements, not just mean motion.

Again, using the same class, 3-1-1, as a test subject, we determined variance and covariance limits for each element for both adjustment methods discussed above. Starting

with the element with the smallest variance, the variance limit for that element was calculated using the same method used to determine $\sigma_{n_{lim}}^2$ described above. That limit was then implemented (i.e., used in the DC if $\sqrt{\sigma^2} < \sigma_{lim}$) and the same process was used on the element with the next smallest variance. This continued until the variance limits for all elements was determined.

Using these 7 limits as an initial guess, the DC model was run, again using only one random observation file. The variance limit for each element was again varied while holding all other limits constant. The output from this process was a listing of the incremented $\sigma_{n_{lim}}^2$ and the corresponding $\sum_{i=24}^N \text{VMAGT}$ for each element. From this output, we determined the variance limit with the largest reduction in $\sum_{i=24}^N \text{VMAGT}$ between the limit used and an adjacent limit. The element variance limit was changed to the adjacent limit and the process repeated until the element variance limits resulting in the minimum $\sum_{i=24}^N \text{VMAGT}$ are determined. A basic assumption is that the local minimum determined by these variance limits is close to the global minimum. This process was performed for both adjustment methods.

Using these limits, the DC model was run on all 16 LUP/OPD combinations for Class 3 1 1 (NORAD Catalog Number 01996). Both methods produced results much better than the baseline data seen in Appendix H.7. However, the full adjustment method did not provide results as accurate as the diagonal adjustment method. Reference Table 6.3 for the element covariances used in the diagonal adjustment and Appendix I.2 for the complete confidence interval analysis, ANOVA analysis and VMAGT graphs for the diagonal adjustment. Of special note is the statistical difference in results based on LUP. Prior to tuning, there was no indicated difference in results. However, the tuning effort highlighted this difference.

To demonstrate the ability of this method to "tune" other orbital classes, the same methodology was applied to Class 1 3 2 (Catalog Number 14199). This class was chosen for three reasons. First, in the initial analysis, this class did not exhibit characteristics indicating the covariance had become too exact. Second, we wanted to see if "tuning" could improve previously "good" results. Third, this class is different from Class 3 1 1 in all three classification categories (i.e., mean motion, eccentricity, and inclination).

Table 6.3. Element Variance Limits Used for DC Tuning of Class 3-1-1.

Element Variance	Limit Imposed
$\sigma_{B^*}^2$	$10^{-7} \text{ (m}^2/\text{kg)}^2$
σ_i^2	10^{-9} rad^2
σ_{Ω}^2	10^{-7} rad^2
σ_e^2	None
σ_w^2	None
σ_M^2	None
σ_n^2	$10^{-15} \text{ rad}^2/\text{min}^2$

Tuning for this class also improved overall VMAGT results. Reference Table 6.4 for the element variance limits used in the diagonal adjustment. Appendix I.1 contains the complete confidence interval analysis, ANOVA analysis and VMAGT graphs for the diagonal adjustment. ANOVA still indicates a difference in results based on LUPI, OPD, and the interaction of LUPI and OPD.

Table 6.4. Element Variance Limits Used for DC Tuning of Class 1-3-2.

Element Variance	Limit Imposed
$\sigma_{B^*}^2$	None
σ_i^2	10^{-9} rad^2
σ_{Ω}^2	10^{-8} rad^2
σ_e^2	10^{-10}
σ_w^2	10^{-7} rad^2
σ_M^2	10^{-8} rad^2
σ_n^2	$10^{-18} \text{ rad}^2/\text{min}^2$

6.3 Differential Correction Model Performance

As illustrated by most of the last-pass VMAGT graphs in Appendixes II and I, the differential corrector typically gave good performance. Some of the last-pass VMAGT graphs had results indicating that further information could be obtained from the data, such as the periodic results and occasional spikes in the data. However, in general, the randomly-distributed, steady-state nature of the data indicated good performance. Typically, the DC required between four and six iterations to converge for each batch of

observations, and only occasionally did not converge within the 50 iteration limit placed in the algorithm.

The actual run time of the program for each satellite investigated was quite long. Running on 25 MHz, 386 PC, a single 60-day run of the differential corrector, using one random observation file, an observation rate of two obs/day, and a single LUPI (between 8 and 30 corrections depending on LUPI) could be performed in approximately two minutes. However, to perform all 16 LUPI/OPD combinations using 10 random observation files (over 2500 corrections) took at least two and a half hours.

In addition, no singularity problems were encountered with the Keplerian elements at low eccentricities and low inclinations. An eccentricity and inclination of 0.0012 and 4.99° respectively were tested. These were both for Class 1-1-1.

VII. CONCLUSIONS AND RECOMMENDATIONS

7.1 Conclusions

Based on the 99 percent confidence level and ANOVA analysis of the simulation runs, we believe our model can be used to show the general differences in the accuracy of an orbital element set based on varying observation rates and correction intervals. In all of our test cases, we observed no results which indicate increasing LUP1 or decreasing OPD would improve accuracy. Our results for mean motion Classes Two, Three, and Four showed either that accuracy improved as a result of increasing OPD or decreasing LUP1, or that no determination could be made due to large overlapping confidence intervals.

Mean motion Class One (deep space satellites) results were not that definitive. They showed that accuracy increased as a result of increasing OPD as expected, but in some cases, the LUP1 effects may have been opposite what we expected. While the large overlapping confidence intervals make determinations difficult, the results of Class 1 3 2 after tuning (Reference Appendix I.1) could be interpreted as the VMAGTs for OPD/LUP1 8/8 being better than those for OPD/LUP1 8/2. This may be related to the LUP1 dependent forgetting factor used in our model.

We believe the problem of the large overlapping confidence intervals is due to insufficient random observation runs for specific satellites. The need for more random observation runs showed up in the overlap of the 95 percent confidence interval of the 99 percent confidence level. This overlap made a determination of LUP1/OPD effects on results impossible for some satellites. We believe the addition of extra runs will narrow the confidence interval and allow better determination of results.

As a separate problem the accuracy of the reported VMAGT data indicates a need for the differential corrector (DC) to be "tuned" prior to use. On several of the output runs, the plotted first-pass VMAGT values demonstrated a significant positive "slope" characteristic. Apparently, this indicated the covariance had become too exact (very small). Therefore, the differential corrector would not allow the elements to be corrected. This problem was first identified early in test runs conducted to debug the DC code.

As indicated in Chapter IV, Section 4.4.1, we examined the impact of the covariance matrix on the correction process. To start the Bayes process, it was necessary to make an initial guess for the values in the matrix. The value of 10^{-7} was chosen based on an analysis of test data. As further test runs were conducted, we noticed the "slope" characteristic in all of the first-pass VMAGT plots. Preliminary analysis of the output indicated this may be the result of the DC "locking on" to a value of mean motion. Once locked on, the DC refused to correct mean motion and attempted to change other elements to make up the difference, thus creating a bad estimate.

As discussed in Chapter VI, we incorporated a constant mean motion variance-limiting factor into the code for the DC. The purpose of this factor was to prevent the DC from locking onto a specific value of mean motion and then refusing to correct it further. This procedure resulted in good first-pass corrections for several satellites, but not for all satellites. Further testing and analysis indicated this limiting factor is required on more than just the mean motion variance. Additionally, the element variance limits appear to be satellite/orbit dependent.

In our research, we manually tuned, or determined the variance limits necessary, for the two test cases analyzed. Based on the methodology described in Section 6.2, an automated process for performing this tuning for all orbit classes could be developed. With automated tuning, we believe our model could better determine the effects of IUPI and OPD on orbital element set accuracy.

7.2 Follow-On Research Recommendations

The most obvious follow-on research recommendation is the continuation of the project, as requested by our sponsors, the 1st Command and Control Squadron (1CAC'S), into the final development of a cost benefit assessment model. The results of this research are intended to be used as the basis for the development of a quantitative cost/benefit model to assess the effects of alterations to the SSN on orbit prediction accuracies. This model, as envisioned by personnel at the 1CAC'S, would be used as a decision-making tool. The purpose of this tool would be to compare the gain or loss of orbit prediction accuracies with the costs or savings associated with the upgrade of a specific sensor site, the closing of

a specific sensor site, or the changing of sensor taskings. This decision-making tool would allow USSPACECOM to make better decisions (in terms of maintaining OE set accuracy) in regards to the SSN.

However, before attempting to incorporate our model into a larger application, an automated method for tuning the differential corrector is required. Coupled with this effort is the validation of the satellite classification method we used to select a representative sample from the satellite population. Based on the results of the classification method validation, a determination of whether the same variance limits can be applied to all satellites within a class, or must be determined independently for each satellite, can be made.

Other areas of recommended further research are:

- Re-coding of the model programs for computational efficiency as opposed to the easily interpretable format used.
- Examination of the effects of "tuning" the forgetting factor used in the differential correction process.
- Development of an interface process to ease the determination of the steady-state values for a representative set of satellites.
- Development of an interface process to allow execution of these models with various changes to SSN sensor characteristics (location and accuracies) to allow comparison to "baseline" run and, therefore, determine affects of alterations to SSN on element accuracy.
- Examination of the effects of "age de-weighting" the actual observations used in the sequential differential correction process.
- Creation of a task scheduling model. The results of this research could also be used as the basis for the development of a scheduling model to optimally schedule SSN sensors to gather only the observational data required to maintain the desired orbit prediction accuracies. This would ensure the SSC computers would process only the minimum required data to maintain the OE set accuracy.

Documentation for
NORAD SGP4/SDP4 Units

Developed by
Dr TS Kelso

Version 2.50
1992 October 01

Copyright (C) 1992. All rights reserved.

PURPOSE

The enclosed Pascal source code implements the NORAD SGP4/SDP4 orbital models for use with the standard two-line orbital element sets to determine earth-centered inertial (ECI) and topocentric coordinates of earth-orbiting objects. This code implements both the near-earth and deep-space portions of the NORAD SGP4 orbital model. These units are designed to make the development of programs based on the NORAD orbital models straightforward and standardized.

INTRODUCTION

In order to properly determine the position of any earth-orbiting object using the standard NORAD two-line element sets, it is necessary that the proper orbital model be used. Since the observations taken by NORAD for each earth-orbiting object are reduced to orbital elements using the SGP4 (Simplified General Perturbations) model, the SGP4 model *must* be used to get the most accurate determination possible of an object's position and velocity. The primary reason for this requirement is that each orbital model handles perturbations (due to atmospheric drag, solar and lunar gravitational effects, irregularities of the earth's gravitational field, etc.) in a different manner. The NORAD two-line element sets incorporate these perturbations using the SGP4 orbital model and that model is required to accurately reconstruct the magnitudes of these effects.

The SGP4 orbital model takes into account perturbations due to atmospheric drag (based on a static, non-rotating, spherically-symmetric atmosphere whose density can be described by a power law), fourth-order zonal geopotential harmonics (J2, J3, and J4), spin-orbit resonance effects for synchronous and semi-synchronous orbits, and solar and lunar gravitational effects to first order. The two portions of the SGP4 model are SGP4 (for objects in orbits with periods less than 225 minutes) and SDP4 (for objects in orbits greater than or equal to 225 minutes). The reason for breaking the model into two parts is that for low-earth orbits the effects of spin-orbit resonance and lunar and solar gravity are not significant. This result allows the development of an analytical model (SGP4) for determining an object's position and velocity, thereby reducing the computational burden. For deep-space orbits, a semi-analytical model (SDP4) is required.

Models which implement the older SGP model should be accurate for low-earth orbits but really won't be adequate for deep-space objects, particularly those in resonance with the geopotential.

COMPUTER IMPLEMENTATION

The enclosed Pascal source code was developed in Turbo Pascal Version 6.0 to fully implement the NORAD SGP4 orbital model. There are now twelve units provided:

SGP4SDP4	Full implementation of NORAD SGP4/SDP4 models
SGP_OBS	Observer-dependent routines for calculating topocentric information
MINMAX	Minimum/maximum functions
SGP_MATH	Various trigonometric and mathematical routines
SGP_TIME	Time-based routines for converting among time systems
SGP_INIT	Code and variables needed to initialize SGP4SDP4
SGP_INTF	Interface between SGP4SDP4 and SGP_CONV (and some special-purpose programs)
SGP_CONV	Routines for converting two-line data and SGP4 state vectors

SGP_IN	Routines to simplify input of data (with error checking)
SGP_OUT	Routines for outputting program results in standard formats
SOLAR	Routines for calculating the position of the sun and whether a satellite is in earth umbral eclipse
SUPPORT	General support routines for machine-dependent features

These units are structured to make development of software as simple as possible and to reduce the time needed for validating results. A certain amount of the development is also tailored toward the development of a similar set of units in C, which is now underway. A more complete description of these Pascal units is included in SGP4-PLB.1TF.

Of the units provided, the most complex is the implementation of the NORAD orbital models (SGP4SDP4). The development of this unit was done to follow as closely as possible the implementation contained in Spacetrack Report Number 3, "Models for Propagation of NORAD Element Sets," (a copy of the LaTeX documentation and complete FORTRAN source code is available on this system). No attempt has been made at this point to optimize the code to run faster. A future release will provide a more streamlined implementation. To ensure the validity of these units, no changes should be made to the units themselves which have been extensively tested and validated. LaTeX documentation to support this validation should be available on this system soon (look for SGP4-VAL.TEXT).

A test program (SGP4TEST.PAS) is included to implement the sample cases included in the Spacetrack Report Number 3 documentation. It should provide a reasonably good idea of how to use these Turbo Pascal units. To determine an object's position and velocity, the object's two-line orbital element set is read into the array {sat_data}. (Note: Variable names will be enclosed within braces to set them apart in this document). A call is then made to the procedure Convert_Satellite_Data passing the satellite's index {satnumber}. In the call to this procedure, a determination is automatically made as to whether the object is in a near-earth or deep-space orbit; the result is returned in {ideep}. If {ideep} is 0, then the object is in a near-earth orbit; if {ideep} is 1, it is in a deep-space orbit. A call is then made to either SGP4 or SDP4 depending on the value of {ideep}.

The time passed in this call, {tsince}, represents the time since (before or after) the satellite epoch in the two-line element set. The four-dimensional vectors {pos} and {vel} are returned containing the x, y, and z ECI coordinates (referenced to the true equator and mean equinox of date) and vector magnitude of the object's position and velocity, respectively, at the specified time. Units are earth radii and earth radii per minute, respectively; appropriate conversions must be made to get the proper units (as demonstrated in the test program using Convert_Sat_State). The variable {iflag} is used internally for keeping track of initialization conditions for the deep-space portion of the model.

Running this test program should provide results quite close to those provided in the Spacetrack Report Number 3 documentation. The minor differences that do occur are due to two primary reasons. The first is the result of differences in the internal precision of the FORTRAN compiler used to generate the report and that of the Turbo Pascal compiler. The second is due to the choice to implement a consistent numerical precision in the Turbo Pascal code. Examination of the FORTRAN source code will reveal inconsistent use of single and double-precision variables and trigonometric functions; the Turbo Pascal code uses double-precision variables and functions throughout.

Because it is not very straightforward to perform calls to the SGP4 units based on the time since each satellite's element set epoch, a procedure is also provided which interfaces between a standard time system and the SGP4 and SDP4 calls. This procedure, SGP, requires only that the user pass the Julian Date of interest; the procedure Julian_Date_of_Epoch converts from a date in the format used in the two-line element set to a Julian Date. The SGP call also takes care of making the determination of whether the object is in a near-earth or deep-space orbit and calls the appropriate model. The SGP_TIME unit contains these procedures as well as routines to convert Julian Dates to more recognizable time formats.

The main advantage of using the Julian Date in SGP is that there is no problem calculating the time interval between the time of interest and the satellite element set epoch, regardless of whether this interval spans the beginning of a year. There is also a function to convert Julian Dates to calendar dates (Calendar_Date) of the form "1992 Jan 30." Epoch_Time transforms the Julian

Dates to the form used in the two-line element sets.

The test program SGP4TST2.PAS gives an example implementation of this approach. It is designed to produce the same results as SGP4TEST.PAS. The main difference is that the Julian Date is calculated to be the time of the epoch for each element set and then the offset (in minutes) is added. Be sure to note that times outside the units are now all in *days* not in minutes (as they are inside the units).

CONCLUSION

These Turbo Pascal units should make it easy to implement the official NORAD orbital models in developing any number of applications. It is now very straightforward to select input files (of satellite and observer data) and time conditions (with full error checking) and output data ranging from spacecraft ECI position and velocity to spacecraft ground tracks (latitude, longitude, and altitude) to look angles (azimuth, elevation, range, and range rate) to right ascension and declination. Each of these outputs uses the WGS '72 geoid (nonspherical) and takes into account atmospheric refraction, where appropriate. These results can be easily output as text or incorporated into advanced graphical applications.

For a full-blown example of how to implement these functions, look for the application TrakStar/SGP4, also available on this system. It allows output for up to 250 satellites (or element sets for a single satellite) in the form of spacecraft ECI position and velocity, spacecraft ground tracks (latitude, longitude, and altitude), look angles (azimuth, elevation, range, and range rate), and right ascension and declination. A separate data file is created for each object/element set -- a great tool for all sorts of analyses.

Future releases of these units will include routines to efficiently determine crossing phenomena (e.g., satellite rise/set, sun rise/set, and satellite entry into/exit from earth eclipse) and local optima (e.g., closest approach). And, of course, the existing units will be converted to C with an eye toward portability.

In a continuing effort to promote standardization of orbital calculations, I will endeavor to continue to improve this package and will gratefully accept user feedback or contributions to this effort.

INTRODUCTION

The following document is intended to provide complete documentation for the interface section of the units provided in this package. Each unit will be presented, in alphabetical order, and the INTERFACE section is reproduced, showing the exact nature of each call. Following this information will be a description of the intended use of each variable and procedure.

**** UNIT MINMAX -- VERSION 1.02 *******

```
Function IMin(arg1,arg2 : integer) : integer;  
Function IMax(arg1,arg2 : integer) : integer;  
Function RMin(arg1,arg2 : real) : real;  
Function RMax(arg1,arg2 : real) : real;  
Function DMin(arg1,arg2 : double) : double;  
Function DMax(arg1,arg2 : double) : double;
```

These functions are used to provide integer, real, and double minimum and maximum calculations used in the libraries.

**** UNIT SGP4SDP4 -- VERSION 1.50 *******

Uses Support,
SGP_Init,
SGP_Math,SGP_Time;

```
Procedure SGP(time : double;  
  var pos,vel : vector);  
Procedure SGP4(tsince : double;  
  var iflag : integer;  
  var pos,vel : vector);  
Procedure SDP4(tsince : double;  
  var iflag : integer;  
  var pos,vel : vector);
```

This unit contains the Pascal implementation of the SGP4 and SDP4 orbital models. Two methods of interfacing are available. The first method is to access the individual routines exactly as described in Project Spacetrack Report Number 3 (Procedures SGP4 and SDP4). This method requires the user to calculate the time (in minutes) since each satellite element set epoch and determine the appropriate model to use. The variable (iflag) is used to keep track of initialization status and is set within these routines and within Convert_Satellite_Data (Unit SGP_CONV). This method is **NOT** recommended.

The second method is to access the orbital models via a call to SGP. Here the user is only required to pass a time (Julian Date) for the calculation and the satellite ECI position and velocity are returned. Determination of the appropriate orbital model is transparent to the user. The only requirement is that a call to Convert_Satellite_Data be made each time a new satellite is selected before calling SGP. Routines for calculating Julian Dates are included in Unit SGP_TIME.

**** UNIT SGP_CONV -- VERSION 1.00 *******

Uses SGP_Math;

```
Procedure Convert_Satellite_Data(arg : integer);  
Procedure Convert_Sat_State(var pos,vel : vector);
```

The first procedure is used to extract the data in a given two-line element set to the variables expected by UNIT SGP4SDP4. The data structures containing the two-line element sets is described in UNIT SGP_INIT. In addition, a determination as to whether the near-earth (SGP4) or deep-space (SDP4) model should be used is made within this unit. These variables are passed between SGP4SDP4 and SGP_CONV using UNIT SGP_INTF. This unit (SGP_INTF) should **NOT** be included in the main program unless absolutely necessary to avoid unintentional changes to these critical variables. Two additional variables, (catnr) and (elset), are provided to identify the satellite element set. Finally, the variable (epoch) is globally available to determine the epoch of the element set.

Convert_Sat_State is used to convert the native units provided by SGP4/SDP4 (position in earth radii, velocity in earth radii/minute) to standard metric

```

units (kilometers and kilometers/sec).
** UNIT SGP_IN -- VERSION 2.00 *****
(** This unit contains machine-specific code **)
  Uses SGP_Math,SGP_Init,Support;
const
  data_type : byte = 3;

Function Good_Elements(lines : two_line) : boolean;
Procedure Input_Satellite(index : word);
Function Input_Satellite_Data(fn : string) : word;
Procedure Select_Satellites(title : string;
  x,y,w,h : byte;
  number : word);
Procedure Input_Observer(var geodetic : vector);

```

This unit is one of two units which contain machine-specific code; this limitation will probably be removed in the future, moving all machine-specific code to UNIT SUPPORT.

The constant {data_type} is preset to 3 and is used to specify the format of the two-line orbital data file. A value of 2 indicates that the satellite data files contain *only* two-line data; a value of 3 indicates that each two-line element set is preceded by a 22-character satellite name. These data are read into data structures as described in UNIT SGP_INIT. The value of {data_type} can be changed in the main program and, if necessary, should be done within the program initialization block.

The variables {fsat} and {fobs} are predefined text files to be assigned to the satellite and observer files, respectively. Routines used in this unit expect to use these file handles.

The first two procedures, Select_Time and Select_Time_Interval, are provided to make it easy to input start/stop times and time intervals for performing calculations. Each procedure will put a window on the screen with the title specified by {message} at the location ({xpos},{ypos}). A default time set is passed to initialize the time; the structure of this variable is set forth in UNIT SUPPORT. The variable {default} may be initialized manually or by a call to Get_Current_Time (for Select_Time) or Zero_Time (for Select_Time_Interval); each of these procedures is also in UNIT SUPPORT. The variable {precision} is used to indicate the precision of the data to be selected. Precision ranges from years down to hundredths of a second. A precision of 7 indicates that all time units are to be input; a precision of 5 would omit inputting seconds and hundredths of seconds. All values beyond the specified precision are set to zero, regardless of any other user action.

The next two functions are used to determine whether a given two-line element set is "good" -- at least in the sense that it passes the modulo-10 checksum on each line and that all the numbers appear to be in the proper fields. A simple call passing the two-line element set {lines} to Good_Elements returns TRUE if the data passes these tests. The function Checksum_Good can be used to test the modulo-10 checksum for a single line of a two-line element set. These functions are not used explicitly during element set input as it is assumed that the user has already done so (all data that I post has already been subjected to these tests). In fact, the program PASSUPDT, which is available on this system for updating files of two-line element sets from a master file, does this checking for you. However, if you are unsure of the quality of your data, it is **STRONGLY RECOMMENDED** that you develop your own preprocessor using these functions to test your data.

The procedure Input_Satellite is used to read in individual two-line element sets. The index indicates its placement within the data array. This call assumes that {fsat} has already been ASSIGNED and initialized. Typically, this call is made from the function Input_Satellite_Data which initializes {fsat} and reads an entire file into memory from the file {fn}; the output of this function is the number of satellites in {fn}. However, due to memory limitations, some files will be too large to read into memory. In these cases, Input_Satellite should be used to sequentially read and process individual element sets, each element set could be read into {index}=1 and

processed before proceeding.

In cases where all the orbital data can be read into memory and {data_type}=3, the procedure Select_Satellites can be used to tag satellites for calculations later in the program using the array {selected}. Initially, no satellites are selected. A call to this procedure will place a window on the screen with the upper-left corner at ({x},{y}) and having a width {w} and maximum height {h} (the height ranges from 1 to the minimum of {h} and the number of satellites). A {title} is also put on the window. The final parameter in this call is the number of satellites available. Selection is achieved by moving with the up/down cursor keys to the appropriate satellite and toggling with the space bar (an asterisk marks an item as being selected); data scrolls in the window as necessary. Toggling advances to the next item in the list, making it easier to quickly mark items. The 'A' key toggles All items (negates their current status). Once the desired items are selected, the [ENTER] key completes the process. Within the main program, items can be tested for selection with a statement such as: if selected[index] then ...

The final procedure for this unit is Input_Observer and it works somewhat like Input_Satellite except that the data is read into a {geodetic} four-vector where {geodetic}[1] is North latitude, {geodetic}[2] is East longitude (that means that West longitudes are negative), and {geodetic}[3] is altitude above mean sea level (AMSL). Input is expected from the file {fobs} in units of degrees and meters but is immediately converted to radians and kilometers for use within these units. Each observer entry in {fobs} consists of a single line beginning with a 25-character site name (passed as {obs_name}); it is expected that this name has a three-character short name (or number), two spaces, followed by a long name. The short name is used within UNIT SGP_OUT for topocentric output. The remaining three numbers on this line are free-field format, beginning on or after character 26.

.. UNIT SGP_INIT -- VERSION 1.10

```
const
  max_sats = 250;

type
  line_data = string[69];
  two_line = array [1..2] of line_data;

var
  visible      : boolean;
  epoch        : double;
  catnr,elset  : string;
  obs_name     : string[25];
  selected     : array [1..max_sats] of boolean;
  sat_name     : array [1..max_sats] of string[22];
  sat_data     : array [1..max_sats] of two_line;
  data_drive,data_dir,
  work_drive,work_dir : string;
```

Procedure Program_Initialize(program_name : string);

This unit is used to initialize most of the data structures specific to the SGP4 family of units. The constant {max_sats} sets the limit (imposed by system memory constraints) on the maximum number of satellites available. This constant affects the storage allocation for two-line element sets in the array {sat_data}, satellite names in the array {sat_name}, and the array of selected satellites in {selected}. Note that type {two_line} is a two-element string of 69-character lines.

The first variable provided is a boolean variable {visible} which is set when making calls to determine topocentric position; if the satellite is visible to the observer, {visible} is set true, otherwise it is set false. Checks of this variable make sense only in this context. Eventually, this variable will also be used in determining other visibility conditions.

The next three variables pertain to the current two-line element set (the last one processed through Convert_Satellite_Data). The variables {catnr} and {elset} are read from the appropriate field of Line 1 and serve to identify the data. The variable {epoch} marks the epoch time (in two-line format) of that element set.

The final four variables are determined in the procedure Program_Initialize. They are used to specify the location of data files ({fsat} and {fobs} files) and output files. Having separate locations for these two groups makes development and testing easier (in my opinion) and allows for standard locations to facilitate integration with other programs (it doesn't make sense to have various versions of two-line element set files scattered all over your hard disk). These values are specified in the configuration file {program_name}.CFG (if it exists; if not, everything defaults to the working disk and directory). For example, in the program TRANSAR, there would be a

file TRAKSTAR.CFG which might look like:

```
d:
\data\
e:
\work\
```

If this program were located in C:\SGP4 and the data was in C:\SGP4\DATA and work files were to go to C:\SGP4\WORK, the configuration file might look like:

```
c:
\sgp4\data\
c:
\sgp4\work\
```

Note that each directory ends with a trailing \ (and should have no blanks). If you wish to run from the default drive (useful when using removable cartridges and moving between systems), you might change the above to:

```
\sgp4\data\
\sgp4\work\
```

To specify directories which are below the working directory, you could also use:

```
data\
work\
```

The call to Program_Initialize will read {program_name}.CFG to determine this information (if it exists) and will also read {program_name}.HDR (if it exists) to place one page of information on the screen to identify the program. It is strongly recommended that these parameters be used in your programs to facilitate traceability and portability.

A call to Program_End is strongly recommended to reset the terminal after program execution. Currently, this procedure positions the cursor to the bottom of the screen and makes sure it is on.

.. UNIT SGP_INTF -- VERSION 1.02

```
const
  ae      = 1;
  tothr3  = 2/3;

var
  iflag,ideep      : integer;
  xno,xnodeo,omegao,ex,xincl,
  xno,xadt2o,xadd6o,betar,
  julian_epoch,xhe : double;
```

This unit defines the constants and variables used internal to SGP4SGP4. Note that this version still uses WGS '72 values (while the impact of switching to WGS '84 is sensed). It is STRONGLY recommended that this unit NOT be included in the main program. All determinations using these constants (such as position of an observer on the earth's surface in the ECI system) should be performed through the appropriate call. Also, note that (iflag) and (ideep) are unavailable to the main program under this recommendation, forcing the use of the procedure SGP to access the SURAD orbital models.

.. UNIT SGP_MATN -- VERSION 1.30

```
type
  vector = array [1..4] of double;
```

```
const
  twopi = 2 * pi;
  zero  vector = (0.0,0.0,0.0);
```

```
Function Sign(arg : double) shortint;
Function Cube(arg : double) double;
```

```

Function Power(arg,pwr : double) : double;
Function Radians(arg : double) : double;
Function Degrees(arg : double) : double;
Function Tan(arg : double) : double;
Function ArcSin(arg : double) : double;
Function ArcCos(arg : double) : double;
Function Modulus(arg1,arg2 : double) : double;
Function Fmod2p(arg : double) : double;
Function AcTan(sinx,cosx : double) : double;
Function Dot(v1,v2 : vector) : double;
Procedure Magnitude(var v : vector);
Procedure Cross(v1,v2 : vector; var v3 : vector);

```

This unit first defines the type {vector} as a four-element array (or four-vector) consisting (typically) of x, y, and z position and a vector magnitude. These vectors are also used for storing other types of information (as will be seen in UNIT SGP_OBS). Next, the constant {twopi} is defined as appropriate for Turbo Pascal Version 6.0. Note that earlier versions of Turbo Pascal will NOT allow constant definitions of this form. The definition of a zero vector has been added for this release.

The remaining routines are defined below.

```

Function Sign(arg : double) : shortint;
    Output is the sign (-1, 0, +1) of {arg}.
Function Cube(arg : double) : double;
    Output is {arg} to the third power.
Function Power(arg,pwr : double) : double;
    Output is {arg} to the {pwr} power. This is a more general-purpose
    function, but is restricted to positive values of {arg}. An error
    message is reported if {arg} violates this restriction.
Function Radians(arg : double) : double;
    Output is an angle in radians where {arg} was input in degrees.
Function Degrees(arg : double) : double;
    Output is an angle in degrees where {arg} was input in radians.
Function Tan(arg : double) : double;
    Output is the tangent of {arg}.
Function ArcSin(arg : double) : double;
    Output is the arcsine of {arg} in radians. Values range between -pi and
    +pi.
Function ArcCos(arg : double) : double;
    Output is the arccosine of {arg} in radians. Values range between 0 and
    2*pi.
Function Modulus(arg1,arg2 : double) : double;
    Output is the remainder after {arg1} is divided by {arg2}. This routine
    is useful for keeping angles between 0 and 2*pi (or 0 and 360 degrees).
Function Fmod2p(arg : double) : double;
    This function is a specific implementation of Modulus where {arg2} equals
    2*pi. Used explicitly within SGP4SDP4.
Function AcTan(sinx,cosx : double) : double;
    Output is the arctangent of {sinx}/{cosx} in radians. Used explicitly
    within SGP4SDP4. The advantage of this function over ArcTan is that it
    returns the correct quadrant of the angle.
Function Dot(v1,v2 : vector) : double;
    Output is the vector dot product of {v1} and {v2}.
Procedure Magnitude(var v : vector);
    This procedure calculates the magnitude of vector {v} using components 1,
    2, and 3, storing the result in component 4.
Procedure Cross(v1,v2 : vector; var v3 : vector);
    Returns vector {v3} which is the vector cross product of {v1} and {v2}.

```

== UNIT SGP_OBS -- VERSION 1.40 =====

Uses SGP_Math;

```

Procedure Calculate_User_PosVel(var geodetic : vector,
                                time : double;
                                var obs_pos,obs_vel : vector);
Procedure Calculate_LatLonAlt(pos : vector;
                              time : double;
                              var geodetic : vector);
Procedure Calculate_Obs(pos,vel,geodetic : vector,
                        time : double;
                        var obs_set : vector);
Procedure Calculate_RADec(pos,vel,geodetic : vector,
                          time : double;
                          var obs_set : vector);

```

These procedures are used to provide observer-specific coordinate

transformations of the output of the NORAD orbital models.

Procedure Calculate_User_PosVel passes the user's geodetic position and the time of interest and returns the ECI position and velocity of the observer. The format of {geodetic} is as explained in UNIT SGP_IN. The velocity calculation assumes the geodetic position is stationary relative to the earth's surface. This routine is made available to the user, although the exact nature of its application is uncertain. This procedure is used, however, as the basis for Calculate_Obs and Calculate_RADec, to be explained later.

Procedure Calculate_LatLonAlt will calculate the {geodetic} position of an object given its ECI position {pos} and {time}. It is intended to be used to determine the ground track of a satellite. The calculations assume the earth to be an oblate spheroid as defined in WGS '72.

The procedures Calculate_Obs and Calculate_RADec calculate the *topocentric* coordinates of the object with ECI position, {pos}, and velocity, {vel}, from location {geodetic} at {time}. The {obs_set} returned for Calculate_Obs consists of azimuth, elevation, range, and range rate (in that order) with units of radians, radians, kilometers, and kilometers/second, respectively. The WGS '72 geoid is used and the effect of atmospheric refraction (under standard temperature and pressure) is incorporated into the elevation calculation; the effect on range and range rate has not yet been quantified.

The {obs_set} for Calculate_RADec consists of right ascension and declination (in that order) in radians. Again, calculations are based on *topocentric* position using the WGS '72 geoid and incorporating atmospheric refraction.

.. UNIT SGP_OUT -- VERSION 1.50

Uses SGP_Math;

```
const
  day_date : boolean = true;
  full_time : boolean = true;
  N_E_W_S : boolean = false;
  D_M_S : boolean = false;
  time_res : byte = 2;
  angle_res : byte = 4;
  dist_res : byte = 3;

var
  fout : text;

Procedure Output_Time(time : double);
Procedure Output_ECI(time : double;
  pos,vel : vector);
Procedure Output_Angle(angle : double;
  width,dec : byte;
  degrees : boolean);
Procedure Output_LatLonAlt(time : double;
  geodetic : vector);
Procedure Output_Obs(time : double;
  obs : vector);
Procedure Output_RADec(time : double;
  obs : vector);
```

This unit begins with a set of constants used for formatting parameters. The intention here is to set these values for consistency in the output and not clutter output calls with formatting information. While the default values are set above, it is easy to change these values either globally or locally. For example, the user may decide to change these values in the program initialization step. Or, these values could be set prior to making calls to routines within UNIT SGP_OUT.

The constant {day_date} allows for selection of output time as day/date (if true) or as a Julian Date (easier to read into other programs).

The constant {full_time} allows the selection of times with colons between the hours and minutes and between the minutes and seconds (i.e., HH MM SS), if set true.

The constant {N_E_W_S} is used with outputs of latitude and longitude to specify an output with North/South or East/West (if true) rather than plus or minus values.

The constant {D_M_S} allows for angular output in degrees, minutes, and seconds (if true) rather than decimal degrees.

The final three constants are used to set the precision of output for time, angle, and distance variables, respectively. The default for {time_res} of 2 indicates output to hundredths of a second. The default for {angle_res} of 4 indicates output to four decimal places (if D_M_S = false) or arcseconds (if D_M_S = true). Outputs in degrees, minutes, and seconds are rounded to tens of

arcminutes, arcminutes, tens of arcseconds, and seconds for values of 1, 2, 3, and 4, respectively. The default for {dist_res} of 3 indicates a precision to three decimal places in distances (i.e., meters) and six decimal places in velocities (i.e., millimeters/second).

The variable {fout} is a pre-defined variable to specify the output file.

The procedure Output_Time is used to output either the calendar date and time of day or Julian Date of {time} to {fout}.

The procedure Output_ECI outputs ECI position {pos} (in kilometers) and velocity {vel} (in kilometers/second) vectors along with the time.

The procedure Output_Angle outputs an angle {angle} in a field of width {width} with {dec} decimal places. The variable {degrees} is used when {D.M.S} is true to specify whether the angular output is degrees or hours.

The procedure Output_LatLonAlt output the time, latitude (in degrees), longitude (in degrees), and altitude (in kilometers) of an object.

The procedure Output_Obs outputs the time, azimuth (in degrees), elevation (in degrees), range (in kilometers), and range rate (in kilometers/second with negative values approaching the observer).

The procedure Output_RADec outputs the time, right ascension (in hours), and declination (in degrees).

Output_ECI and Output_LatLonAlt now write ECL at the end of each line if the satellite is in earth umbral eclipse.

Output_Obs and Output_RADec now output a blank line at the completion of a pass.

.. UNIT SGP_TIME -- VERSION 1.50

Uses SGP_Math;

type

clock_time = string[12];
date = string[11];

const

minpda = 1440.0; (Minutes per day)
secday = 86400.0; (Seconds per day)
omega_E = 1.00273790934; (Earth rotations per sidereal day (non-constant))
omega_ER = omega_E*2pi; (Earth rotation, radians per sidereal day)

var

ds50 : double;

Function Julian_Date_of_Year(year : double) : double;

Function Julian_Date_of_Epoch(epoch : double) : double;

Function Epoch_Time(jd : double) : double;

Function DOY(yr,mo,dy : word) : word;

Function Fraction_of_Day(hr,mi,se,hu : word) : double;

Function Calendar_Date(jd : double) : date;

Function Time_of_Day(jd : double;

full : boolean;

res : byte) : clock_time;

Function YthetaG(epoch : double) : double;

Function ThetaG_JD(jd : double) : double;

Function Delta_ET(year : double) : double;

This unit contains all the routines to perform time conversions.

The function Julian_Date_of_Year calculates the Julian Date of Day 0.0 of {year}. This function is used to calculate the Julian Date of any date by using Julian_Date_of_Year, DOY, and Fraction_of_Day.

The function Julian_Date_of_Epoch returns the Julian Date of an epoch specified in the format used in the EURID two-line element sets.

The function DOY calculates the day of the year for the specified date. The calculation uses the rules for the Gregorian calendar and is valid from the inception of that calendar system.

Fraction_of_Day calculates the fraction of a day passed at the specified input time.

The function Calendar_Date converts a Julian Date to a string of the form "yyyy Mon dd". It is typically used as the major output time format.

Time_of_Day takes a Julian Date and calculates the clock time portion of that date. The variable {full} is set true if it is desired to place colons between hours and minutes and minutes and seconds. The variable {res} is used to determine the number of decimal places after the seconds in the output. zero gives a resolution of seconds, one gives a resolution of tenths of

seconds, etc. The variable {res} can take on values between 0 and 3.

The function ThetaG calculates the Greenwich Mean Sidereal Time for an epoch specified in the format used in the NORAD two-line element sets. The function ThetaG_JD provides the same calculation except that it is based on an input in the form of a Julian Date.

The function Delta_ET has been added to allow calculations on the position of the sun. It provides the difference between UT (approximately the same as UTC) and ET (now referred to as TDT). This function is based on a least squares fit of data from 1950 to 1991 and will need to be updated periodically.

== UNIT SOLAR -- VERSION 1.20 =====

```
Uses SGP_Math;

const
  eclipsed : boolean = false;
  show_vis : boolean = false;

var
  civil,
  nautical,
  astronomical : double; {Twilight elevations}
  solar_pos    : vector;

Procedure Calculate_Solar_Position(time : double;
                                   var solar_vector : vector);
Function Depth_of_Eclipse(time : double;
                          r1 : vector) : double;
```

The variable {eclipsed} is provided for use with the Function Depth_of_Eclipse to reflect whether a satellite is in earth umbral eclipse. The constant {show_vis} is used to indicate whether information should be output for all passes or only visible passes (i.e., satellite above the observer's horizon, not in earth umbral eclipse, and the sun below the appropriate threshold for skies to be dark at the observer's location).

The variables {civil}, {nautical}, and {astronomical} are initialized to the thresholds for solar elevation defining the corresponding twilights. These are defined to occur at 6, 12, and 18 degrees below the horizon, respectively.

The variable {solar_pos} is provided to track the position of the sun as calculated in Depth_of_Eclipse, thus avoiding an additional call to Calculate_Solar_Position.

The procedure Calculate_Solar_Position calculates the position of the sun in the ECI coordinate system at the designated time (UTC). The procedure makes an adjustment for the difference between UT and TDT by calling Delta_ET in Unit SGP_TIME. The variable {solar_vector} returns the ECI position in kilometers and calculates the distance to the sun.

The function Depth_of_Eclipse calculates the distance an object at position {r1} at {time} is into the cone enclosing both the earth and the sun. On the side of the earth away from the sun, this cone defines the earth's umbral shadow. This distance is determined by first finding the perpendicular distance of the object from the line going through the centers of both the earth and the sun and then calculating the distance of the edge of the cone from this same line along the perpendicular. The depth into eclipse is defined as the difference of these two distances. Positive values reflect distances outside the eclipse zone. Because the object can be within the cone on either side of the earth, the variable {eclipsed} is set true if the object is within the cone on the side of the earth opposite of the sun.

Function Select_File(title,pattern,default : string; x,y,w,h : byte) : string;
Function Select_Option(menu : options; number,x,y,w,h : byte) : byte;

This unit is considerably different from the other units in this library and
is intended to be a general support library for a specific hardware
implementation, in this case the IBM PC compatible family of microcomputers
running Microsoft DOS. Eventually, *file* machine-specific code will be put in
this unit to enhance portability, meaning that only these routines will have
to be changed to port it to another machine. I have decided not to delay the
release of the package to achieve this goal since there is no widely available
standard implementation of Pascal to necessitate such changes. However, when
these units are converted to C, all machine-specific routines will be limited
to this unit.

The unit begins with a set of constants which define the specifics of various
keys and characters on IBM PCs; their definitions are commented above.

The two types defined are an array of {options} which are used with the
function Select_Option and {time_set} which is a record containing the year,
month, day, hour, minute, second, and hundredth of seconds.

The remaining routines are described below.

Procedure Cursor_On.
  Turns on a block cursor on the screen at the current cursor location.
Procedure Cursor_Off.
  Hides the cursor from view.
Procedure Save_Cursor.
  Saves the current position of the cursor.
Procedure Restore_Cursor.
  Restores the cursor location to the last saved location.
Procedure ReverseVideo.
  Changes the text attributes to reverse video (black on white).
Procedure NormalVideo.
  Changes the text attributes to normal video (white on black).
Procedure BoldVideo.
  Changes the text attributes to bold (yellow on black).
Procedure FrameWindow(x,y,w,h,color : byte; title : string).
  Puts a frame around a window (and is usually called by MakeWindow).
Procedure MakeWindow(x,y,w,h,color : byte; title : string).
  Makes a window, located at (x,y) with width (w) and height (h) in
  color {color}. A {title} is put on the window.

```

```

Procedure ClearWindow(x,y,w,h : byte);
  ClearWindow simply clears a window from the display. The code does not,
  at this time, allow restoration of underlying screen text.
Procedure Show_Status_Line(title : string);
  Shows status on the left side of the last line of the display. Usually
  used in support of providing brief instructions during input.
Procedure Show_Instructions(title : string);
  Similar to Show_Status_Line except providing right-justified output on
  the last line of the display.
Procedure Clear_Status_Line;
  Clears the last line of the display.
Procedure Report_Error(x,y : byte; title : string);
  Reports the error as specified by {title} in BoldVides at the position
  ({x},{y}) and then exits the program.
Procedure Beep;
  Sounds a high-pitched tone to draw attention.
Procedure Buzz;
  Sounds a lower-pitched tone to indicate an error condition.
Procedure Mark_Time;
  A rotating cursor to serve as a visual indication that the machine is
  still operating during time-intensive operations.
Procedure Zero_Time(var time : time_set);
  Places zeros in all element of {time}. Useful in initializing in
  preparation for a call to Select_Time_Interval.
Procedure Get_Current_Time(var time : time_set);
  Reads the current system time into variable {time}. Useful for
  initializing Select_Time.
Function Yes : boolean;
  A function which waits for the entry of a Y or N in response to a
  question. The words Yes or No are printed in response to the appropriate
  input and Yes is set true if a affirmative response is received. For
  example,
  Write('Are you ready? ');
  if Yes then Do_Ready else Do_Not_Ready;
Function TwoDigit(arg : integer) : string;
  Converts an integer to a two-digit string with leading zeros.
Function ThreeDigit(arg : integer) : string;
  Converts an integer to a three-digit string with leading zeros.
Procedure Convert_Blanks(var field : string);
  Used with the next two functions to convert leading spaces to zeros to
  facilitate text conversion to integers or reals.
Function Integer_Value(buffer : string;
  start,length : integer) : integer;
  Takes the segment of {buffer} beginning at {start} and having length
  {length} and converts it to an integer number.
Function Real_Value(buffer : string;
  start,length : integer) : double;
  Takes the segment of {buffer} beginning at {start} and having length
  {length} and converts it to a double precision real number.
Function File_Exists(filename : string) : boolean;
  Checks to see if {filename} exists.
Function Select_File(title,pattern,default : string; x,y,w,h : byte) : string;
  Allows for easy selection of input files. Select_File places a window on
  the screen with upper-left corner at location ({x},{y}) and having width
  {w} and maximum height of {h}. The window is labeled with {title} and
  {pattern} specifies the pattern of files to look for; {default} is the
  default pattern (this filename is highlighted, if present). Select_File
  returns the filename selected.
Function Select_Option(menu : options; number,x,y,w,h : byte) : byte;
  Allows for the easy selection of an option from a menu {menu}. The
  values of {x}, {y}, {w}, and {h} are the same as for Select_File;
  {number} indicates the total number of options available. Select_Option
  returns the option number selected.

```

  { Author:   BMV }
  { Original Version: 21 Oct 1992 }
  { Current Revision: 30 Oct 1992 }
  { Version: 1.20 }
}

{ Description: Contains a procedure used to propagate orbital elements
  { (bstar, xincl, e, xnode, omega, xm, xn) and the position
  { covariance. It first propagates for the time prop_time,
  { typically the input time of the last observation. It then
  { calculates the time of the last ascending node crossing
  { and propagates the elements and Phi matrix to that time.
  { It then deweights the COV matrix with an exponential factor
  { and checks if the diag elements of the COV exceed a limit.
  { If exceeded, the element is reset to the limit.
  { This procedure gives only a first order propagation using
  { only J2.
}

INTERFACE

Appendix E. *SATELLITE COMPOSITION ANALYSIS*

E.1 Cumulative Distribution and Frequency Histograms

This section includes the cumulative distribution and histogram frequency plots of all satellites included in the current satellite population as investigated in this research.

Figure E.1. Histogram and Distribution Plots — Angle From Node, B^* .

Figure E.2. Histogram and Distribution Plots — Eccentricity, Epoch.

Figure E.3. Histogram and Distribution Plots — Perigee, NORAD Catalog Number.

Figure E.4. Histogram and Distribution Plots — Inclination, Mean Anomaly.

Figure E.5. Histogram and Distribution Plots — Mean Motion Time Derivatives.

Figure E.6. Histogram and Distribution Plots — Node, Kozai Mean Motion.

E.2 Scatter Plots

Two-variable scatter plots were done for all possible combinations of two-line element set variables. Only plots that were between variables of interest or that showed an unexpected correlation are included in this appendix section or in the body of the text.

Figure E.7. Scatter Plot — β^* and Mean Motion Dot over 2.

Figure E.8. Scatter Plot — Mean Motion Double Dot over 6 and Mean Motion Dot over 2.

Figure E.9. Scatter Plot — Mean Motion Double Dot over 6 and B^* .

Figure E.10. Scatter Plot — Eccentricity and Inclination.

E.5 Orbital Element Classification Scatter Plots.

Included in this section are the plots showing how the satellites fell into the different Orbital Element Classes. The six plots are for each inclination class. The grid-lines on each plot represent the mean motion and eccentricity combinations.

Figure E.11. Classification Breakout — Inclination Class 1.

Figure E.12. Classification Breakout — Inclination Class 2.

Figure E.13. Classification Breakout — Inclination Class 3.

Figure E.14. Classification Breakout — Inclination Class 4.

Figure E.15. Classification Breakout — Inclination Class 5.

Figure E.16. Classification Breakout — Inclination Class 6.

F.3 Satellites that Failed Satellite Division Criteria

Satellites that did not have a two-line element set in our data file after 1 March 1990 but did have an entry between 1 January and 28 February 1990.¹

02473

Satellites that had $B^* > 1.0$ on first and possibly subsequent occurrences of two-line element set entries after 28 February, but did have at least one entry with a $B^* < 1.0$.²

Vita

Captain Jeff M. Berger was born on 27 January 1963 in Oslo, Norway. As the only child of an Air Force enlisted family he lived in many places prior to his father's retiring and settling in Nazareth, Pennsylvania in 1975. Jeff graduated from Nazareth Area Senior High School in 1981 and attended Pennsylvania State University. In August 1984 he enlisted in the Air Force under the College Senior Engineering Program with the understanding that an Officer Candidate slot would be reserved for him at Officer Training School after graduation. In May 1985, then Airman 1st Class Berger graduated from Penn State with a Bachelor of Science degree in Aerospace Engineering. Following graduation he attended OTS, receiving his commission on 13 September 1985. As a new second lieutenant, his first assignment was to Air Force Systems Command, Air Force Satellite Control Network, Operating Location AB, Peterson AFB, Colorado, where he received training as a Global Positioning System Planner/Analyst. When training was completed he was reassigned to Air Force Space Command, 2nd Space Wing, as part of the initial activation group for the 1st Satellite Control Squadron at Falcon AFB, Colorado. While assigned to the 1st Satellite Control Squadron, he participated in the successful launches of the first 10 Block II Global Positioning System Satellites, was certified in the following crew positions; Planner/Analyst, Satellite Vehicle Engineer, and Flight Commander, and as a staff operations training instructor he was responsible for managing the qualification training program for all crew positions. Two promotions and an augmentation to a regular commission later, Captain Berger departed Colorado in March 1991. While enroute to his next assignment he attended Squadron Officer School in residence, afterward entering the Graduate Space Operations Program in the School of Engineering, Air Force Institute of Technology in May 1991.

Vita

Captain Joseph B. Moles was born on 25 September 1959 in Atlanta, Georgia. He graduated from South Cobb High School in Austell, Georgia in 1977. After one year at the Georgia Institute of Technology, Captain Moles was accepted for admission into the United States Military Academy. After graduation in May 1982, Captain Moles was commissioned as a second lieutenant in the Ordnance Corps and entered the Missile and Munitions Officer Basic Course (OBC) at Redstone Arsenal, Alabama. After completing OBC, he served with two units located at Fort Bliss, Texas. In 1985 he was selected to command the 118th Ordnance Detachment, 11th Air Defense Artillery Brigade. After successfully completing command and the Ordnance Officer Advanced Course (OAC), Captain Moles was assigned to the office of the Assistant Deputy Chief of Staff for Logistics (ADCSLOG), US Army, Europe (USAREUR), as the Chief of the Operations Branch, Missile System Division and subsequently as the Chief of the Operations and Plans Branch, Munitions Division. As an additional duty, Captain Moles acted as the Inspector General for the 200th Theater Army Material Management Command from 1988 to 1990. While in Germany, Captain Moles was assigned a functional area specialty of Research and Development and selected for assignment to the Army Acquisition Corps. Additionally, Captain Moles completed the requirements for a Masters Degree in Systems Management from the University of Southern California while studying during off duty hours. After completing his tour in Germany, Captain Moles was selected for the Army's Training With Industry (TWI) program and assigned to the Northrop Corporation, Hawthorne, California, to study low observable technology. While in the TWI program Captain Moles was selected, in January of 1991, to attend the Air Force Institute Of Technology to pursue a Masters Degree in Space Operations. Captain Moles entered the School of Engineering in May 1991. Captain Moles is married but has no children except two large, pampered cats.

Vita

Captain David G. Wilsey was born on 17 October 1962 in Atlantic City, New Jersey. He graduated from Mainland Regional High School in Linwood, New Jersey in 1981 and entered the University of Michigan. In 1982, he enrolled in the Air Force ROTC program and in December 1985 graduated "cum laude" with a Bachelor of Science degree in Aerospace Engineering. Upon graduation, he received his commission as a Second Lieutenant and attended Space Operations Training at the 3400th Technical Training Wing, Lowry AFB, Colorado. After completing training, he was assigned to the Defense Satellite Communication Systems Program Office, Headquarters Space Division, Los Angeles AFB, California. While there he served first as a Program Control Officer, and then as the program's Budget Execution Officer, responsible for over 500 million dollars in active appropriations. In March 1988, he was reassigned to the 16th Surveillance Squadron, Shemya AFB, Alaska, as a Space Surveillance Operations Crew Commander, commanding a 25 person operations and support crew responsible for the operations of the Cobra Dane radar system in performance of intelligence collection, ballistic missile early warning, and space surveillance missions. He also served as a line crew instructor and evaluator, Squadron Intelligence Officer, and Chief of Standardization and Evaluation. In May 1989, he departed Alaska, attended the 1013th Combat Crew Training Squadron, and reported to the 5th Defense Space Communications Squadron, Woomera, South Australia, as a Satellite Operations Crew Commander. There he commanded a 48 person multi-service/multinational operations and support crew responsible for the operation of DSP satellite and ground station resources in the performance of ballistic missile early warning and space launch reporting missions. He also served as a line crew instructor, and the Squadron Intelligence Officer. Departing Australia in March 1991, he attended Squadron Officer School in residence and entered the School of Engineering, Air Force Institute of Technology in May 1991.

13. ABSTRACT (Maximum 200 words) This study provides the basis for the development of a cost/benefit assessment model to determine the effects of alterations to the Space Surveillance Network (SSN) on orbital element (OE) set accuracy. It provides a review of current methods used by NORAD and the SSN to gather and process observations, an alternative to the current Gabbard classification method, and the development of a model to determine the effects of observation rate and correction interval on OE set accuracy. The proposed classification scheme is based on satellite J_2 perturbations. Specifically, classes were established based on mean motion, eccentricity, and inclination since J_2 perturbation effects are functions of only these elements. Model development began by creating representative sensor observations using a highly accurate orbital propagation model. These observations were compared to predicted observations generated using the NORAD Simplified General Perturbation (SGP4) model and differentially corrected using a Bayes, sequential estimation, algorithm. A 10-run Monte Carlo analysis was performed using this model on 12 satellites using 16 different observation rate/correction interval combinations. An ANOVA and confidence interval analysis of the results show that this model does demonstrate the differences in steady state position error based on varying observation rate and correction interval.

GENERAL INSTRUCTIONS FOR COMPLETING SF 298

The Report Documentation Page (RDP) is used in announcing and cataloging reports. It is important that this information be consistent with the rest of the report, particularly the cover and title page. Instructions for filling in each block of the form follow. It is important to *stay within the lines* to meet optical scanning requirements.

Block 1. Agency Use Only (Leave blank)

Block 2. Report Date. Full publication date including day, month, and year, if available (e.g., Jan 88). If not, enter at least the year.

Block 3. Type of Report and Dates Covered. State whether report is interim, final, etc. If applicable, enter inclusive report dates (e.g., 10 Jun 87 - 30 Jun 88).

Block 4. Title and Subtitle. A title is taken from the part of the report that provides the most meaningful and complete information. When a report is prepared in more than one volume, repeat the primary title, add volume number, and include subtitle for the specific volume. On classified documents enter the title classification in parentheses.

Block 5. Funding Numbers. To include contract and grant numbers, may include program element number(s), project number(s), task number(s), and work unit number(s). Use the following codes:

C - Contract	PR - Project
G - Grant	TA - Task
PE - Program Element	WU - Work Unit
	Accession No

Block 6. Author(s). Name(s) of person(s) responsible for writing the report, performing the research, or credited with the content of the report. If editor or compiler, this should follow the name(s).

Block 7. Performing Organization Name(s) and Address(es). Self-explanatory.

Block 8. Performing Organization Report Number. Enter the unique alphanumeric report number(s) assigned by the organization performing the report.

Block 9. Sponsoring/Monitoring Agency Name(s) and Address(es). Self-explanatory.

Block 10. Sponsoring/Monitoring Agency Report Number. (If known)

Block 11. Supplementary Notes. Enter information not included elsewhere such as Prepared in cooperation with, Trans of, To be published in. When a report is revised, include a statement whether the new report supersedes or supplements the older report.

Block 12a. Distribution/Availability Statement.

Denotes public availability or limitations. Cite any availability to the public. Enter additional limitations or special markings in all capitals (e.g., NOFORN, REL, ITAR).

DOD - See DoDD 5230 24, "Distribution Statements on Technical Documents."

DOE - See authorities

NASA - See Handbook NHB 2200 2

NTIS - Leave blank.

Block 12b. Distribution Code.

DOD - Leave blank

DOE - Enter DOE distribution categories from the Standard Distribution for Unclassified Scientific and Technical Reports.

NASA - Leave blank

NTIS - Leave blank

Block 13. Abstract. Include a brief (Maximum 200 words) factual summary of the most significant information contained in the report.

Block 14. Subject Terms. Keywords or phrases identifying major subjects in the report.

Block 15. Number of Pages. Enter the total number of pages.

Block 16. Price Code. Enter appropriate price code (NTIS only).

Blocks 17. - 19. Security Classifications. Self-explanatory. Enter U.S. Security Classification in accordance with U.S. Security Regulations (i.e., UNCLASSIFIED). If form contains classified information, stamp classification on the top and bottom of the page.

Block 20. Limitation of Abstract. This block must be completed to assign a limitation to the abstract. Enter either UL (unlimited) or SAR (same as report). An entry in this block is necessary if the abstract is to be limited. If blank, the abstract is assumed to be unlimited.
